Supportive management is often sufficient to care for dissociative agent overdose.^{38,45,62} Because airway reflexes are preserved in dissociative agent toxicity, relatively few patients require orotracheal intubation and airway support. Excessive airway secretions can be controlled by atropine or glycopyrrolate; clinicians should be aware that phencyclidine may hyperstimulate oropharyngeal musculature, and care should be taken to prevent laryngospasm during passage of an orotracheal tube.

Basic emergency measures that include measurement of vital signs and intravascular access should be performed immediately. All patients should receive intravenous saline solution; this therapy corrects dehydration and prevents renal failure secondary to rhabdomyolysis from muscle breakdown. Hypertension and tachycardia may respond well to sedating agents such as diazepam, but nitroprusside may be necessary in patients who fail chemical sedation.

Patients should receive sedation if necessary. Auditory, tactile, and visual stimuli should be minimized. The technique of "talking down" a patient, often applied effectively to ketamine and dextromethorphan overdose, is generally ineffective in PCP poisoning; the practice may even provoke hostile behavior in PCP-poisoned patients. Combative or hostile patients should receive chemical sedation with either benzodiazepines or phenothiazines. The preferred agent is intravenous lorazepam (initial dose 0.1 mg/kg, total dose titrated to desired level of sedation). However, intramuscular haloperidol (5 to 10 mg) has been demonstrated to improve schizophreniform symptoms seen in PCP poisoning. Notably, phenothiazines may produce unintended adverse reactions such as anticholinergic reactions, dystonia, or seizure activity. These adverse reactions are, however, rare. Physical restraints are highly undesirable and may contribute to mortality by enforcing isometric muscle contractions that are associated with severe lactic acidosis and hyperthermia.²⁷ If used, physical restraints must be rapidly replaced with chemical sedation.

Hyperthermia and metabolic acidosis arise from excess muscle activity; treatment of these findings may require neuromuscular blockage and mechanical ventilation. Although benzodiazepines have a beneficial

effect in moderate cases, severely ill, hyperthermic patients ($T \geq 40^\circ \text{C}$) should receive immediate paralysis with nondepolarizing agents such as vecuronium followed by orotracheal intubation and ventilation. Clinicians should avoid succinylcholine because of the risks of arrhythmia from rhabdomyolysis-associated hyperkalemia. There is no role for antipyretics in the management of hyperthermia from dissociative agent overdose; the increase in body temperature is due to muscular activity, not an alteration in the hypothalamic temperature set point.

Activated charcoal is indicated in cases of recent dextromethorphan ingestion (e.g., less than 1 hour after ingestion), but is of unclear benefit in PCP or ketamine toxicity since these agents are infrequently administered via oral routes. Because PCP is actively secreted in the stomach, multiple-dose activated charcoal may offer some benefit, although its efficacy has not been rigorously established. Continuous gastric suctioning has also been recommended for evacuating PCP-laden secretions. Close monitoring of electrolytes is warranted since continuous suctioning may remove potassium, hydrogen, and other essential ions.

There are no antidotes for dissociative agent poisoning. Respiratory depression, rarely described in severe dextromethorphan intoxication, intermittently responds to high-dose intravenous naloxone.⁴⁸ Clinicians should consider physostigmine to reverse anticholinergic signs if present.

Laboratory assessment of intoxicated individuals should include measurement of serum electrolytes, hepatic and renal function, acid-base status, serum creatinine phosphokinase, a toxic screen, and urinalysis. In addition, physicians should always measure the serum acetaminophen concentration and treat potentially toxic concentrations or hepatic injury with *N*-acetylcysteine.

Amphetamines and Derivatives

TIMOTHY E. ALBERTSON, MD, MPH, PHD ■ NICHOLAS J. KENYON, MD ■ BRIAN MORRISSEY, MD

At a Glance...

- Amphetamine abuse and toxicity account for significant morbidity, mortality, and emergency medicine and intensive care unit admissions.
- The impact of amphetamine toxicity is amplified by its association with violent crime and trauma.
- The ability of the various amphetamine-related compounds to cause significant behavioral and multiple organ system dysfunction contributes to the clinical challenge.
- After decontamination, treatment is primarily supportive.
- Community education and prevention approaches can reduce the incidence of this increasing problem.

INTRODUCTION AND RELEVANT HISTORY

Amphetamines and related stimulant compounds represent an increasingly important class of recreational drugs of abuse in the United States as well as in many other parts of the world. In some locales, they rival cocaine as a cause of drug-related Emergency Department (ED) and intensive care unit (ICU) admissions. Although altered mental status, psychiatric disorders, and cardiovascular symptoms are most commonly encountered with amphetamine use, toxic manifestations in nearly every organ system have been reported (Box 44-1).

The amphetamine-like compounds have a long medical history. Related phenylisopropylamines including the alkaloids ephedrine, obtained from *Ephedra mahuang*, and norpseudoephedrine, or cathine, obtained from *Catha edulis*, have been used for more than 5000 years in China and 600 years in East Africa, respectively.¹ Ephedrine was classified as a food additive in the United States. Because of this classification, the Food and Drug Administration (FDA) had little regulatory jurisdiction over it. Documentation of increasing cases of toxicity and deaths associated with its use resulted in an FDA ban of ephedrine in April 2004.

Although racemic β -phenylisopropylamine was first synthesized in 1887, initial investigations into the pharmacology of amphetamine derived from the basic phenylethylamine structure (Fig. 44-1) were not reported until 1930 by Piness.^{2,3} Early medicinal uses of amphetamine included the treatment of rhinitis and asthma.¹ The Smith, Kline and French Pharmaceutical Company introduced the Benzedrine Nasal Inhaler in the United States in 1932. Each inhaler contained 250 mg of synthetic racemic amphetamine base with menthol and various other aromatics.⁴ Abuse of amphetamines was quickly noted and increased with a 1936 report claiming

enhanced intellectual performance with use of the inhaler.^{4,5} Because of reports of medical complications, amphetamines became prescription drugs in the United States in 1938; however, inhalers initially remained available without prescription. Limited use and abuse of amphetamine and related compounds continued until World War II, when they were extensively used by the Allies and the Axis powers as stimulants in combat. D-Amphetamine is still used by the U.S. military as a “go pill” for sustained operations and during deployments, and often followed by a benzodiazepine as a “no go pill.”

The psychologically addicting characteristics were first realized when amphetamine abuse became epidemic in

BOX 44-1 MAJOR SIGNS, SYMPTOMS, AND NONINFECTIOUS MEDICAL COMPLICATIONS ASSOCIATED WITH USE OF AMPHETAMINES AND RELATED COMPOUNDS

Cardiac		Neurologic	
Chest pain	+++	Headaches	+

FIGURE 44-1 Chemical structures of several amphetamine-like compounds. The basic phenylethylamine structure is labeled. Both α and β side chain positions and the phenyl ring itself can be modified to alter the pharmacologic effects of these related compounds.

several countries including Japan and Sweden after World War II.⁶ The 1950s and 1960s brought widespread abuse of amphetamines to the United States. Abuse was initially limited to use as an anorectic or as a stimulant in an effort to improve intellectual and physical performance or to combat fatigue.⁷ A second pattern of abuse emerged later, with recreational use of amphetamines in an attempt to achieve a euphoric state.⁷ In addition to oral use, nasal and intravenous routes were popularized at this time.

Large amounts of amphetamines were legally produced in the United States, peaking in 1965 with more than 10 billion pills (10,000 kg) manufactured.⁷ Much of this amphetamine was diverted from legitimate pharmaceutical sales, mainly for the treatment of obesity, to illicit street use. Additional amphetamine-like compounds that have emerged have limited proven medical uses and varying abuse potential (Box 44-2). Compounds such as methamphetamine, propylhexadrine, aminorex fumarate, fenfluramine, and methylphenidate (Ritalin) are a few of these agents. After the passage of the Controlled Substances Act of 1970, manufacture and distribution of amphetamines were better regulated in the United States, and legal production was markedly reduced.⁷

The use of the phenethylamine derivative and amphetamine-like compound methylphenidate (Ritalin) has increased over the last 20 years primarily for the treatment of attention-deficit hyperactivity disorder (ADHD) in children and increasingly in adults. Toxic effects are similar to those of other amphetamines with agitation, tachycardia, and lethargy being the most

BOX 44-2 AMPHETAMINES AND RELATED COMPOUNDS

common symptoms.⁸ Exposures in children tend to be due to dosing errors or ingestion of a sibling's drug. Teenage and adult exposures tend to be associated with abuse or suicide attempts.

With reduced amounts of diverted pharmaceutical-grade amphetamines such as D-amphetamine (Dexedrine), large-scale illegal manufacture and illegal importation of amphetamines began. Methamphetamine is synthesized easily in crude street laboratories from readily available precursors such as L-ephedrine.⁶ Methamphetamine provides illicit users with equal or longer acting stimulant and euphoric action than that of D-amphetamine. During the past 20 years, "designer" illicit amphetamines have enjoyed popularity on the street (see Box 44-2).

EPIDEMIOLOGY

Colorful names have been used to refer to methamphetamines on the street, including "meth," "speed," "crystal," and "crank." Studies in the late 1980s established the illicit manufacture of methamphetamine to be a 3 billion dollar per year industry in the United States, localized primarily in Hawaii, California, Oregon, and Texas.¹ By the early 1990s, the crude techniques had given way to illicit manufacturers who were able to synthesize very pure methamphetamine. A 99% to 100% pure form of methamphetamine called "ice" (because of

its purity) demonstrates increased volatility when heated. Inhaling these volatile vapors, or “smoking meth,” provides the same “rush” as IV use of methamphetamine. Increasing use has been noted in many western states, and nearly epidemic use is reported in some parts of Hawaii and California.

Death associated with amphetamine use has been frequently reported the past 25 years to the present.⁹⁻¹¹ These deaths are often associated with assault, suicide, or homicide.^{9,10} Cocaine was involved in one fifth and methamphetamine in about one eighth of all homicides in San Diego County in 1987.¹² By 1989, methamphetamine accounted for 60% of illicit drug seizures by San Diego County law enforcement agencies and 40% of all drug rehabilitation referrals in the area.¹³ A large university teaching hospital in San Diego found an increase in the detection of amphetamine compounds on toxicology screens from 3% to 10% of all tests during a 7- to 8-year period.¹⁴ Predominantly men (56%) between the ages of 21 and 30 years (61%) had positive results.¹⁴ Between 1986 and 1988, a 1.7-fold increase in ED visits for methamphetamine abuse was reported nationwide.¹³ White males that are unemployed and of low income are most likely to use methamphetamine.¹⁵ Abuse of methcathinone, a cathinone-methamphetamine analog easily made as an oxidative product of ephedrine, has been widely reported in Russia and most recently in the midwestern United States. *p*-Methoxyamphetamine (PMA) is a substituted synthetic amphetamine used in the recreational drug culture including at “raves.” A number of fatal overdoses of this drug have been reported in South Australia and the United States.¹⁶⁻¹⁸

Stimulants are used differently in different regions. In California in 2003, the DEA identified methamphetamine as the primary drug threat, with MDMA (“ecstasy”) as the most popular “club” or “rave” drug.¹⁹ The 2002 federal drug seizures in California alone included 9551 kg of cocaine and 311.2 kg of methamphetamine along with the destruction of 1718 clandestine drug laboratories. In contrast, in Florida in 2002, 26,258 kg of cocaine and only 103.1 kg of methamphetamine were seized. A 2000 report noted that more than 35 million individuals abuse amphetamines compared with approximately 15 million who regularly abuse cocaine worldwide.²⁰

STRUCTURE AND STRUCTURE-ACTIVITY RELATIONSHIPS

As noted above, the various “designer” illicit amphetamines (see Box 44-2) have additional hallucinogenic properties gained by methoxyl group substitutions on the phenyl ring, especially at the 3,4 position (see Fig. 44-1). These drugs include agents such as 3,4-methylenedioxymethamphetamine (MDMA), 3,4-methylenedioxyamphetamine (MDA), and 2,5-dimethoxy-4-methylamphetamine (DOM). These agents have had intermittent popularity on the streets of various communities. The addition of the methyl group on the nitrogen of D-amphetamine generates methamphetamine, a longer

acting compound with more profound euphoric action. The appetite suppression effect is unchanged.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Amphetamines have complicated and diverse pharmacologic mechanisms. They work primarily (as indirect sympathomimetics) by affecting the release of catecholamines at the neuronal presynaptic terminal.¹⁻³ Amphetamines and related compounds work indirectly to cause neuronal stimulation by increasing postsynaptic catecholamines. This is accomplished by blocking the presynaptic uptake transport activity from the synaptic cleft, by blocking presynaptic vesicular storage, and by reducing cytoplasmic destruction of catecholamines by inhibiting mitochondrial monoamine oxidase.¹⁻³ Together these activities increase the rate of postsynaptic receptor stimulation. Both central and peripheral norepinephrine and dopamine neurotransmitters are affected. Some amphetamine-related compounds (e.g., ephedrine) are thought also to have the ability to directly stimulate sympathetic receptors (direct sympathomimetics), but this is probably not a major mechanism of action for most of these compounds.⁷ Amphetamines lack the local anesthetic effects of cocaine on cardiac and nervous tissue. The catecholamine toxicity of amphetamines is similar qualitatively to that of cocaine.

Increased norepinephrine postsynaptically causes sympathetic nervous system stimulation. This results in bronchodilation and increased heart rate, cardiac output, pupil size, and blood pressure, all of which are seen in the fight-or-flight response.¹ The central nervous system (CNS) effects of amphetamine appear to be mediated primarily by dopaminergic alterations, which cause changes in mood, excitation, motor movements, and appetite.¹ Some evidence suggests that repeated high-dose amphetamine exposure in both adults and fetuses or neonates results in long-lasting destruction or depletion of central dopamine neurons.¹ Further alteration in mood, psychotic behavior, and aggressiveness may be the result of CNS serotonin release or reuptake blockade.² The extent to which serotonin neurotransmission alterations function in the clinical manifestations of amphetamine toxicity is controversial.¹⁻³

PHARMACOKINETICS

Amphetamines are weak bases with pK_a values around 8.8 to 10.4. For example, amphetamine has a pK_a of 9.9.^{7,21} Amphetamines are easily absorbed across most biologic membranes including gut, airway, nasopharynx, muscle, and vagina. Peak plasma concentrations occur in minutes by the intravenous route, in about 30 minutes by the intramuscular or topical nasal route, and within 2 to 3 hours after ingestion.⁷ Tissue redistribution is extensive, and the high lipid solubility of the amphetamines leads to increased concentrations relative to serum in the liver, kidneys, and lungs. This results in

large volumes of distribution ranging from 3 to 6 L/kg for amphetamine, phentermine, and phenylephrine and 12 to 33 L/kg for fenfluramine and methylphenidate.⁷

Cerebrospinal fluid levels are about 80% of plasma levels at steady state. Therapeutic levels of amphetamine itself range between 30 and 40 ng/mL (0.030 to 0.040 mg/L), and death is associated with average levels of 8600 (range, 500 to 44,000) ng/mL in the blood.^{7,21} Wide variations in doses and blood levels are reported to cause toxicity. This is in part related to the tolerance to amphetamines that can develop. The serum half-lives of various amphetamine-related compounds are urine pH dependent and range between 7 and 34 hours.²¹ The more acidic the urine, the shorter the half-life because of reduced renal reabsorption of ionized urinary amphetamines. This leads to increased renal clearance of the ionized amphetamines.

Both active and inactive metabolites exist. Metabolism that results in aromatic hydroxylation, aliphatic hydroxylation, and *n*-dealkylation of amphetamines can give rise to active metabolites such as the potent hallucinogen *p*-hydroxyamphetamine.⁷ Other metabolic pathways, including deamination and subsequent side chain oxidation, produce inactive amphetamine derivatives.⁷ Glucuronide and glycine conjugation pathways result in urinary excretion of metabolites.²¹ As much as 30% of amphetamine is excreted unchanged in the urine, whereas between 86% and 97% of ephedrine, pseudoephedrine, and phenylpropanolamine is excreted unchanged.^{7,21}

Methylphenidate is metabolized by various pathways to ritalinic acid, *p*-hydroxymethylphenidate, or lactam. Increasing evidence suggests that the co-ingestion of ethanol and methylphenidate results in the novel metabolite ethylphenidate that may contribute to its toxicity.^{22,23}

Concomitant use of drugs such as the opiates (“speed-balling”) can increase the overall toxicity of amphetamines. However, major alterations of the metabolic pathways of amphetamine have not been postulated as an explanation for the increased toxicity.²¹ Simultaneous use of methamphetamine and ethanol has more psychological and cardiac effects than use of methamphetamine alone. This response also is presumed to be pharmacodynamic in nature rather than a result of any specific pharmacokinetic interaction.²⁴

TOXICOLOGY

The amphetamines can cause toxic effects to every organ system. Both acute and chronic and direct and indirect abnormalities have been reported. Figure 44-2 summarizes the clinical presentation of acute amphetamine toxicity. The exact prevalence and incidence of the toxicities summarized in Box 44-1 have not been determined and probably vary with route, dose, and length of exposure to each of the amphetamine-related agents.

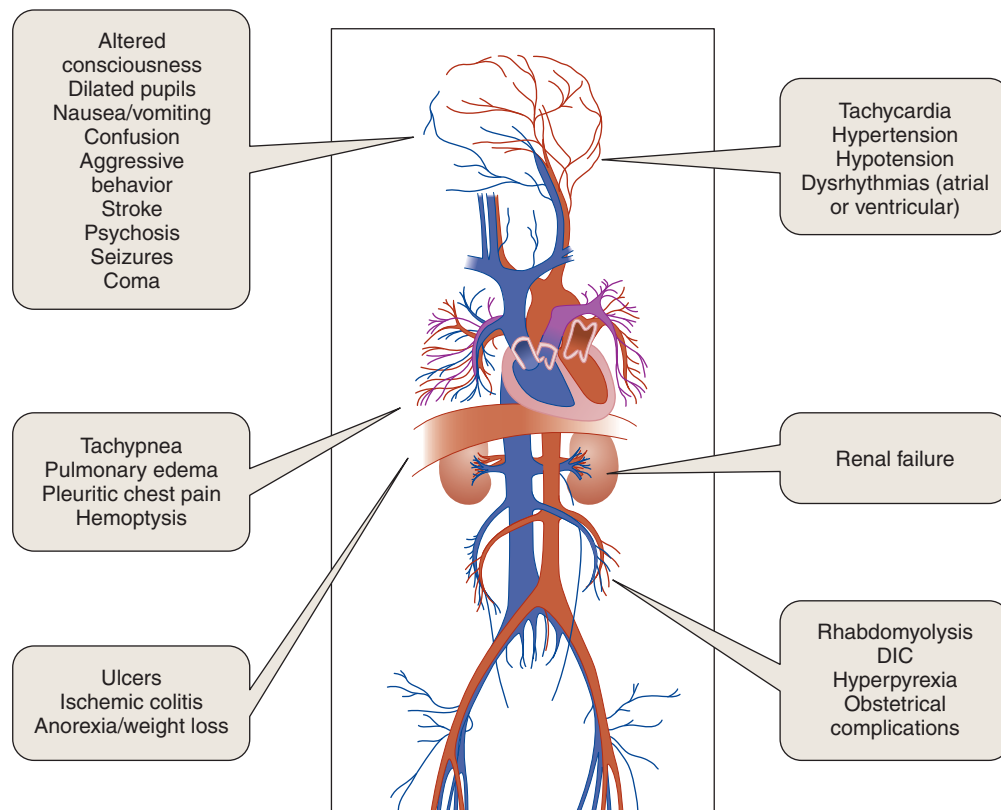

FIGURE 44-2 Major signs and symptoms associated with acute amphetamine toxicity.

Central Nervous System Toxicity

The CNS is the target organ for the pharmacologic effects of most amphetamine-related compounds. As such, significant CNS toxicity can result from use of amphetamines. With the resurgence of amphetamines as drugs of abuse in the 1960s, it was quickly recognized that the initial sensation of extreme physical and mental powers following amphetamine use could rapidly deteriorate with high doses or chronic moderate doses to recurrent affective lability, confusion, and hallucinations.^{25,26} In a series of 127 amphetamine-poisoned patients presenting to an ED, 57% were determined to have altered mental status.²⁷ Agitation, suicidal ideation, hallucinations, delusions, confusion, and despondent affect were the most common major signs and symptoms noted. The presenting manifestations of headache affected 4%, seizure 3%, and paresthesia 2%.²⁷ An additional 10% were unresponsive.²⁷

Tolerance to the autonomic effects of amphetamine has been reported for body temperature, blood pressure, heart rate, and respirations. The anorectic effects of amphetamines exhibit tolerance as well.²⁸ In contrast, the motor stimulant and stereotypic behavior effects of amphetamine display progressive enhancement with repeated intermittent administration.²⁸ This is termed *behavioral sensitization* or *reverse tolerance*.

Researchers have postulated that the acute paranoid delusional psychosis associated with amphetamine use may produce a psychosis similar to schizophrenia that persists through behavioral sensitization long after elimination of the amphetamine.²⁹ Whether this represents emergence of an underlying psychiatric disorder or simply a lowering of the threshold for drug-induced psychosis is not known.^{30,31} When challenged with large doses of IV methamphetamine, patients dependent on amphetamine developed drug-induced psychosis.³¹ This same dose of methamphetamine failed to produce drug-induced psychosis in non-amphetamine users.³¹ Drug-induced psychotic states have been reported with abuse of most of the stimulant amphetamine-related compounds, including cathinone, pemoline, and phenmetrazine.³²⁻³⁴ Psychosis is common with derivatives of amphetamine that are hallucinogens, such as mescaline, DOM, MDA, *p*-methoxyamphetamine, and MDMA.³³ Although tolerance to the hallucinogenic properties of these agents has been noted, prolonged psychotic reactions are also well documented.³³ Acute severe hallucinations with bizarre and risky behavior due to the use of agents such as MDA, MDMA, and 3,4-methylenedioxyamphetamine have resulted in traumatic deaths.³⁵ Mild to moderate amphetamine-induced agitated behavior and psychosis can be treated with benzodiazepines (e.g., diazepam or lorazepam), but severe symptoms should be treated with high-potency antipsychotic agents (e.g., haloperidol, droperidol, or thiothixene).^{7,27,36} Minimizing sensory stimuli with low doses of benzodiazepines in combination with low doses of antipsychotic agents has been a useful approach to amphetamine-induced psychosis.

In addition to behavioral effects including agitation, hallucinations, and psychosis, amphetamine use is associated with several other neurologic toxicities. Amphetamine-induced changes in sexual function and performance including enhancement and inhibition are complicated and have been reviewed.³⁷

Cases of juvenile parkinsonism associated with MDMA have been reported.³⁸ Positron-emission tomography (PET) scans suggest that amphetamine compounds have profiles of binding to the dopamine transporter and changes in synaptic dopamine levels similar to cocaine.³⁹ The chorea of patients with Huntington's disease is exacerbated by use of amphetamines.⁴⁰ The dopaminergic receptor blocker haloperidol was shown to inhibit the amphetamine-induced exacerbation of the choreoathetoid movements.⁴⁰ Choreoathetoid movement disorders have also been seen with acute and chronic amphetamine exposures in patients who do not have Huntington's disease.^{41,42} Treatment of acute amphetamine-induced choreoathetoid movement disorders includes supportive care, gastrointestinal decontamination with activated charcoal, and administration of haloperidol.⁴¹

Seizures have been reported with severe intoxications of amphetamine and related compounds.^{27,43-45} The seizures have been isolated or associated with hyperpyrexia, coma, metabolic acidosis, and shock. IV benzodiazepines (e.g., diazepam, lorazepam), phenytoin, and barbiturates (e.g., pentobarbital, amobarbital) have been used to terminate amphetamine-induced seizures.^{7,44}

Intracerebral hemorrhage is associated with the use of amphetamines and related compounds. Amphetamine-related cerebral hemorrhage has occurred in patients with arteriovenous malformations⁴⁶ and drug-induced cerebral vasculitis.⁴⁷⁻⁵⁰ Both oral and IV amphetamine exposures have resulted in cases of cerebral vasculitis.⁴⁷⁻⁵¹ Traditional approaches to intracerebral hemorrhage have focused on supportive care, correction of the hypotension, use of corticosteroids, and employment of antifibrinolytic agents such as ϵ -aminocaproic acid.⁴⁷⁻⁵⁰ Treatment directed at the vasculitis in these cases has included use of dexamethasone and cyclophosphamide therapy.^{47,48} The efficacy of these agents in the treatment of amphetamine-associated vasculitis is unknown.

Ischemic strokes have been reported with amphetamine compounds taken orally, intravenously, and by inhalation.⁵² Supportive care and hypervolemic hemodilution therapy using albumin or 10% dextran 40 has been advocated after angiographic demonstration of cerebral artery spasm and occlusion.⁵² Elective extracranial/intracranial bypass was performed in at least one case of amphetamine-associated occlusive stroke, but its efficacy is unproved.⁵² A case of transient cortical blindness in an infant exposed to methamphetamine has been reported.⁵³ The blindness resolved within 12 hours without specific therapy. It was postulated to represent a manifestation of amphetamine-induced cerebral vasospasm.⁵³

Methamphetamine neurotoxicity in human abuse is thought to be in part due to necrotic and apoptotic mechanisms.⁵⁴ The central nervous system is the main

target of the pharmacologic actions of the amphetamines and is also the most frequent organ system to manifest amphetamine-induced toxicity.

Cardiovascular System Toxicity

In a retrospective study of patients with amphetamine toxicity presenting to an ED, hypertension and tachycardia were commonly encountered. The same study found that patients complained of chest pain 9% and palpitations 3% of the time.²⁷ Direct pharmacologic effects of the amphetamines most likely account for the frequently encountered hypertension and the tachycardia. In a double-blind, placebo-controlled study of eight healthy adults, modest doses of MDMA increased heart rate, blood pressure, and myocardial oxygen consumption in a magnitude similar to that of dobutamine without causing the positive inotropic effects of dobutamine.⁵⁵ Hypertension and agitated behavior associated with amphetamine use are initially approached by minimizing stimulus or sensory inputs and by using sedating agents. If more specific treatment is needed, the use of IV nitroprusside or oral or IV calcium channel blockers (e.g., nifedipine or nicardipine) may be indicated. β blockers should not be used in the treatment of amphetamine-induced hypertension without concomitant α blockade, because unopposed α blockade can produce intense vasospasm and paradoxical hypertension.

Appetite suppressants and amphetamine derivatives have been associated with an increased risk of cardiac valvular insufficiency.⁵⁶⁻⁵⁸ The use of fenfluramine or dexfenfluramine for 4 months or longer was associated with an increased risk of valvular changes.⁵⁹ Fenfluramine has been used with the phenylethylamine derivative phentermine (Fen-Phen) extensively to suppress appetite. By 1997, reports of aortic mitral regurgitation associated with the use of these drugs surfaced. The mechanism of this effect is unknown; incidence estimates vary from less than 1% to greater than 20% after exposure to Fen-Phen for more than 4 months.^{60,61} Some echocardiographic improvement with cessation of use has been noted. These findings coupled with evidence of associated pulmonary hypertension resulted in the removal of fenfluramine from the market.

Ectopic ventricular beats as well as supraventricular and ventricular tachyarrhythmias have been reported with amphetamine use. Direct catecholamine effects and ischemic effects secondary to coronary vasospasm generated by amphetamine use are probably responsible for the arrhythmias.⁶² Although not normally studied, short-acting β -adrenergic receptor blockers (e.g., esmolol), calcium channel blockers (e.g., verapamil, diltiazem), or lidocaine can be used to treat these arrhythmias. Correction of hypoxia and electrolyte abnormalities also is required.

Myocardial infarction associated with amphetamine use is thought to be secondary to direct cardiac toxicity (myocarditis), vasospasm, and thrombus formation.^{62,63} Cardiac irritability and myocardial infarction in a 13-year-old has been reported after amphetamine overdose.⁶⁴ In

addition to treatment with nitrates and analgesics, at least one report describes the use of thrombolytics in treating amphetamine-induced myocardial infarctions.⁶³ Profound hypotension, bradycardia, and metabolic acidosis have occurred with massive amphetamine overdoses. Treatment includes aggressive hemodynamic support with intravascular volume replacement and vasopressor agents (e.g., norepinephrine or phenylephrine). Direct-acting catecholamines (norepinephrine or phenylephrine rather than dopamine) are preferred because massive overdoses may result in a relative catecholamine-depleted state.

Both acute and chronic cardiomyopathies have been associated with amphetamine use. This effect is thought to be secondary to direct amphetamine toxicity and indirect hypertension.⁶⁵ Treatment includes avoidance of amphetamines, use of diuretics and digoxin, and afterload reduction (e.g., nitroprusside acutely and angiotensin-converting enzyme inhibitors such as captopril for long-term use).⁶⁶ IV amphetamine use is associated with bacterial endocarditis, which can lead to abnormal cardiac valves, dilated cardiomyopathy, and formation of mycotic aneurysms. Acute aortic dissection, necrotizing angitis, and both visceral and cerebral aneurysms have also been reported to occur in amphetamine users.^{62,67}

Arterial or tissue-extravasated amphetamine quickly leads to tissue ischemia. Immediate intra-arterial or local tissue injection of α -adrenergic blocking agents such as phentolamine or phenoxybenzamine is indicated to reverse the local vasopressor effects of amphetamines. General supportive or symptomatic care is most important to maintain the cardiac system during acute amphetamine toxicity.

Pulmonary System Toxicity

Respiratory symptoms including chest pain and dyspnea have been presenting complaints of patients with amphetamine toxicity presenting to an ED.²⁷ The actual incidence of respiratory toxicity with amphetamines is not known. The incidence and types of toxicity may vary, depending on the amphetamine compound and the route of exposure. One review examined pulmonary effects of exposure to amphetamine-related compounds.⁶⁸ Although amphetamines are often snorted, inhaled, and smoked, the literature does not note an association with barotrauma. On the other hand, a few case reports have associated cocaine, which has similar routes of administration, with barotrauma.⁶⁸

Despite increased use of inhaled or smoked methamphetamine, no extensive reports of exacerbation of reactive airway disease have been noted. In comparison, the association between asthma and cocaine, which has similar pharmacologic properties and patterns of abuse to methamphetamine, is much stronger. One death due to asthma has been reported with the use of the hallucinogenic amphetamine MDMA.³⁵ In that case, a young man was found dead clutching an inhaler and had pathologic features of asthma at postmortem examination. The contribution of his MDMA use to his

asthma death is speculative. Thirteen patients in two small case series have noted obstructive findings associated with 20% to 60% reductions in carbon monoxide diffusion capacity after IV methylphenidate use.^{69,70} These patients showed variable responses to β -adrenergic agonist bronchodilators (e.g., albuterol) and were noted to have panlobular emphysema. Foreign particle embolization from IV dosing of methylphenidate was postulated as the cause rather than a direct drug effect, as similar findings have been found with other IV drugs (e.g., methadone).^{68,71}

Case reports describe acute noncardiogenic pulmonary edema associated with amphetamine toxicity.⁶⁸ Not only smoking but also ingesting amphetamines has been associated with the development of pulmonary edema.⁷² At least one death with pulmonary edema has been related to the use of MDMA.³⁵ Animal data suggest, at least in part, a direct amphetamine toxicity leading to leaky pulmonary capillaries partly mediated by free-radical and oxidant injury.⁷³ Alternatively, edema may occur owing to indirect neurogenic (e.g., seizure) or cardiovascular (e.g., shock, hydrostatic leak) consequences. Although noncardiogenic pulmonary edema with cocaine abuse is reported more frequently in the literature than with amphetamine abuse, its mechanism also has not been determined and may be similar.⁶⁸

The literature has for some time described amphetamine use associated with pulmonary hypertension. Users of IV amphetamines obtained from nasal inhalers available until the 1960s were noted to have pulmonary artery foreign body granulomas and muscle hypertrophy.^{4,68} Long-term inhalation of methamphetamine and propylhexedrine also has been associated with marked pulmonary hypertension at autopsy in at least one case and in a second case of sudden death.^{74,75} Proposed mechanisms include direct toxic endothelial injury caused by the drugs or their contaminants, recurrent hypoxic insults, direct spasm in genetically determined sensitive hosts, vasculitis, and dysregulation of the mediators of vascular tone such as nitric oxide. The amphetamine-like anorectic agents fenfluramine and aminorex fumarate have also been associated with several European reports of pulmonary hypertension.⁶⁸ Pulmonary artery vasodilation and remodeling agents have been used for these drug-induced cases of pulmonary hypertension, along with the avoidance of stimulants and supportive care, including supplemental oxygen for hypoxic patients.

With the increased incidence of smoking methamphetamine, the authors have noted pulmonary toxicities similar to those reported with the use of the stimulant crack cocaine. These include hemoptysis, alveolar hemorrhage, and alveolar accumulation of carbonaceous material associated with cough, bronchitis, sinusitis, and thermal epiglottitis.⁶⁸ Basic airway management and supportive care are the only approaches to these complications. In severe cases of amphetamine-induced pulmonary edema, aggressive mechanical ventilatory support with the addition of positive end-expiratory pressure and high levels of inspired oxygen flow often are required.

Systemic Toxicity

Severe systemic toxicity has been reported with overdoses of amphetamine-related compounds. A pattern of fulminant hyperthermia, convulsions, disseminated intravascular coagulation (DIC), hepatocellular damage, rhabdomyolysis, acute renal failure, arrhythmias, and refractory hypotension has been seen with use of MDMA.⁴³

Hyperthermia, shock, pulmonary edema, rhabdomyolysis, acute renal failure, and DIC have been encountered with use of “designer” amphetamines as well as with phenmetrazine and methamphetamine.^{43,45,76-78} In certain parts of the country, trauma may have a high association with methamphetamine. Severe metabolic acidosis associated with methamphetamine use has exaggerated the estimated severity of the injury in trauma patients.⁷⁹ Aggressive cooling, cardiopulmonary support, large amounts of intravascular volume replacement, electrolyte replacement, temperature control measures, and early extracorporeal hemodialysis are needed to overcome the amphetamine-induced hyperthermia with severe rhabdomyolysis in these patients.^{43,76} If cooling and sedation do not control the hyperthermia, then neuromuscular blockade and mechanical ventilation may be needed.⁷⁷ This combination of severe systemic toxicity from amphetamines appears to predict a poor outcome.

Hepatotoxicity with hepatocellular damage has occurred with use of MDMA and other amphetamines.⁸⁰⁻⁸² Postulated mechanisms for the hepatotoxicity include direct toxic effects, lipid peroxidation, necrotizing angiitis, contaminants, hypotension, and genetic variations in metabolism, which create toxic intermediates. Treatment consists of supportive care and avoidance of amphetamines. At least one liver transplant has been attempted.⁴³ To further complicate this issue, a case of thrombocytopenic purpura after MDMA-induced acute liver failure has been reported.⁸³

In addition to the severe systemic toxicities described above, reversible ischemic colitis induced by methamphetamine abuse has been reported. Abdominal pain was the presenting complaint in 4% of amphetamine-poisoned patients presenting to an ED.²⁷ The exact incidence of amphetamine-related ischemic bowel and hemorrhagic colitis in abusers of amphetamines is unknown.⁸⁴ Diagnostic efforts to rule out necrotic bowel would be prudent in amphetamine-associated cases of persistent abdominal pain, particularly with bloody stools. Giant gastric and duodenal ulcers are strongly associated with methamphetamine use.⁸⁵

Skin changes including lichenoid drug eruptions and burns complicated by “rave” use of amphetamine derivatives have been noted.^{86,87}

Obstetric and Prenatal Toxicity

Gestational exposure to amphetamines has been postulated but not proved to have lasting effects on neonates.⁸⁸ After illicit amphetamine exposure, infants have had hypoglycemia, sweating, poor feeding, poor visual tracking, and seizures.⁸⁸ As with cocaine exposure,

fetal amphetamine exposure was associated with intrauterine growth retardation, decreased head circumference, preterm delivery with fetal distress, anemia, and placental abruption in one study.⁸⁸ An amphetamine withdrawal pattern similar to that of cocaine withdrawal was noted in these infants. This pattern consisted of abnormal sleep patterns, tremors, hypertonia, high-pitched cry, poor feeding, vomiting, sneezing, frantic sucking, and tachycardia.⁸⁹ Although long-term behavioral and neurologic follow-up of these infants is not yet available, early reports suggest that chaotic lifestyles with minor neurologic abnormalities continue for these infants after discharge from the hospital.⁸⁸ Other studies have reported reduced birth weight with methamphetamine exposure relative to normal populations but no increase in other adverse outcomes.⁸⁹ In a report of eight cases of fetal and infant deaths, blood levels of methamphetamine averaged 0.36 µg/mL (range, 0.03 to 1.20 µg/mL).⁹⁰

A large retrospective study in the United States and Canada of vasoactive compounds such as pseudoephedrine, phenylpropanolamine, ephedrine, and methylenedioxymethamphetamine exposure during the first 2.5 months of pregnancy resulted in doubling the risk of gastroschisis and small intestinal atresia.⁹¹ Combination exposure to vasoactive drugs and 20 or more cigarettes per day increased the risk with an odds ratio of 3.6 (1.3 to 10.3) for gastroschisis and 4.2 (1.1 to 16.2) for small bowel atresia.⁹¹ One hypothesis is that these small intestine defects are the result of vascular disruption by toxins in early gestation.

Pregnant women exposed to amphetamines are at increased risk of serious obstetric complications, including intracranial hemorrhage, seizures, and amniotic fluid embolism.⁸⁹ No specific therapy has been identified for neonates or pregnant women heavily exposed to amphetamines. Identification of at-risk women before pregnancy and during prenatal care would afford an opportunity to educate. Unfortunately, many pregnant women using amphetamines do not seek prenatal care and may be unable or unwilling to reduce their gestational exposures.

DIAGNOSIS

The clinician should consider the diagnosis of toxicity from amphetamine-related compounds in the differential diagnosis when behavioral stimulation is coupled to evidence of catecholamine excess. Inadvertent exposure to amphetamines can occur in pediatric patients, particularly around adults participating in illegal manufacture and distribution.

Urine screening tests primarily utilizing immunoassay techniques exist for amphetamine-related compounds and are often part of “drug abuse” screens.⁹² Confirmation of urine and blood samples is made by a gas chromatography coupled with mass spectroscopy (GC-MS) analysis.⁹³ Urine can remain positive for greater than 48 hours after exposure depending on route, rate of absorption, urine pH, and hydration status.⁹⁴ Many

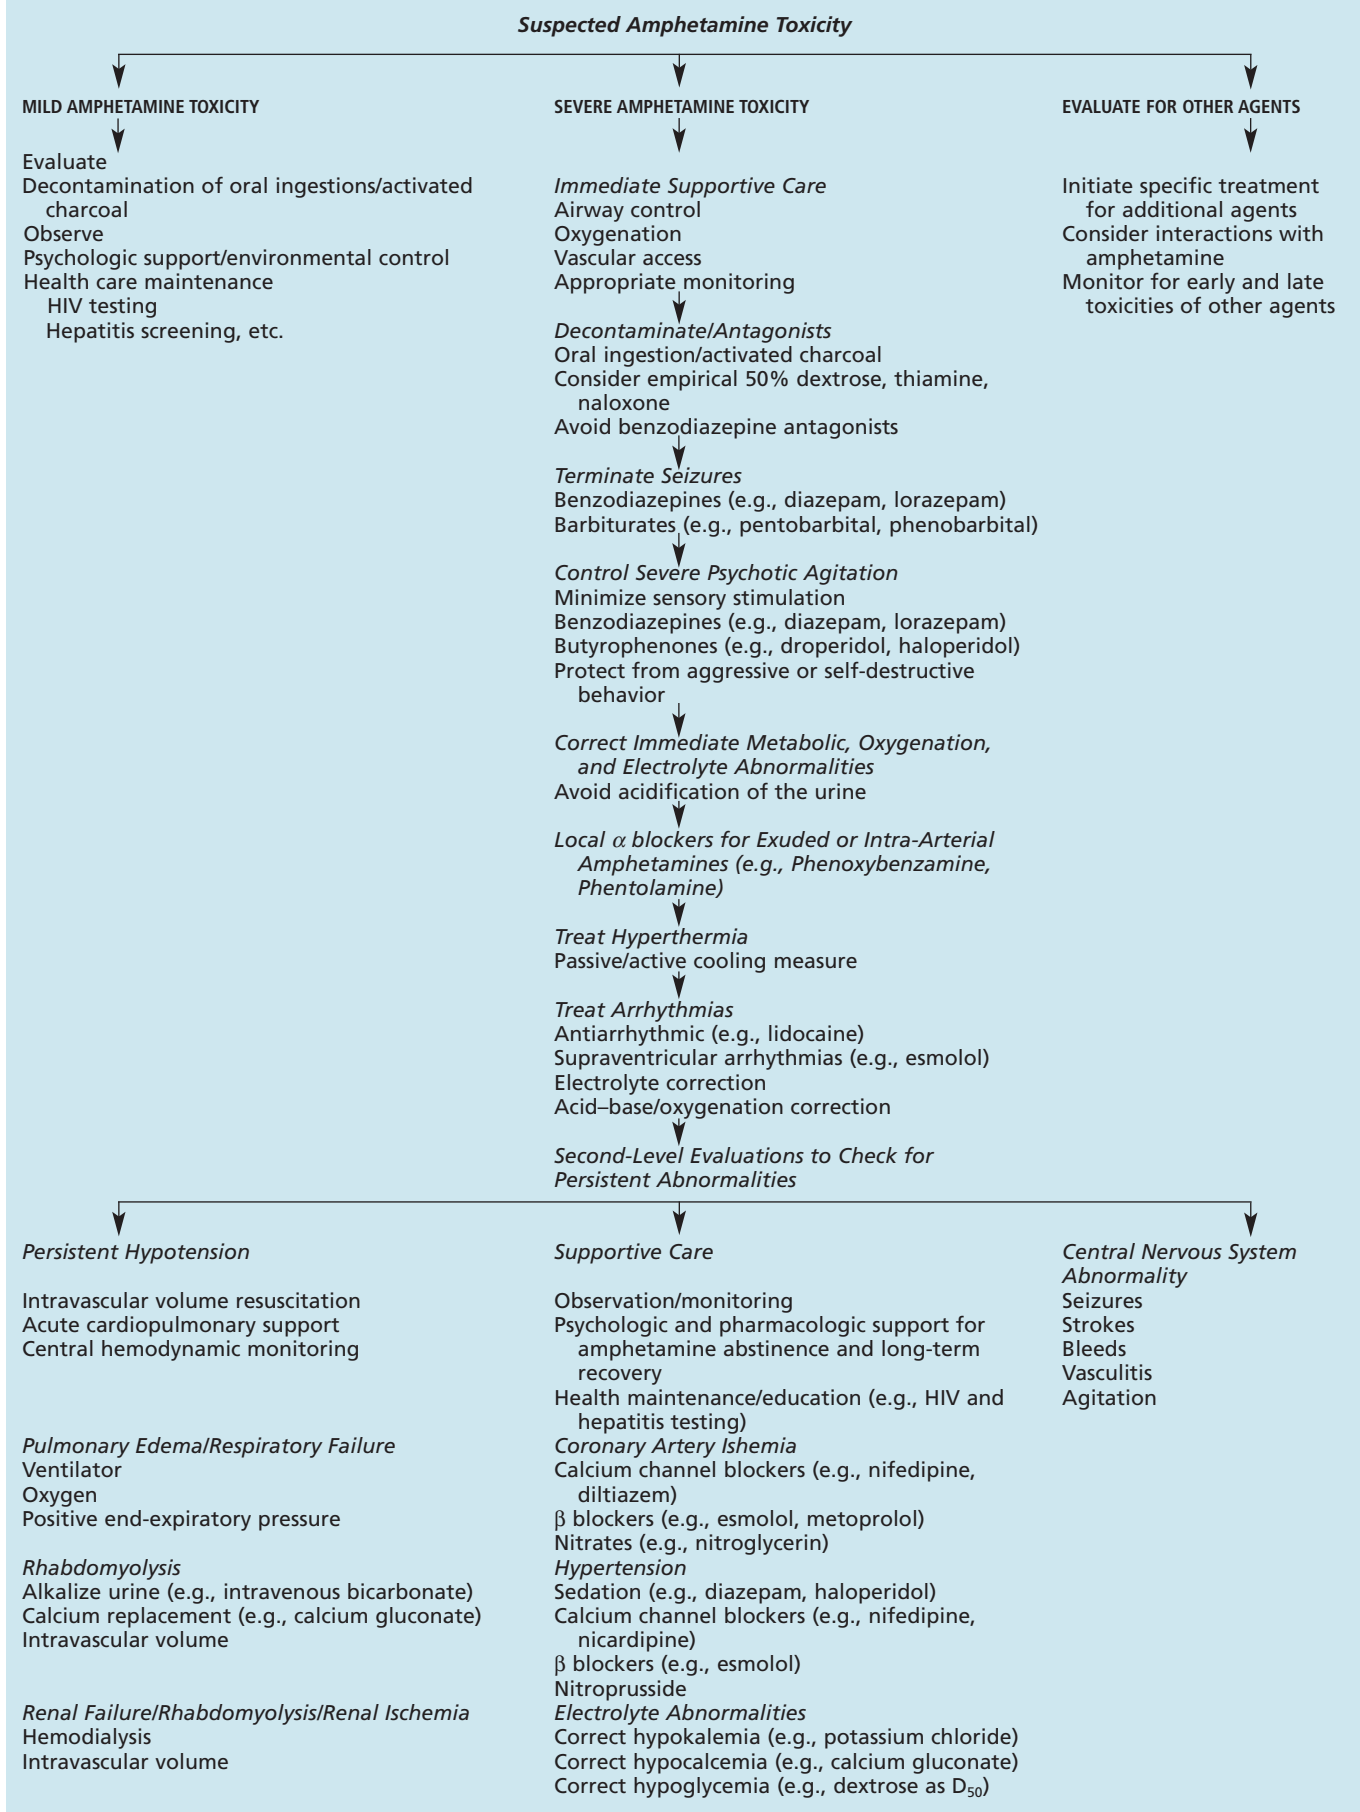

laboratories used to monitor persons in sensitive occupations have thresholds for reporting positive amphetamine results in the urine. Drug detected below these thresholds is not reported. Some laboratories require the D-isomer of methamphetamine to be present along with detectable amphetamine (a metabolite) to report a urine sample positive for methamphetamine. For example, selegiline is metabolized to L-amphetamine and L-methamphetamine (both have minimal toxicity) and will be reported as positive for methamphetamine unless an isomer analysis is performed.⁹⁵ Other drugs such as clobenzorex, a Mexican anorectic drug, are metabolized to actual D-amphetamine and will give a positive result on confirmation by GC-MS analysis.⁹⁶ Infrared transmission spectroscopy has been used to detect methamphetamines.⁹⁷ A rapid-detection, non-aqueous capillary electrophoresis-fluorescence spectroscopy method for MDMA has been reported.⁹⁸ The use of hair analysis for amphetamine-related compounds has also been reported but is of little use clinically because of interlaboratory variability.⁹⁹⁻¹⁰²

MANAGEMENT

An algorithm for the general approach to a suspected amphetamine-poisoned patient is shown in Table 44-1. No prospective human trials have evaluated different treatment options. Most recommendations are based on animal studies or case reports of humans. For example, the efficacy of activated charcoal in treating oral methamphetamine exposure has been demonstrated in a study in mice but lacks human trials.¹⁰³ Early recommendations to acidify the urine in amphetamine overdoses were based on a single case.¹⁰⁴ The risks of systemic acidification and the potential problems for the kidneys when rhabdomyolysis is present have prevented this recommendation from being widely adopted until controlled trials have demonstrated improved patient outcomes. Clinicians must be aware of the problem of contaminants in addition to the direct toxic effects of amphetamines. A cluster of at least 14 cases of acute lead poisoning was found in IV methamphetamine users in Oregon in 1988. Amphetamine products manufactured in clandestine laboratories may be grossly contaminated with toxic heavy metals and chemicals. In addition, the authors have noticed a cluster of 20 cases of acute botulism poisoning associated with illicit drug use.^{105,106}

General supportive care; decontamination of the gastrointestinal tract with activated charcoal for ingestions; and control of behavior, seizures, arrhythmias, and temperature remain the mainstay of therapy for amphetamine-poisoned patients. An animal model failed to demonstrate the utility of multiple doses of activated charcoal after IV methamphetamine.¹⁰⁷ In the absence of renal failure, dialysis and hemoperfusion have no role in amphetamine overdose. Specific measures when available for each complication associated with amphetamine use have been mentioned above. Vaccines and antibodies directed against methamphetamine are currently under development to treat overdoses and long-term drug

TABLE 44-1 Amphetamine and Related Compound Toxicity and Treatment and Decision Algorithm

abuse.¹⁰⁸ Infectious diseases should be considered. Patients should be evaluated for complications attendant to IV drug abuse such as bacterial endocarditis, viral hepatitis, and human immunodeficiency virus. Once the acute symptoms of amphetamine poisoning have passed, treating physicians should consider referring patients for rehabilitation or psychiatric care to break up the destructive drug abuse pattern.

45 *Hallucinogens*

STEPHEN J. TRAUB, MD

At a Glance...

- Most hallucinogens are indoleamine or phenylethylamine derivatives that are structurally similar to the neurotransmitter serotonin.
- Hallucinogens commonly used today include lysergic acid diethylamide, mescaline, 5-methoxy-*N,N*-diisopropyltryptamine (“foxy methoxy”), and psilocybin (in “magic mushrooms”).
- Hallucinogens produce disturbances of perception, mood, and thought.
- Occasionally, hallucinogens produce negative experiences, often referred to as a “bad trip.”
- Treatment of hallucinogen toxicity is primarily supportive; agitation often necessitates “talking the patient down” and/or treatment with benzodiazepines.
- Hallucinogen persisting perceptual disorder, more commonly known as “flashbacks,” is a syndrome whereby previous users of LSD experience perceptual distortions despite abstinence from the drug.
- Hallucinogens rarely cause life-threatening alterations in physiology, but severe impairments in judgment may lead to severe disability or death.

The term *hallucination* is derived from the Latin word *hallucinari*, which means “to wander in mind.” Hallucinations are false sensory perceptions that occur in the absence of real external stimuli; hallucinogens are substances that produce these perceptions. Many drugs may produce hallucinations, but those classified as hallucinogens or “psychedelics” produce disturbances of perception, mood, and thought as their primary effect with each use.

HISTORY

Although most commonly associated with the “psychedelic” era of San Francisco’s Haight-Ashbury district during the 1960s, hallucinogens have a rich history and have been used by humans for millennia.¹ Hallucinogens have been and still are regularly used as integral parts of religious rituals. The Aztecs consumed psilocybin-containing mushrooms (*teonanacatl*, or “flesh of the gods”) during their ceremonies. Mescaline, the major active alkaloid of the peyote cactus (*Lophophora williamsii*), is still used in religious ceremonies by Native American tribes in the Desert Southwest of the United States.

The modern era of hallucinogen use was inadvertently ushered in by Albert Hoffman of Sandoz Laboratories in 1943. Hoffman was working with synthetic ergot derivatives in an attempt to create new vasoactive medications when he inadvertently absorbed

one of them, lysergic acid diethylamide (LSD), percutaneously. Soon afterward, he reportedly began to experience sensations we now recognize as characteristic of hallucinogen use:

The external world became changed as in a dream. Objects appeared to gain in relief; they assumed unusual dimensions; and colors became more glowing. Even self-perception and the sense of time were changed. When the eyes were closed, colored pictures flashed past in a quickly changing kaleidoscope. After a few hours, the not unpleasant inebriation, which had been experienced whilst I was fully conscious, disappeared.²

Sandoz later marketed LSD as Delysid. It was touted as a cure for several psychiatric ailments, including alcoholism³ and, interestingly, schizophrenia.⁴ It was also used regularly by psychiatrists for analytical psychotherapy^{5,6} and as an adjunct to treat those with terminal illness. LSD, however, was prohibited from use in the United States in 1966, and the drug was classified as a schedule I substance by the Drug Enforcement Agency as part of the Controlled Substances Act of 1970. This dramatically curtailed further human research with hallucinogenic drugs.

The use of hallucinogens as a means to “expand the mind” was popularized in the 1960s. In 1960, Dr. Timothy Leary, a Harvard psychologist, used psilocybin for the first time. His interest in this drug led to the development of the Harvard Psilocybin Project, in which hallucinogens were given to volunteers. Leary first tried LSD in 1962, and shortly thereafter began touting its benefits. He was (not coincidentally) fired from his Harvard position in 1963 but went on to become one of the strongest public advocates of hallucinogen use. The popularity of LSD and other hallucinogens grew during the rest of that decade, until it reached its height of popularity in the late 1960s.

At the same time that Leary was urging people to “tune in, turn on, and drop out,” however, more established institutions began paying attention to—and expressing alarm at—the “epidemic” of hallucinogen use. A review of LSD in the *New England Journal of Medicine* in 1968 opened with the statement that “no drug use by man has stimulated greater public debate than lysergic acid diethylamide,” and opined that “the widespread use of LSD, or similar drugs waiting in the psychedelic wings, could lead to a whole generation of psychedelic dropouts, incapable of and uninterested in addressing themselves to the important sociologic problems that challenge our times. If this happened, the very structure of this democratic society would be threatened.”⁷

EPIDEMIOLOGY

Although the use of LSD and other hallucinogens has decreased since the 1960s, it has not disappeared. According to a 1999 report by the National Institutes of Health National Institute on Drug Abuse, approximately 10% of the U.S. population aged 12 and older has experimented with hallucinogens.⁸ Use generally begins between ages 15 and 19, peaks at age 19, and becomes less common after age 30.⁹ Whites are more likely than African Americans or Hispanics to report hallucinogen use⁹ and are less likely to perceive that LSD is a dangerous drug.

A recent report from the Drug Abuse Warning Network (DAWN) notes a significant decline in emergency department (ED) visits related to LSD from 1994 to 2001.¹⁰ DAWN estimates that in 2001, LSD was associated with 2821 ED visits in the coterminous United States; this represents a 45% decline from that reported in 1994. In 2001, LSD accounted for only 11% of ED visits associated with club drugs and 0.4% of all drug-related ED visits. Still, adolescents (12 to 17 years of age) and young adults (18 to 25 years) account for 34% and 48% of all ED visits related to LSD, respectively.

Members of previous generations may have relied on friends to tell them about their experiences with hallucinogenic drugs before trying them. Today, however, websites such as Erowid (www.erowid.org) and Lycaenum (www.lycaenum.org) contain information and descriptions (many very positive) of the effects of hallucinogen use. These websites are attractive to adolescents and young adults and may serve to reinforce the use of hallucinogenic drug use in this group of patients.

CLASSIFICATION

There are several classes of hallucinogens that are commonly used today. They include the indoleamines, phenylethylamines, piperazines, arylcyclohexylamines, tetrahydrocannabinoids, anticholinergics, and diterpene alkaloids (Table 45-1). The indoleamines include lysergamides (e.g., LSD) and alkyltryptamines (e.g., *N,N*-dimethyltryptamine [DMT], psilocybin, and bufotenine). The phenylethylamines include mescaline, dimethoxymethylamphetamine, methylenedioxymethamphetamine, and other amphetamine derivatives. Piperazines are structurally similar to phenylalkylamines and include benzylpiperazine and trifluoromethylphenylpiperazine. The synthetic amphetamine and piperazine derivatives are discussed in Chapter 44. The arylcyclohexylamines include phencyclidine, ketamine, and dextromethorphan and are discussed in Chapter 43. Tetrahydrocannabinoids include marijuana and hashish and are discussed in Chapter 41. The anticholinergics include belladonna alkaloids and a wide variety of pharmaceutical agents (see Chapter 39). The diterpene alkaloids are found in the plant *Salvia divinorum*. This chapter will largely discuss the two primary hallucinogen classes, indoleamines and phenylalkylamines, as well as diterpene alkaloids.

Lysergamides

The lysergamides or ergolines include the synthetic D-lysergic acid diethylamide and naturally occurring indole alkaloids from the morning glory and Hawaiian baby wood rose plants. LSD is synthesized from lysergic acid and diethylamine; the former is derived from the wheat or rye fungus *Claviceps purpurea*. Seeds from the morning glory plants *Ipomoea violacea* and *Rivea corymbosa* (Mexican ololiuqui), the Hawaiian baby woodrose (*Argyreia nervosa*), and the Hawaiian woodrose (*Merremia tuberosa*) contain D-lysergic acid amide and D-isolysergic acid amide; these indole alkaloids have about one tenth the potency of LSD.¹¹ LSD is the most potent hallucinogenic drug known, with psychedelic effects occurring with doses as little as 25 to 50 μ g.¹² The psychedelic effects from morning glory occur after ingestion of approximately 250 seeds.¹¹

Tryptamines

The alkyltryptamines include both synthetic and naturally occurring compounds. These agents include DMT, α -methyl- and α -ethyltryptamine (AMT and AET), 5-methoxy-*N,N*-diisopropyltryptamine (5-MeO-DIPT, “foxy methoxy,” or “methoxy”), 5-methoxy-*N,N*-dimethyltryptamine (5-MeO-DMT), psilocin, psilocybin, and bufotenine (5-hydroxydimethyltryptamine [5-OH-DMT]). Both bufotenine and 5-MeO-DMT are present in the secretions and skin of the cane toads, *Bufo* genus. The toad *Bufo alvarius* (Colorado River toad) produces the hallucinogen 5-MeO-DMT.¹³ AMT and 5-MeO-DIPT are relatively new, potent, synthetic, hallucinogenic tryptamines popularized by their easy access via the Internet and as club drugs.^{14,15} These drugs were recently made schedule I by the Drug Enforcement Administration.¹⁴ DMT is another hallucinogenic tryptamine that is produced synthetically (known as the “businessman’s trip”) and found naturally in the bark of the yackee plant (*Vivola calophylla*). In Brazil, DMT is known as *yurema* and is basic to the Brazilian Indian Kariri religion.¹⁶ DMT is prepared as snuff from the seeds, leaves, and pods of *Piptadenia peregrina*, *Prestonia amazenicum*, *Anadenanthera peregrina* (yopo tree), and *Mimosa hostilis*. The dose of tryptamines necessary to produce hallucinations varies according to the agent and route of exposure. Hallucinogenic effects have been demonstrated with oral doses of 4 to 10 mg for 5-MeO-DIPT, 100 mg for AMT, and 0.2 to 0.4 mg/kg IV for DMT.^{14,15,17} Another naturally occurring, hallucinogenic alkaloid is ibogaine, which is derived from the shrub *Tabernanthe igoba*.

Psilocybin and psilocin are found naturally in mushrooms that belong mainly to the genera *Psilocybe*, *Conocybe*, *Gymnopilus*, *Lycoperdon*, *Pluteus*, *Panaeolus*, and *Stropharia* (see Chapter 23).^{16,18,19} Some specific mushrooms containing psilocybin and/or psilocin include *Psilocybe mexicana*, *Psilocybe cubensis*, *Stropharia cubensis*, *Psilocybe semilanceata*, *Psilocybe pelliculosa*, *Panaeolus subbalteatus*, *Psilocybe cyanescens*, *Gymnopilus spectabilis*, and *Psilocybe baeocystis*. Psilocybin mushrooms are usually

**TABLE 45-1** Classes of Hallucinogens

CHEMICAL NAMES	PLANTS OR NATURAL SOURCES; SYNTHETIC AGENTS; "SLANG NAMES"
Indoleamines	
LYSERGAMIDES (ERGOLINES)	
D-Lysergic acid diethylamide	LSD; Delysid; "acid," "blotter," "stamps," "dots," "trips," "paper," "a-bombs," "pyramids"
D-Lysergic acid amide	<i>Ipomoea violaceae</i> (morning glory), <i>Rivea corymbosa</i> (Mexican ololiuqui), <i>Argyrea nervosa</i> (Hawaiian baby woodrose), <i>Merremia tuberosa</i> (Hawaiian woodrose)
ALKYTRYPTAMINES	
α -methyltryptamine	AMT; "alpha"
<i>N,N</i> -dimethyltryptamine (DMT)	<i>Piptadenia peregrine</i> , <i>Anadenanthera peregrina</i> , <i>Prestonia amazenicum</i> , <i>Mimosa hostilis</i> , <i>Vivola calophylla</i> ; "businessman's trip"
5-methoxy- <i>N,N</i> -dimethyltryptamine (5-MeO-DMT)	<i>Bufo alvarius</i>
Psilocybin (4-phosphoryloxy-DMT)	<i>Psilocybe</i> sp, <i>Panaeolus</i> sp, <i>Conocybe</i> sp,
Psilocin (4-OH-DMT)	<i>Inocybe</i> sp, <i>Gymnopilus</i> sp, <i>Lycoperdon</i> sp, <i>Pluteus</i> genus; "magic mushrooms," "shrooms," "alice"
5-methoxy- <i>N,N</i> -diisopropyltryptamine (5-MeO-DIPT)	"Foxy methoxy," "foxy"
Bufotenine (5-OH-DMT)	Ch'an Su
Diethyltryptamine	DET
Ibogaine	<i>Tabernanthe igoba</i>
Phenylethylamines	
Mescaline (3,4,5-trimethoxyphenethylamine)	Peyote cactus (<i>Lophophora williamsii</i>)
3,4-methylenedioxymethamphetamine (MDMA)	Ecstasy; "XTC," "X," "E," "Adam," "the hug drug"
3,4-methylenedioxymethamphetamine (MDEA)	"Eve"
Methylenedioxyamphetamine (MDA)	
4-bromo-2,5-dimethoxyamphetamine (DOM)	"Serenity, tranquility, and peace" [STP]
Paramethoxyamphetamine (PMA)	
Arylcyclohexylamines (Piperidine Derivatives)	
Phencyclidine (PCP)	Angel dust; "hog," "wacky weed," "T," "killer weed"
Ketamine	Ketalar, ketaject, ketanest, "special K," "K," "K-hole," "vitamin K"
Dextromethorphan	"DXM," "dex," "robotripping," "CCC," "skittles," "red devils"
Piperazines	
Benzylpiperazine (BZP)	"Legal E," "legal X," "A ² "
Trifluoromethylphenylpiperazine (TFMPP)	
Methylenedioxybenzylpiperazine (MDBP)	
<i>m</i> -chlorophenylpiperazine (mCPP)	
<i>p</i> -methoxyphenylpiperazine (MeOPP)	
Tetrahydrocannabinoids	
Tetrahydrocannabinol (Δ^9 -THC, Δ^1 -THC)	Dronabinol (Marinol); <i>Cannabis sativa</i> (marijuana, hashish)
Diterpene Alkaloids	
Salvinorin A, C	<i>Salvia divinorum</i> ; sage
Myristicin, saffrole	<i>Myristica fragrans</i> (nutmeg, mace)
Anticholinergic Agents	
Atropine (D,L-hyoscyamine)	<i>Atropa belladonna</i> (deadly nightshade), <i>Datura stramonium</i> (jimson weed)
Scopolamine (L-hyoscyne)	Transderm Scop; <i>Datura stramonium</i> (jimson weed), <i>Hyoscyamus niger</i> (henbane)

found in moist warm climates but are widely distributed across the United States. These mushrooms grow overnight in cow pastures after a rainfall. Characteristically, the stalks of some psilocybin mushrooms turn blue with handling secondary to oxidation.¹⁸ Psilocybin is quite stable; both dried mushrooms and boiled extract retain their hallucinogenic potency. Concentrations of psilocybin vary greatly from mushroom to mushroom (both within and between species), by season, and by location.¹⁹ The initial hallucinogenic effects (e.g.,

detachment and relaxation) of psilocybin are evident with as little as 4 mg of toxin.^{18,19} There is a dosage effect, with a dose of 12 mg or more producing vivid hallucinations. Due to the varied psilocybin content of each mushroom, it may take the ingestion of from 3 to 60 mushrooms to achieve the desired effect. In general, 4 to 8 mg of psilocybin is present in 20 g of fresh and 2 g of dried mushroom. Psilocybin sold on the street may be nonspecific mushrooms adulterated with LSD or other substances.

Phenylethylamines

Mescaline is the active phenylethylamine alkaloid from the peyote cactus (*Lophophora williamsii*), which is found in the deserts of the southwestern United States and Mexico. Peyote is a spineless cactus, which forms buttons with seven to ten ribs. The cactus contains about 6% mescaline when dried. Peyote buttons are the round fleshy tubercles from the cactus. One peyote button contains about 40 to 50 mg of mescaline. The average hallucinogenic dose of synthetic mescaline is 5 mg/kg body weight or 4 to 12 peyote buttons.²⁰ The legal use of peyote and mescaline in the United States is limited to Indian tribes in the Native American Church, who use peyote as part of religious ceremonies.

Nutmeg

Both nutmeg and mace are narcotic hallucinogens derived from a tall evergreen tree, *Myristica fragrans*, native to the Molucca Islands of the South Pacific and now cultivated on Grenada and Trinidad. Nutmeg is the dried seed kernel of the fruit and mace is derived from the fleshy outer covering of the seed.^{21,22} Nutmeg and mace are commonly used as spices. The volatile oils present in nutmeg and mace contain the active ingredients, which include myristicin, saffrole, and terpenes. The toxic dose of nutmeg is one to three whole nutmegs, or 5 to 15 g of the ground spice. To produce toxicity from ingestion of nutmeg, the seeds must first be crushed to release the active oils.

Salvinorin A and C

Salvia divinorum is a perennial herb in the mint family native to certain areas of the Sierra Mazateca region of Oaxaca, Mexico.²³⁻²⁵ *Salvia* is used medicinally and for divination by Mazatec Indians. Numerous species of *Salvia* are found in North and South America. *Salvia* is grown locally as sage or imported from Mexico. The active component of *S. divinorum* is salvinorin A and C, neoclerodane diterpenes (terpenoid essential oils). The hallucinogenic dose of *Salvia* is 10 to 20 fresh leaves chewed or two to five dried leaves smoked or vaporized. This is equivalent to inhaling 200 to 500 μg of salvinorin A.^{24,25} Thus, salvinorin A is a very potent hallucinogen, similar to LSD.

STRUCTURE, STRUCTURE-ACTIVITY RELATIONSHIPS, AND PHARMACOLOGY

The neurotransmitter serotonin (5-hydroxytryptamine [5-HT]) is thought to play a major role in the pharmacology of most hallucinogens.²⁶ The two major classes of hallucinogens, indoleamines and phenylalkylamines, display similar euphoric and psychedelic effects, are cross-tolerant, and are close structural analogs to serotonin (Fig. 45-1).^{27,28} These observations suggest that these hallucinogens share a common mechanism of

FIGURE 45-1 Chemical structures of serotonin and select hallucinogens.

action that involves serotonin. Evidence for this is solidified by numerous human studies that demonstrate a strong correlation between the relative affinity that these compounds have for 5-HT_{2A} receptors and their potency as hallucinogens.²⁹⁻³¹ When normal subjects are pretreated with adequate doses of the 5-HT_{2A} antagonists ketanserin or risperidone, the hallucinogenic effects of psilocybin are completely blocked.³² These findings suggest further that the 5-HT_{2A} receptor mediates the psychedelic effects of indoleamines and phenylethylamines. The importance of receptor subtype selectivity is underscored by the fact that drugs and medications that increase overall serotonergic tone (such as the serotonin selective reuptake inhibitors) do not produce the same clinical effects as hallucinogens. Partial agonist activity at 5-HT_{2A} receptors is central to the hallucinatory effects of these agents, and binding at other serotonin receptor subtypes likely modulates these effects. Both hallucinogen classes are also agonists at 5-HT_{2C} receptors.²⁶ In addition, the indoleamines are agonists at 5-HT_{1A} and dopamine D₂ receptors.³³ Interestingly, LSD has the structures of both serotonin and dopamine embedded in its nucleus; this latter finding may explain its dopamine receptor agonist properties.

In general, addition of methyl hydroxyl groups to the benzene ring of the tryptamines or phenylethylamines increases lipophilicity, central nervous system (CNS) penetration, and hallucinogenic potency. For instance, addition of a methyl hydroxy group to bufotenine creates 5-MeO-DMT, a hallucinogen with greater CNS potency. Addition of methyl hydroxy groups to the benzene ring of phenylethylamines (e.g., mescaline) markedly increases CNS penetration and effects.

Anatomically, the regions of the brain that appear to be the major targets of hallucinogens are the olfactory bulb, locus ceruleus, dorsal raphe nucleus, nucleus accumbens, and cerebral cortex (in particular, the medial prefrontal cortex).^{26,34,35} These brain regions are heavily concentrated with 5-HT_{2A} receptors. These brain areas receive and process a large amount of sensory inputs from the body and environment and transfer this information to the cerebral cortex via extensive cortical projections.^{36,37} The cerebral cortex is responsible for final processing and interpretation of neuronal data. Hallucinogens facilitate neuronal activation in the aforementioned brain areas in response to external stimuli. They activate afferent inputs to the cortex while also filtering out tonic inhibitory influences; the end result is asynchronous neuronal activation of numerous cortical regions.

Although serotonin pathways are integral to hallucinogen effects, other neurotransmitters are involved, and include glutamate, norepinephrine, dopamine, and γ -aminobutyric acid (GABA).^{26,38} Hallucinogen binding to central 5-HT_{2A} receptors activates release of norepinephrine from the locus ceruleus, serotonin from raphe nuclei, GABA from specific cortical interneurons, and glutamate from multiple cortical areas.²⁶ Enhanced glutamate activity is diffuse and asynchronous and results in cognitive, perceptual, and affective distortions.

Tolerance to hallucinogens develops rapidly after regular use of these drugs.^{39,40} This is likely due, at least in part, to a rapid down-regulation of 5-HT_{2A} receptors.^{41,42} Cross-tolerance between hallucinogens is also reported.^{27,28} Tolerance occurs to the euphoric and psychedelic effects, but not to autonomic effects.

Although some users elect to use hallucinogens extensively, this class of drugs is not considered physiologically addicting. Tolerance does develop to the psychedelic effects, but no withdrawal syndrome has been observed. A recent review⁴³ noted that there are no studies in which animals are trained to self-administer hallucinogens; animal self-administration is an important predictor of addiction. In rhesus monkeys, LSD was actually a negative reinforcer.⁴⁴

The hallucinogenic mint *S. divinorum* contains the psychoactive neoclerodane diterpenes salvinorin A and C. These bioactive compounds are structurally distinct from other naturally occurring hallucinogens (e.g., indoleamines and phenylalkylamines) and do not bind 5-HT₂ receptors. Rather, salvinorin A and C are potent, selective, opioid, κ receptor agonists and activate the dynorphin peptide system to induce analgesia, sedation, and perceptual distortion.^{23,45-48}

PHARMACOKINETICS

Formulations and Route of Administration

Most hallucinogens are ingested but may also be chewed and absorbed orally, administered sublingually, insufflated, smoked, or injected intramuscularly or intravenously. LSD is a clear or white, odorless, tasteless powder. The powder is formulated as capsules, tiny tablets (“microdots”), and small gelatin squares (“windowpanes”) or applied to postage stamp-sized sheets (“blotter acid”) or sugar cubes.⁴⁹ Each unit dose varies from 50 to 300 μ g or more.¹² LSD is typically ingested but may be smoked or injected. Exposure to natural lysergamides (e.g., morning glory) occurs following ingestion of seeds. The hallucinogenic tryptamines are typically ingested with the exception of DMT and 5-methoxy-DMT; these latter compounds are often insufflated, smoked, or injected. *S. divinorum* is administered in many ways; it is smoked (roll dried leaves into a “joint”), ingested (“oral infusion”), or chewed (“the quid”) and absorbed sublingually or from the buccal mucosa.

Bufotenine can be isolated from secretions of the parotid and sebaceous glands of *Bufo* toads. “Toad licking” has been touted by some as a means to intoxication with this hallucinogen. This is misguided for two reasons. First, *N,N*-hydroxydimethyltryptamine is not well absorbed from the gastrointestinal (GI) tract and does not readily cross the blood-brain barrier; hallucinations will not result from toad licking. Second, several species of toads secrete potent cardioactive steroids or bufadienolides (e.g., bufalin) from their skin glands. Thus, toad licking may result in serious cardiac toxicity without a hallucinogenic effect.⁵⁰

Absorption, Peak Clinical Effects, and Duration of Clinical Effects

Certain pharmacokinetic parameters and clinical characteristics for select hallucinogens are provided in Tables 45-2 and 45-3. The time of onset and duration of clinical effects from hallucinogens vary according to the route of exposure and agent administered. In general, most hallucinogens are rapidly absorbed and distributed to the CNS after ingestion; clinical effects begin within 30 to 60 minutes after ingestion, peak by 2 to 4 hours, and last 4 to 8 hours. Certain agents have a very rapid onset and short duration of effects (e.g., DMT), whereas others may have effects that last 12 to 24 hours or more (e.g., mescaline, nutmeg, and ibogaine).

Metabolism and Excretion

Most agents are extensively metabolized in the liver (by *N*-demethylation, hydroxylation, and glucuronidation) to inactive metabolites (see Table 45-2). Mescaline is also excreted unchanged in the urine.

TABLE 45-2 Pharmacokinetics of Select Hallucinogens

HALLUCINOGEN	TIME TO PEAK SERUM CONCENTRATION AFTER ORAL DOSING (hr)	ELIMINATION HALF-LIFE (hr)	PROTEIN BINDING (%)	Vd (L/kg)	ROUTE OF METABOLISM	ACTIVE METABOLITE
LSD	3–5	2–4	80–90	0.27	Hepatic	No
Psilocybin	1–2	1.8–4.5	*	2.5–5	Hepatic	Yes (psilocin)
DMT	1.5	0.5–1.5		38–53	Hepatic	No
Mescaline	2	6			Renal (55%–60%); hepatic	No

*Data not available.
DMT, *N,N*-dimethyltryptamine; LSD, lysergic acid diethylamide; Vd, volume of distribution.
Pharmacokinetic data obtained from references 18 and 55.

TABLE 45-3 Time of Onset and Duration of Effects of Select Hallucinogens

HALLUCINOGEN	HUMAN RECREATIONAL DOSE	TIME OF ONSET OF CLINICAL EFFECTS	DURATION OF CLINICAL EFFECTS (hr)
LSD	Oral: 25–250 μ g (3 μ g/kg) IV: 140 μ g (2 μ g/kg)	Oral: 0.5–1 hr	4–12
AMT	Nasal insufflation: 100 mg	Smoke, nasal: 5 min Oral: 15 min	8–16
DMT	Smoke: 30–150 mg IV/IM: 0.2–0.4 mg/kg	IV: 1–5 min IM: 10 min Oral: 30–60 min	0.5–1
5-MeO-DMT 5-MeO-DIPT	IV or smoked: 5–10 mg Oral: 5–30 mg	IV: 1–5 min Oral: 20 min Smoke: 10 min Oral: 20–30 min	0.33–0.5 3–6
Psilocybin	Oral: 4–12 mg (0.02 mg/kg); 20–30 fresh mushrooms or 1–2 g dried mushroom*	Oral: 20–30 min	4–6
Mescaline	Oral: 200–600 mg (5 mg/kg)	45–60 min	10–12
Nutmeg	Oral: 5–15 g ground spice; 1–3 nutmegs	2–4 hr	24
<i>Salvia divinorum</i>	Oral: 1 mg Smoked: 200–500 μ g	15 min	1–3

*The recreational dose of mushroom varies by mushroom genus and species, season, geographic location, and habituation of the user.
AMT, α -methyltryptamine; DMT, *N,N*-dimethyltryptamine; 5-MeO-DIPT, 5-methoxy-*N,N*-diisopropyltryptamine; 5-MeO-DMT, 5-methoxy-*N,N*-dimethyltryptamine; IM, intramuscularly, IV, intravenously; LSD, lysergic acid diethylamide;

TOXICOLOGY

Physiologic Disturbances

In addition to their CNS effects, most hallucinogens produce a variety of autonomic (parasympathetic and sympathetic) effects that include mydriasis, tachycardia, hypertension, cutaneous flushing, salivation, lacrimation, hyper-reflexia, nausea, vomiting, abdominal cramps, hyperthermia, and tachypnea. These effects may occur directly from the drug or indirectly from the anxiety and CNS stimulation produced by the hallucinogen. The sympathomimetic effects from hallucinogens, for instance, may be mediated by stimulation of noradrenergic neurons in the locus ceruleus. Physiologic effects occur concurrently with the CNS disturbances. Other non-specific effects include dizziness, ataxia, vertigo, weakness, headache, and paresthesias. Seizures have been rarely reported. Nutmeg, mescaline, and psilocybin ingestion

have a greater frequency of GI adverse effects (i.e., nausea, vomiting, epigastric cramps) than those associated with other hallucinogens.^{18,51} An anticholinergic-type syndrome has been associated with nutmeg intoxication.⁵² Although life-threatening physiologic disturbances are unusual, one series of eight patients with massive LSD overdose developed hyperthermia, coma, respiratory arrest, and coagulopathy.⁵³

Central Nervous System Psychedelic Effects

Acute perceptual distortions are the common thread that links the hallucinogens. Inanimate objects may begin to pulsate or move. Concrete physical boundaries, such as a wall or a person's face, may appear to waver or even blend in with the surroundings; users frequently perceive that inanimate objects are "melting." Geometric patterns are frequently described, and may be readily

“visible” even when the eyes are closed. An object that moves across the user’s visual field may leave a “trail” that persists for several seconds. Synesthesias (the melding of sensory modalities) may occur, in which users may hear colors or see sounds. Sensory inputs such as sights or noises may seem more striking, and ordinary thoughts may seem quite profound. The user’s sense of time may be markedly distorted, or completely lost. Time contraction is common such that the user overestimates chronologic time.

Most people who knowingly ingest hallucinogens welcome these perceptual distortions and find the experience quite pleasant. Occasionally, however, users have a profoundly dysphoric experience when using hallucinogens, typically referred to as a “bad trip.” The reason why one experience with hallucinogens is good and another bad is not entirely clear. Drug dose, the user’s environment, and the user’s attitude when taking the drug may all play a role. An interesting but uncontrolled convenience study of LSD users compared a group of 25 users with positive experiences with 25 users with negative experiences. There were no historical or clinical variables that accurately predicted a bad trip. Those with bad trips were not more likely to have a previous psychiatric diagnosis.⁵⁴

Dose-Response Characteristics

The usual recreational doses that produce hallucinogenic effects in humans are listed in Table 45-3. Psychedelic effects are dose related, such that low doses produce mild illusions and perceptual distortions whereas large doses may produce severe neurovegetative disturbances, extreme anxiety or dysphoria, disorientation, or the inability to discriminate between reality and illusion (true hallucinations).¹⁸ In general, hallucinogens have a remarkably low likelihood for producing significant acute morbidity and mortality. For instance, LSD has a therapeutic index of approximately 1000.⁵⁵

“Flashbacks”: Hallucinogen Persisting Perception Disorder

Perceptual distortions may recur months or years after hallucinogen abstinence. Commonly referred to as “flashbacks,” these perceptual distortions are formally known as hallucinogen persisting perception disorder (HPPD). HPPD is a recognized psychiatric diagnosis in which distressing “geometric hallucinations, false perceptions of movement in the peripheral visual fields, flashes of color, intensified colors, trails of images of moving objects, positive afterimages, halos around objects, macropsia, and micropsia”⁵⁶ cannot be ascribed to an acute drug intoxication or another psychiatric illness or condition.

The physiologic basis of HPPD is incompletely understood. Various theories have been proposed, including an LSD-induced decrease in tonic inhibitory tone in visual areas of the brain⁵⁷ and/or LSD-induced sensitization of areas of visual processing within the brain.⁵⁸ A genetic predisposition has also been postulated.⁵⁹

Although several quantitative studies have addressed HPPD, this literature suffers from methodologic flaws, and firm conclusions are difficult to draw.⁶⁰

Various pharmacologic treatments have been proposed to treat HPPD, which include clonidine^{61,62} and clonazepam.^{63,64} Interestingly, risperidone (which possesses antagonist activity at the 5-HT₂ receptor) has been reported to exacerbate this condition,⁶⁵ as have the serotonin selective reuptake inhibitors.⁶⁶

Hallucinogen-Induced Psychiatric Disorders

Prolonged perceptual distortions and hallucinosis that last a few days may occasionally occur after hallucinogen use. In addition, hallucinogens may induce acute anxiety, panic disorder, major depression, or schizophrenic episodes in susceptible individuals. There is some evidence that repeated hallucinogen use is a risk factor for the development of chronic or persistent thought disturbances.⁶⁷ One case series described four patients diagnosed with schizophrenia within a few years of ingesting LSD between 50 and 300 times.⁶⁸ The lack of a control group in this study significantly limits their findings. In addition, all of the patients were in their early 20s and an age at which first psychotic breaks occur in those who subsequently develop chronic schizophrenia. Another paper compared 46 schizophrenics and 46 controls and found no statistical difference in drug use in general, but a trend toward more LSD use among schizophrenics.⁶⁹ A poorly chosen control group (all controls were employed, students, or hospital volunteers) significantly limits this study’s findings. Subsequent reviews of this subject^{70,71} have noted the flawed methodology of these and other similar reports, and concluded that there is no significant association between hallucinogen use and chronic thought disorders.

Chromosomal Abnormalities

Reports suggesting that LSD use led to chromosomal damage both in vitro⁷² and in vivo⁷³ surfaced in the late 1960s and early 1970s and received sensational media attention. Subsequent reports,⁷⁴⁻⁷⁷ however, disputed the link between LSD use and chromosomal damage. The belief that LSD damages human chromosomes is no longer widely held.

Morbidity and Mortality Due to Impaired Judgment

Hallucinogens are generally thought to be “safe” drugs, in that they do not produce the potentially life-threatening alterations in physiology that one might see with opiates, barbiturates, or cocaine. It should be noted, however, that significant injury or death may result from decisions that are made when hallucinogens have markedly impaired the user’s judgment. People under the influence of hallucinogens have mistakenly believed they could fly⁷⁸ or have stared directly into the sun⁷⁹⁻⁸¹ with disastrous consequences.

DIAGNOSIS

The diagnosis of hallucinogen intoxication is made clinically and based on a positive history of exposure and suggestive physical findings. Most patients should be able to provide a history of hallucinogen use. Suggestive physical findings include mild to moderate sympathomimetic and GI effects coupled with a patient with ongoing perceptual and sensory illusions (e.g., visual distortions). Hallucinogens do not produce any characteristic abnormalities of the electrolytes or the complete blood count, so these basic ancillary tests are unlikely to aid in the diagnosis. Standard urinary toxicology (immunoassay) screens do not detect LSD or most other hallucinogens; specialized urinary testing kits for LSD are commercially available but not stocked by most hospitals. Even when available, false-positive test results⁸²⁻⁸⁵ limit the utility of such kits (Box 45-1). It should be understood that drugs of abuse screens designed to detect amphetamines and PCP are both insensitive and nonspecific for detection of designer drugs that are frequently abused. Confirmatory testing by gas chromatography/mass spectroscopy or high-pressure liquid chromatography is sensitive and specific, but the results of such testing often take days to return.

In the absence of a clear history of hallucinogen use, patients who have ingested this class of drugs are best approached as an undifferentiated patient with an alteration in mental status. A thorough history and physical examination should be obtained. Comprehensive ancillary testing, both basic (blood glucose level, serum electrolytes, complete blood count) and advanced (computed tomography of the head, lumbar puncture) should be considered.

Differential Diagnosis

The manifestations of hallucinogen intoxication may be similar to intoxication with anticholinergic, sympatho-

mimetic (e.g., cocaine, amphetamines, methylxanthines), and other psychotropic (e.g., lithium) agents; withdrawal from alcohol or sedative-hypnotics; functional psychiatric disorders (e.g., acute panic disorder, schizophrenia); CNS or systemic infections; traumatic head injury; cerebrovascular accidents; and several metabolic disturbances (e.g., uremia, hepatic encephalopathy, hyponatremia, or hypoglycemia). In addition, the various hallucinogenic classes may be difficult, if not impossible, to differentiate from each other clinically. Patients may be differentiated from anticholinergic agent toxicity by the absence of delirium, repetitive picking behavior, urinary retention, ileus, or dry skin. Patients may be differentiated from amphetamine poisoning by the absence of stereotypic behavior (e.g., formication, lip smacking, and teeth grinding). Unlike those with hallucinogen intoxication, patients with functional psychoses are alert and oriented, have auditory hallucinations predominantly, lack synesthesias, and cannot differentiate their illusion from reality (true hallucinosis).

MANAGEMENT

Most patients with hallucinogen intoxication have an uncomplicated course and do not require medical treatment. For those patients who require hospital evaluation due to unexpected adverse clinical effects, treatment is largely supportive.

Although uncharacteristic for hallucinogen poisoning, patients with significant CNS or respiratory depression should have their airway protected, breathing assisted, and cardiovascular support provided as necessary. Supplemental oxygen, continuous pulse oximetry, and parenteral thiamine, dextrose (or rapid fingerstick glucose determination), and naloxone should be considered for patients with altered mental status or seizures. Significant CNS or respiratory depression, seizures, and hypotension are unlikely findings after hallucinogen use; their presence should prompt a search for another process. Hypertension, when present, is usually mild and rarely requires treatment. In the event that the clinician is concerned about hypertension in an agitated, hallucinating patient, a benzodiazepine (i.e., lorazepam, 1 to 2 mg IV) is an appropriate first intervention.

GI decontamination is not routinely necessary for hallucinogen poisoning unless there is concern for co-ingestants. Since hallucinogens are rapidly absorbed after ingestion, the effectiveness of GI decontamination is marginal. In addition, since uncomplicated hallucinogen poisoning usually resolves without sequelae, the risks involved in performing decontamination procedures, particularly in the anxious patient, may outweigh any benefits. If GI decontamination is performed, single-dose administration of activated charcoal (1 g/kg orally or by nasogastric tube) is the preferred method. Orogastric lavage is not recommended for this group of patients due to lack of efficacy and associated procedural morbidity. Gastric emptying procedures have not been found to have an effect on the severity and duration of

BOX 45-1

SUBSTANCES THAT MAY CAUSE FALSE-POSITIVE URINARY LSD TESTING

Ambroxol (mucolytic)
 Amitriptyline
 Brompheniramine
 Bupivacaine

 Doxepin
 Doxylamine
 Ergonovine
 Fentanyl
 Imipramine
 Lidocaine
 Methylphenidate
 Metoclopramide
 Prilocaine
 Ranitidine
 Tramadol

symptoms when performed on series of patients intoxicated with hallucinogenic mushrooms.^{86,87}

Patients that are anxious, frightened, or agitated due to negative or punitive distortions (a bad trip) should be provided rest and reassurance in a dark, quiet environment; this approach has been advocated successfully for over 30 years.⁸⁸ In the event that concurrent sedation is indicated, benzodiazepines are the preferred pharmacotherapy, providing safe, nonspecific sympatholysis.⁸⁹ The use of atypical antipsychotic agents, which specifically antagonize 5-HT₂ receptors (e.g., ziprasidone, risperidone, clozapine), are theoretically attractive for the treatment of bad trips but have not been adequately studied.

DISPOSITION

Most patients with hallucinogen poisoning develop only mild toxicity and are medically safe for psychiatric evaluation (if necessary) and disposition after an observation period of 4 to 6 hours in the ED. Patients who have continued evidence of agitation, perceptual distortions, and physiologic disturbances at 6 hours should be admitted to a monitored bed for continued observation.

LAWRENCE S. QUANG, MD

At a Glance...

- GHB, a schedule I drug, is a potent central nervous system depressant that is abused illicitly for its sedative, euphoric, and hallucinogenic effects.
- GHB has also been popular as a sports and dietary health supplement for its growth hormone–releasing, anxiolytic, and soporific effects as well as numerous other unproven “natural health benefits.”
- GBL and 1,4-BD are chemical precursors that are converted in vivo to GHB via simple enzymatic biotransformation steps; GVL, GHV, and THF are GHB structural analogs with anecdotal case reports of abuse and overdose.
- Acute toxicity from GHB and its chemical precursors and analogs consists primarily of central nervous system and respiratory depression; chronic abuse of GHB, GBL, and 1,4-BD has resulted in chemical dependency and a severe withdrawal state upon abrupt cessation.
- Treatment of acute GHB overdose and its withdrawal state consists of aggressive supportive care.

Despite the known dangers of illicit γ -hydroxybutyric acid (GHB) abuse, greatly publicized by the harmful, illicit, and unlawful use of GHB by high-profile celebrities, such as professional basketball player Tom Gugliotta,¹ Hollywood actor Nick Nolte,² and Max Factor heir Andrew Luster,^{3,4} GHB has developed into a favorite party drug in popular culture during the past 15 years.⁵⁻⁸ GHB and its many chemical precursors and structural analogs, most notably γ -butyrolactone (GBL) and 1,4-butanediol (1,4-BD), have become fashionable and trendy recreational drugs during the past decade as reports of its “natural” euphoric and hallucinogenic properties popularized its illicit abuse. GHB, GBL, and 1,4-BD represent an emerging group of drugs among the broad class of recreational drugs known as “club drugs.” According to the National Institute on Drug Abuse/National Institutes of Health, the term *club drugs* derived from the association of these drugs with dance clubs and all-night dance parties called “raves,” and include other such drugs as *N*-methyl-3,4-methylenedioxymethamphetamine (see Chapter 44), ketamine (see Chapter 43), flunitrazepam (see Chapter 35), methamphetamine, (see Chapter 44), and lysergic acid diethylamide (see Chapter 45).⁹ Like most club drugs, GHB, GBL, and 1,4-BD are physically and psychologically addictive, with acute and chronic toxicity that may be severe or lethal. However, GHB, GBL, and 1,4-BD possess many epidemiologic characteristics and pharmacologic properties that are distinctive from other club drugs. Ironically, before their recent emergence as popular recreational club drugs, GHB, GBL, and 1,4-BD had a relatively quiescent

history of medical research and licit therapeutic use spanning more than six decades. This chapter will review the unique history and complex evolution of GHB into a contemporary drug of abuse as well as its pharmacology, toxicology, and clinical diagnosis, management, and disposition.

RELEVANT HISTORY

Of the three principal GHB analogs, GBL was discovered first, in 1947, 13 years before GHB and 19 years before 1,4-BD.^{10,11} GHB was subsequently discovered in 1960 by the French scientist Henri Laborit, who synthesized it as a structural analog of the inhibitory neurotransmitter γ -aminobutyric acid (GABA), which was capable of traversing the blood-brain barrier (BBB) after peripheral administration.¹²⁻¹⁴ Three years after its laboratory synthesis, GHB was discovered to be a naturally occurring neurochemical in the mammalian brain.^{15,16} In 1966, Sprince and colleagues were the first investigators to make the association of 1,4-BD with GHB. Noting the close structural similarity of 1,4-BD with GHB, they demonstrated that 1,4-BD could produce an anesthetic response similar to that of GHB and GBL. In this rodent study, GHB, GBL, and 1,4-BD all produced an anesthetic state that was characterized by the loss of voluntary movement, righting reflex, struggle response, and body and limb tone, as well as myoclonic jerking. They further demonstrated that the electroencephalographic (EEG) tracings of GHB, GBL, and 1,4-BD had very similar wave patterns.¹⁷ As a result of these discoveries, GHB found its first clinical application as an anesthetic agent in the early 1960s.¹²⁻¹⁴ Several clinical studies in the 1960s, involving a total of 376 patients, confirmed the potential of GHB to serve as an adjuvant to anesthesia.^{18,19} However, those same studies also documented several adverse reactions to GHB anesthesia, including the occurrence of gross muscular movements when rapidly administered, as well as inadequate analgesia (abrupt rise in systolic and diastolic pressure during surgical incision), emergence delirium, and bradycardia. Although GHB continues to be investigated and used as an anesthetic adjuvant abroad,²⁰⁻²² it has never gained widespread acceptance in the United States for this clinical application.

In the decades since its initial scientific discovery as a GABA-mimetic neurochemical, GHB has been diverted from an investigational drug with legitimate research applications and licit medical uses to the toxic ingredient in banned nutritional supplements and illicit recreational drugs. An important milestone in this devolution occurred in 1977, when Takahara and colleagues reported that an intravenous dose of 2.5 g of GHB resulted in a

significant increase in plasma growth hormone (GH) and REM sleep in six healthy male subjects.²³ This discovery launched concerted efforts to study and develop GHB as a potential therapeutic agent for sleep disorders such as narcolepsy. However, as an unintended and misappropriated consequence of this and similar other studies, GHB became popular as a sports supplement and “natural” soporific. Subsequently, in the late 1980s, GHB was introduced to the health and dietary supplement market with dubious claims that it could metabolize fat, enhance muscle building, and improve sleep. However, it was quickly associated with severe adverse effects and deaths as overzealous self-administration of GHB-containing nutritional supplements resulted in a well-characterized toxidrome of coma, cardiorespiratory depression, apnea, seizure-like activity, and, in several instances, death.^{5,6,7} Accordingly, the U.S. Food and Drug Administration (FDA) intervened in November 1990 to prohibit over-the-counter (OTC) sale of GHB in nutritional supplements.⁷ However, GHB purveyors easily circumvented the FDA ban on OTC sale of GHB-containing products by substituting GBL for GHB as the active ingredient. Predictably, toxic effects similar to GHB, including deaths, were reported and confirmed to be attributable to GBL soon after its substitution into dietary health supplements.^{8,24-34} Consequently, the FDA issued a recall of GBL-containing health supplements in February 1999, which was easily evaded by the substitution of GBL with 1,4-BD.^{35,36} Predictably, the consequences of 1,4-BD misuse and abuse were clinically similar to that of GHB and GBL, including death.³⁵⁻⁴²

In the midst of its emergence as an illicit drug, GHB received both orphan drug and investigational new drug (IND) status from the FDA for clinical trials as a therapeutic agent for narcolepsy. Confounding and nearly preventing its clinical development as a narcolepsy treatment, GHB also developed forensic notoriety as a chemical submission agent used in the commission of drug-facilitated sexual assault, or “date rape.” After several highly publicized GHB-related date rape deaths, the Hillory J. Farias and Samantha Reid Date-Rape Prohibition Act (Public Law 106-72) was legislated by Congress and signed into law by President Clinton on March 11, 2000.^{43,44} Under this federal statute, GHB received dual scheduling as a schedule III drug for IND use in clinical trials for narcolepsy and as a schedule I drug for illicit purposes. GBL, which has numerous legitimate uses as an industrial solvent, was recognized as a federal list I chemical under this federal statute. Under this law, authority was granted to federal law enforcement agencies to monitor the commercial and industrial sale and distribution of GBL for potential diversionary activity. There was no specific mention of 1,4-BD in this federal law, but 1,4-BD, which also has many legitimate uses as an industrial solvent, was classified by the FDA as a class I health hazard in response to several 1,4-BD-related deaths in 1999.^{29,37,38,42} This FDA categorization recognized 1,4-BD to be a potentially life-threatening health hazard but did not impose any regulatory actions on its commercial sale or distribution.

EPIDEMIOLOGY

National statistics from the American Association of Poison Control Centers–Toxic Exposure Surveillance System (AAPCC-TESS), Drug Abuse Warning Network (DAWN), and Monitoring the Future Study (MTFS) have demonstrated a trend of escalating GHB abuse and poisoning throughout the past decade. In 2002, 1386 exposures with GHB and its analogs and precursors were reported to the AAPCC-TESS, representing more than a twofold increase from approximately 600 GHB cases reported in 1996. Among these, 1181 exposures (85%) required treatment in a health care facility and resulted in 272 major outcomes and 3 deaths.⁴⁵ Eighty-five percent of these exposures involved individuals over the age of 19. According to DAWN, emergency department (ED) episodes related to GHB increased significantly from 1994 to 1999, and GHB mentions increased dramatically from 1997 to 2000 (Fig. 46-1).⁴⁶ Since 2000, trends in ED mentions of GHB appear to have leveled off, with GHB mentions lower in 2002 than in 2000 (Fig. 46-2). ED mentions of GHB appeared to have peaked in 2000, but there was nevertheless a significant long-term increase in ED episodes for GHB from 1995 to 2002 (2197% increase, from 145 to 3330). Almost half (46%) of these ED mentions of GHB were attributed to patients age 20 to 25, nearly 90% were white, and two thirds were male. In 2001, the estimated rate of GHB ED mentions per 100,000 population, by metropolitan area, was highest for San Francisco (9.3%), Dallas (6.7%), New Orleans (5.6%), and Atlanta (4.6%), and GHB abuse increased in 9 of the 21 cities monitored in 2001.⁴⁷ Overdose was the predominant reason for ED contact in episodes involving GHB (88%), and the recreational pursuit of its psychic effects was the predominant motive for use among patients with adverse events from GHB (46%).

FIGURE 46-1 Emergency department trends for GHB. Final estimates from the Drug Abuse Warning Network (DAWN), 1995–2002. (Compiled from the Substance Abuse and Mental Health Services Administration, Office of Applied Studies: Emergency Department Trends from DAWN, Final Estimates 1995–2002, DAWN Series: D-24. DHHS Publication No. SMA 03-3780. Rockville, MD, Department of Health and Human Services, 2003.)

FIGURE 46-2 A, GHB powder, GHB powder dissolved in a water vial and in water bottles, and GHB capsules and drinking solutions. B, GBL in various dietary supplements. C, 1,4-Butanediol in various dietary supplements and in a 55-gallon drum confiscated by the Drug Enforcement Agency.

Seventy-four percent of ED visits for GHB intoxication involved another club drug. Alcohol was the most frequently mentioned co-ingestant in visits that involved GHB (54%), followed by marijuana (14%) and 3,4-methylenedioxymethamphetamine (MDMA, or “Ecstasy,” 12%).⁴⁸ While most GHB abusers are young adults, adolescents have also abused GHB, and the 2002 MTFS reported an annual prevalence rate of GHB use of 0.8%, 1.4%, and 1.5% in grades 8, 10, and 12, respectively.⁴⁹ These prevalence rates have shown little change since they were first measured for GHB in 2000. Although epidemiologic data are unavailable for each specific GHB analog, the rising abuse of GHB documented by AAPCC-TESS, DAWN, and MTFS likely reflects a parallel increase in GHB analog abuse as well.

The illicit use of GHB and its precursors appears to have plateaued in the United States, but recent international statistics have reported GHB abuse to be on the rise worldwide. The escalating international abuse of GHB has resulted in its scheduling by the United Nations (UN). On March 20, 2001, the UN’s Commission on Narcotic Drugs, at the recommendation of the World Health Organization, added GHB to schedule IV of the 1971 Convention on Psychotropic Substances.^{50,51} Schedule IV mandates international licensing for manu-

facture, trade, and distribution of GHB and requires all nation signatories of this treaty to comply with prohibition of and restrictions on export and import of GHB, and to “adopt measures for the repression of acts contrary to these laws and regulations.” However, since the implementation of this international GHB schedule in 2001, most of the literature reporting toxicity from acute overdoses with GHB has emerged from outside the United States, including the United Kingdom,⁵² Spain,⁵³ Switzerland,⁵⁴ the Netherlands,⁵⁵ and Australia and New Zealand.^{56,57} In Spain, GHB was responsible for 3.1% of all toxicologic emergencies in an urban public hospital ED during a 15-month study period and ranked second in illicit drugs requiring emergency consultation.⁵³ Conversely, while European and Asian countries have reported recent rises in acute poisonings from GHB and its chemical precursors and structural analogs, virtually all of the reports of GHB dependence and withdrawal have emerged from the United States.

Illicit use of GHB and its analogs have primarily occurred in one of four settings: in the recreational setting of dance raves or night clubs, in the athletic setting of bodybuilding gyms and fitness centers, in the home consumer setting of individuals seeking its “natural health benefits,” and in the criminal setting of drug-

facilitated sexual assault. At raves and nightclubs, GHB is used to achieve effects that have been equated to a combination of alcohol (euphoria, disinhibition, and anxiolysis) and ecstasy (enhanced sensuality, emotional warmth).⁵¹ Current street names for GHB and its precursors and analogs include liquid ecstasy, liquid E, Fantasy, grievous bodily harm, Georgia home boy, great hormones at bedtime, great human benefit, organic quaalude, liquid X, soap, salty water, easy lay, and liquid FX.^{42,58-61} In gyms and health food stores, GHB is sold as a performance-enhancing additive in bodybuilding formulas and drinks that are promoted as growth hormone releasers and muscle builders. GHB and its analogs have also been sold to home consumers as “natural” health food and nutritional supplements purporting to enhance weight loss, sexual potency, baldness reversal, and eyesight improvement, and to decrease aging, depression, insomnia, and alcohol, and drug addiction.⁶² Products containing GHB, GBL, or 1,4-BD and marketed for these purposes—Somatomax PM, Natural Sleep-500, Renewtrient, Revivarant or Revivarant G, Blue Nitro or Blue Nitro Vitality, GH Revitalizer, Gamma G, Remforce, Invigorate, Jolt, Renewtrient, Verve Revitalize Plus, Serenity, Enliven, GHRE, SomatoPro, NRG3, Thunder Nectar, Weight Belt Cleaner, Inner G, Serenity, Soma Solutions, Blue Nitro, and others—are generally no longer sold because of law enforcement pressure; however, comparable products with similar brand names are available (see Fig. 46-1).^{38,42,58-61} Criminally, GHB has been employed in the commission of date rape, and the Drug Enforcement Agency (DEA) has documented 15 drug-facilitated sexual assaults involving 30 victims under the influence of GHB.⁵⁸ In the only known published study on the prevalence of drugs used in cases of alleged sexual assault, urine specimens from 1179 cases were submitted to forensic toxicologists nationwide to test specifically for date rape drugs. Approximately 711 samples (60%) tested positive for one or more drugs, and GHB was specifically detected in 48 of these positive samples (6.75%).⁶³

Presently, the major distributors of street GHB are clandestine laboratories, both domestic and foreign, that manufacture GHB using a relatively simple synthesis procedure with commercially available, easily accessible, and inexpensive solvents (GBL) and reagents (a base, such as sodium hydroxide). An alternative source for GHB has been home synthesis via recipes and kits that have been available thorough the Internet and mail order.^{38,64} Once synthesized, GHB is a clear and odorless liquid that is often distributed in “spring water” bottles and dispensed to the user by the water-bottle cap, with a “capful” being the most common dosage unit.^{58,59} GBL and 1,4-BD have been directly substituted for GHB in such packaging. In many instances, these illicit preparations are disguised by adding food coloring and flavoring agents and stored in water or sports drink bottles or in unsuspecting packaging such as eye-dropper bottles, glass vials, and mouthwash bottles. At nightclubs, bars, and “rave” parties, GHB is often sold for \$5 to \$20 per capful, which is orally consumed in an average dose

of 1 to 5 g.⁵⁸⁻⁶¹ When consumed by the capful, one 55-gallon drum of GBL can yield 240,000 capfuls, potentially yielding \$1.9 million per 55-gallon drum.⁵⁹ While oral ingestion of liquid GHB is the most common route of consumption, capsule and tablet forms are also available, as is powdered GHB, which is snorted or dissolved in a liquid.⁶¹ Because of its salty taste, powdered or liquid GHB is typically mixed into a beverage. The quality, purity, and concentrations of GHB in these illicit preparations are usually so varied that the user is often unaware of the actual dose that is being consumed.

An important epidemiologic trend in GHB abuse is the increased use of analogs. To evade law enforcement detection, GHB distributors have recently developed and distributed new analogs, which are abused in substitution of GHB or used to synthesize GHB. The list of GHB analogs known to be used for these purposes continues to evolve and expand. At present, this list includes GBL, 1,4-BD, GHV, GVL, and THF.^{58-61,65} Both GBL and 1,4-BD are well documented to be abused as chemical precursors of GHB, which will rapidly metabolize to GHB after ingestion. Although rarely reported in cases of acute GHB poisoning, THF is also a chemical precursor of GHB. GVL is abused as a substitute for GHB because it metabolizes to GHV, an analog with physiologic effects similar to GHB. Among the GHB analogs, only GBL is used as a precursor ingredient for the illicit synthesis of GHB. GHB analogs are usually distributed as liquids and orally consumed. Despite federal anti-GHB legislation, GHB analogs remain legally available in products not intended for human consumption, since GBL, 1,4-BD, GVL, and THF have legitimate uses as solvents for industrial production of polyurethane, pesticides, elastic fibers, coatings on metals and plastics, and other manufacturing products. Exploiting this legal loophole, GHB purveyors have recently diverted these analogs into thinly veiled household products sold as “fish tank cleaner,” “ink stain remover,” “ink cartridge cleaner,” and “nail enamel remover” for approximately \$100 per bottle.

STRUCTURE AND STRUCTURE-ACTIVITY RELATIONSHIPS

GHB has several endogenous structural analogs and chemical precursors as well as several well-characterized synthetic structural analogs and precursors. The chemical structures, structure-activity relationships, and biotransformation steps of GHB and its numerous endogenous and synthetic analogs are shown in Figure 46-3. The structure-activity relationships of GHB and these analogs have been methodically examined with the use of [³H]GHB binding studies by Bourguignon and colleagues and are summarized in Table 46-1.⁶⁶⁻⁶⁸

PHARMACOLOGY

GHB has a dual pharmacologic profile, with the intrinsic neuropharmacology of endogenous GHB distinct and divergent from that of exogenously administered GHB.

FIGURE 46-3 Chemical structures, biotransformation reactions, and metabolic steps of gamma-hydroxybutyric acid and its chemical precursors and analogues. Numbered enzymes/reactions include 1, tetrahydrofuran hydroxylase; 2, 2-hydroxy tetrahydrofuran dehydrogenase; 3, 2-hydroxy tetrahydrofuran isomerase; 4, alcohol dehydrogenase; 5, aldehyde dehydrogenase; 6, nonenzymatic hydrolysis or peripheral tissue and serum lactonases; 7, GHB dehydrogenase or hydroxyacid-oxoacid transhydrogenase; 8, succinic semialdehyde reductase; 9, β -oxidation; 10, succinic semialdehyde dehydrogenase, 11, GABA transaminase; and 12, an uncharacterized reaction (involving 2-carbon condensation?) forming 4,5-dihydroxyhexanoic acid from succinic semialdehyde.

The principal difference between their profiles is that the intrinsic neuropharmacologic activity of endogenous GHB appears to be mediated by the GHB receptor, while the neuropharmacologic activity of exogenously administered GHB is likely mediated by the GABA(B) receptor. Whereas other pharmacologic aspects of endogenous GHB are presently well characterized, research on exogenous GHB neuropharmacology is only in its nascent stages. Therefore, while other pharmacologic differences probably exist between endogenous and exogenous GHB, they are under investigation and have yet to be clarified.

Endogenous GHB

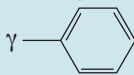

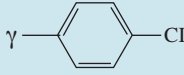

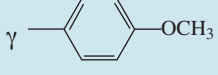

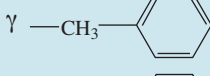

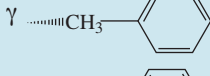

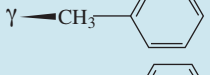

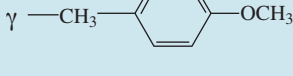

Although the precise physiologic function of endogenous GHB is unknown, GHB is a putative neurotransmitter or neuromodulator because it possesses the requisite pharmacologic properties for recognition as such:

1. It has a discrete regional and subcellular distribution in the central nervous system (CNS).⁶⁹⁻⁷²

2. It has subcellular systems for synthesis, vesicular uptake, and storage in presynaptic terminals.^{71,73-92}
3. It is released in a Ca^{2+} -dependent manner following depolarization of neurons.^{71,93-95}
4. Subsequent to neuronal release, GHB binds to GHB-specific receptors and modulates neurotransmitter systems.^{71,96-118}
5. Following neuronal release, GHB activity is terminated by active uptake from the synaptic cleft for metabolism by specific cytosolic and mitochondrial enzymes.^{71,119-140}
6. Localized application of GHB can produce a response that mimics the action of endogenous GHB released by nerve stimulation (i.e., synaptic mimicry).¹⁴¹⁻¹⁴⁶

These pharmacologic properties of GHB are major preconditions if GHB is to play a role in interneuronal signaling or neuromodulation. GHB is heterogeneously distributed throughout the mammalian CNS, with its highest concentrations found in the hippocampus, basal ganglia, hypothalamus, striatum, and substantia nigra.⁶⁹⁻⁷¹ GHB is concentrated in the cytosolic and

The names and structures of endogenous and synthetic GHB analogues and precursors are presented with respect to their substitutions and modifications on the GHB molecule:

The structure-activity relationships of these endogenous and synthetic GHB analogs and precursors have been examined by binding studies with [³H]GHB. The GHB analogs and precursors in this table have been tested at concentrations of 1 and 10 $\mu\text{mol/L}$ for their ability to inhibit [³H]GHB (25 $\mu\text{mol/L}$) binding to GHB receptors on rat brain membrane preparations. The IC₅₀ concentrations were available for the most active compounds. Not depicted in the table, GHB itself produced 55% and 35% inhibition of [³H]GHB binding at concentrations of 10 and 1 $\mu\text{mol/L}$, respectively, and shows an IC₅₀ value of 6.6 $\mu\text{mol/L}$. The GHB derivatives that demonstrated a greater potency than GHB (IC₅₀ < 6.6 $\mu\text{mol/L}$) for inhibiting [³H]GHB binding to GHB receptors were the endogenous structural analog T-HCA (IC₅₀ 2.9 $\mu\text{mol/L}$) and the synthetic structural analogs γ -benzyl-GHB (IC₅₀ 2.3 $\mu\text{mol/L}$), *R*- γ -benzyl-GHB (IC₅₀ 1.8 $\mu\text{mol/L}$), and γ -(*p*-methoxybenzyl)-GHB (NCS 435, IC₅₀ 0.1 $\mu\text{mol/L}$). Of note, none of the endogenous or synthetic GHB ring analogs (GBL, GCL, GVL, THF) were recognized by the GHB receptor, evidence that the open form of ring analogs is necessary for GHB receptor binding. Also, the endogenous precursor 1,4-BD and the endogenous structural analog GABA were recognized by the GHB receptor. IC₅₀, inhibition concentration of 50%; NA, no affinity; NR, not reported.

synaptosomal fractions in studies of the subcellular distribution of GHB in rat brain, signifying a mechanism for its presynaptic synthesis and accumulation.¹²⁷

As summarized in Figure 46-3, the subcellular presynaptic synthesis of endogenous GHB involves three precursors (GABA, GBL, and 1,4-BD) and five enzymes (GABA-transaminase [GABA-T], succinic semialdehyde reductase [SSR], alcohol dehydrogenase [ADH], aldehyde dehydrogenase, and serum and peripheral tissue lactonases). The major precursor of endogenous brain GHB is GABA,^{71,77,78} which is converted to succinic semialdehyde (SSA) by the brain mitochondrial enzyme, GABA-T. SSA can enter into one of two subsequent biotransformation pathways. In the major pathway, SSA is oxidized by the mitochondrial enzyme succinic semialdehyde dehydrogenase (SSADH) to succinic acid. Production of succinic acid by SSADH allows entry of the GABA carbon skeleton into the tricarboxylic acid cycle for catabolism to H₂O and CO₂.^{71-74,77,78} Alternatively, in the minor pathway, SSA is reduced by the neuronal cytosolic enzyme SSR to GHB. The vast majority of GABA enters the mitochondrial oxidative pathway to produce succinic acid by SSADH, because only about 0.05% (in vitro) to 0.16% (in vivo) of the metabolic flux coming from GABA enters the cytosolic reductive pathway to form GHB by SSR.^{74,85} Thus, GHB formation is colocalized in GABAergic neurons, or in neurons that can synthesize GABA, which are regionally most prominent in the cerebellum, colliculi, median hypothalamus, and hippocampus.^{80,82,84,85}

The second source for subcellular presynaptic synthesis of endogenous GHB is the precursor 1,4-BD, which is present at brain concentrations of about 1/10 of those of GHB.⁸⁶ 1,4-BD is the dihydroxy alcohol precursor of GHB, which undergoes in vivo biotransformation by oxidation of one alcohol group on the molecule to γ -hydroxybutyraldehyde by liver ADH followed by the subsequent formation of GHB either by liver aldehyde dehydrogenase or auto-oxidation.^{17,73,86-88} The potential sources of the small endogenous concentrations of 1,4-BD found in the mammalian brain are the polyamines ornithine, spermine, spermidine, and putrescine.⁸⁹ The third source for subcellular presynaptic synthesis of endogenous GHB is the precursor GBL, which is also present at brain concentrations (200 pmol/g tissue weight) of about 1/10 of those of GHB.^{75,90} GBL can undergo rapid in vivo biotransformation to GHB by serum or peripheral tissue lactonases.⁹¹ However, in contrast to ADH and aldehyde dehydrogenase, no lactonase activity has been described in the brain cell.⁹² Therefore, the role of GBL as a brain precursor to endogenous GHB is enigmatic. Nevertheless, the equilibrium of GBL and GHB in the mammalian brain might be explained by a chemical nonenzymatic hydrolysis rather than an enzymatic process.⁷¹

Although the existence of a putative GHB-specific receptor has been speculated⁹⁶⁻⁹⁸ and disputed for some time, its existence was recently verified by the cloning of a G protein-coupled receptor in the rat that is activated by endogenous GHB.⁹⁹ This newly cloned receptor exhibits no binding affinity for GABA, baclofen, or

glutamate, which have no capacity to displace radioactive GHB from this binding site, but it does exhibit binding affinity for the GHB structural derivative γ -*p*-phenyl-hydroxybutyrate (see discussion of GHB analogs earlier under Structure and Structure-Activity Relationships) and the GHB β -oxidation derivative *trans*-4-hydroxycrotonic acid and its γ -*p*-chloro-phenyl and γ -*p*-nitro-phenyl substitute derivatives. Interestingly, however, this receptor exhibited no binding affinity for the GHB receptor-specific antagonist NCS 382. This observation, in combination with the study's additional finding that three distinct bands were present on Northern blot analysis of total RNA extracted from several rat organs (including brain), suggests the existence of a family of GHB receptors in the brain with NCS 382-sensitive and -insensitive subtypes identified.

GHB modulates several neurotransmitter systems. GHB appears to exert a dose-related effect on both the GABAergic and dopaminergic systems. The administration of low-dose GHB inhibits GABA release in the thalamus, thereby implicating a role for GHB in producing absence seizures,¹⁰¹ and decreases the extracellular GABA concentration in the frontal cortex.¹⁰² However, higher doses of GHB have been shown to enhance GABA concentrations in the frontal cortex.¹⁰² The accentuation of GABA neurotransmission produced by high-dose GHB might underlie the CNS-depressant effect of GHB in experimental animals and overdose patients (see later section on Exogenous GHB). GHB also exerts a prominent modulatory effect on dopamine neurotransmission. Acute administration of GHB inhibits dopamine release and results in the accumulation of dopamine in the presynaptic cells. This effect has been shown to be mediated by GHB inhibition of dopamine neuron firing in the substantia nigra and mesolimbic regions¹⁰³⁻¹⁰⁵ and the subsequent autoreceptor-mediated stimulation of tyrosine hydroxylase activity, resulting in increased presynaptic dopamine production.^{106,107} The attenuation of dopamine neurotransmission following GHB administration may be the pharmacologic basis for the loss of locomotor activity in experimental animals and overdose patients. Interestingly, it also has been proposed that GHB can produce a biphasic effect on dopamine neurotransmission that is dose and time dependent. While attenuated dopaminergic activity is the primary response after GHB administration, several investigators have demonstrated a second phase of GHB modulation that ensues after the initial decrement in dopamine release, when dopamine neurotransmission is enhanced in the striatum and corticolimbic structures.^{71,104,108} Such a biphasic, secondary increase of dopaminergic neurotransmission might represent the pharmacologic basis for its reported euphoric effect and the reward mechanism responsible for its abuse potential.

Other systems modulated by GHB include the serotonin system, cholinergic system, and opioid system. GHB modulates the serotonin system by increasing its turnover rate, without altering total brain serotonin levels, likely by elevating presynaptic tryptophan concentrations.^{71,109,110} GBL, but not GHB itself, has been shown to increase total brain acetylcholine concen-

trations by decreasing firing of cholinergic neurons.¹¹¹⁻¹¹³ Such an increase in brain acetylcholine might underlie the pharmacologic basis for the reported analeptic effect of GHB in narcolepsy. Despite having no binding affinity for opioid receptors, GHB has been reported to stimulate an increase in release of endogenous opioids in various brain regions.^{104,114-116} Furthermore, despite naloxone having no affinity for the GHB receptor, the administration of the opioid antagonists naloxone and naltrexone can attenuate or reverse the electrophysiologic and behavioral actions of GHB on dopamine neuron firing and catalepsy in experimental animals.^{117,118}

After its release from GHBergic presynaptic membranes, GHB activity is terminated by an active vesicular uptake system driven by the vesicular inhibitory amino acid transporter (the same transporter that mediates the vesicular uptake of GABA and glycine) or by an active cellular uptake from the synaptic cleft by means of a high affinity Na⁺-dependent transport protein specific for GHB and its analogs.^{96,119,120} Once within the cell, the degradation of endogenous GHB in the mammalian brain can occur via four pathways leading to (1) succinic acid (which enters the tricarboxylic acid cycle, and represents the most quantitatively significant degradative pathway), (2) GABA, (3) *trans*-4-hydroxycrotonic acid, or (4) 4,5-dihydroxyhexanoic acid (see Fig. 46-3).

Exogenous GHB

Although accumulating evidence favors the role of endogenous GHB as a neuromodulator, because it is synthesized, stored, and released at particular synapses that express GHB-specific receptors, the study of the pharmacologic profile of exogenous GHB is still in its infancy, having only recently been impelled by the increasing problem of GHB abuse. Nevertheless, accumulating data suggest that the GABA_B receptor is a major component of the neural substrate mediating the pharmacologic, behavioral, clinical, and toxicologic actions of exogenous GHB and its precursors, particularly when the brain GHB concentration exceeds its physiologic concentration by two to three orders of magnitude, saturating GHB-specific receptors and producing GABA_B receptor-mediated brain perturbations.¹⁴⁷⁻¹⁵³ Thus, data accumulated since 2001 support the role of the GABA_B receptor in mediating acute and chronic toxicity from GHB and its precursor 1,4-BD. Under conditions of excess exogenous administration or endogenous production (see Human Inborn Error of Metabolism, 4-hydroxybutyric aciduria/SSADH deficiency),¹⁵⁴ it is theorized that GHB may act both directly as a partial GABA_B receptor agonist and indirectly through a GHB-derived GABA pool. GHB itself is a weak GABA_B receptor agonist with an affinity in the mmol/L range, which far exceeds the 1 to 4 μmol/L physiologic concentrations of GHB in the brain.^{147,155,156} Therefore, the supraphysiologic concentration of GHB that could accumulate after its exogenous administration may exert its effects through a weak, direct agonistic effect on GABA_B receptor-mediated mechanisms. Alternatively, GHB could act as an indirect agonist of the GABA_B receptor by its biotrans-

FIGURE 46-4 Schematic model of GHB receptor pharmacology. *a*, Physiologic concentrations of GHB in the human and mammalian brain (nanomolar to micromolar) activate the GHB receptor, which exists as NCS 382-sensitive and -insensitive subtypes. *b*, Supraphysiologic concentrations of GHB (high micromolar to millimolar) might be metabolized to a concentration of GABA sufficient enough to activate the GABA_B receptor. *c*, Supraphysiologic concentrations of GHB may alternatively result in the direct binding of GHB itself to the GABA_B receptor. (From Wong CGT, Gibson KM, Snead OC III: From the street to the brain: neurobiology of the recreational drug γ -hydroxybutyric acid. *Trends Pharmacol Sci* 2004;25[1]:29-34.)

formation to GABA.⁷¹ This hypothesis is supported by the previous observation that inordinately high concentrations of GHB (high μmol/L to low mmol/L) are needed to produce enough GHB-derived GABA to induce displacement and induce GABA_B receptors.¹⁵⁷ In summary, it appears that the pharmacologic and toxicologic effects of supraphysiologic concentrations of GHB, either from exogenous administration (overdose) or endogenous production (inherited SSADH deficiency), are due to saturation of GHB receptors, direct and indirect activation of GABA_B receptors, and/or a combination of these effects (Fig. 46-4).

PHARMACOKINETICS

Human pharmacokinetic data are available only for GHB and are summarized in Table 46-2,¹⁵⁸⁻¹⁶¹ but such data are lacking for its precursors and analogs, GBL, 1,4-BD, GVL, GHV, and THF. Following oral administration, GHB is rapidly absorbed from the gastrointestinal tract and reaches peak plasma concentrations within 1 hour of dosing. Due to a probable first-pass mechanism, GHB has a low oral bioavailability (less than 30%). GHB does not bind to plasma proteins, readily crosses the placenta and the blood-brain barrier, and has an apparent volume of distribution of 202 to 384 mL/kg. Orally administered GHB exhibits nonlinear elimination pharmacokinetics, with elimination from the human body being dose dependent. As the oral dose is increased, there is a disproportionate increase in systemic exposure, and the elimination half-life is increased. However, plasma GHB was nondetectable or only at negligible concentrations 8 hours after oral administration of 9 g (2.5 times the coma-inducing dose). In general, only 1% to 7% of an oral GHB dose is renally eliminated as parent compound in human urine. Therefore, metabolism is the major elimination pathway for GHB.

Special Populations

Human pharmacokinetic data for GHB in special patient populations with narcolepsy, alcoholism, and liver cirrhosis as well as those undergoing general surgery and cesarean section are summarized in Table 46-3.¹⁶²⁻¹⁶⁸ There are no significant variations in the kinetics of GHB between males and females (see Table 46-2)¹⁵⁹ or between healthy human volunteers and narcoleptic patients^{162,163} and alcohol-dependent patients¹⁶⁵ (see Tables 46-2 and 46-3). However, compared with healthy adult volunteers, the mean oral clearance and elimination half-life were markedly reduced and significantly prolonged, respectively, in patients with biopsy-proven liver cirrhosis¹⁶⁴ (see Tables 46-2 and 46-3).

Pharmacologic Agents

ANESTHESIA

GHB found its first clinical application as an anesthetic agent in the early 1960s. Several clinical studies in the 1960s, involving a total of 376 patients, confirmed the potential of GHB to serve as an adjuvant to anesthesia.^{169,170} However, those same studies also documented several adverse reactions to GHB anesthesia, including the occurrence of gross muscular movements when rapidly administered, as well as inadequate

analgesia (abrupt rise in systolic and diastolic pressure during surgical incision), emergence delirium, and bradycardia. Although GHB continues to be used and investigated as an anesthetic adjuvant abroad,¹⁷¹⁻¹⁷³ it has never gained widespread acceptance in the United States for this clinical application. At present, GHB use as an anesthetic agent is limited to France, as well as Germany and Austria.¹⁷⁴

NARCOLEPSY

The clinical development of GHB in the United States began in 1994, when the National Organization of Rare Disorders and the FDA Orphan Products Development Division encouraged the development of GHB as a treatment for narcolepsy based on the promising results of several preliminary clinical studies.¹⁷⁵⁻¹⁷⁹ After the safety and efficacy of GHB as a narcolepsy treatment were established by two randomized, double-blind, placebo-controlled studies,¹⁸⁰⁻¹⁸³ the FDA approved GHB (sodium oxybate, Xyrem [Jazz Pharmaceuticals, Palo Alto, CA]) as a treatment for narcolepsy-related cataplexy on July 17, 2002.

ALCOHOL DEPENDENCE AND WITHDRAWAL

GHB has been widely used in Italy to treat alcohol dependence and withdrawal since 1988.¹⁸⁴ The use of a GHB pharmaceutical for this clinical indication was

based on two randomized, double-blind, placebo-controlled clinical trials conducted by Gallimberti and colleagues. In the first trial, 23 patients who met the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) criteria for alcohol withdrawal syndrome were recruited for treatment with GHB 50 mg/kg/day ($n = 11$) or placebo ($n = 12$).¹⁸⁵ GHB treatment resulted in a significant decrease in the Alcohol Withdrawal Score.¹⁸⁵ This was followed by a second randomized, double-blind clinical trial with 71 alcoholic patients who were randomized to receive GHB 50 mg/kg/day ($n = 36$) or placebo ($n = 35$). After the study period and a 3-month follow-up period, GHB-treated patients significantly increased their days of abstinence and reduced the number of drinks they consumed daily. Furthermore, GHB-treated patients reported a significant reduction in Alcohol Craving Scale scores.¹⁸⁶ Similar results were also reported by fellow Italian investigators in clinical studies.^{187,188} As a result of these clinical trials, GHB is widely used in Italy today to treat alcohol dependence at the dosage of 50 mg/kg/day in three or more divided doses.¹⁸⁴

EXPERIMENTAL THERAPIES

Presently, GHB is undergoing clinical and preclinical investigations for diverse indications. Although GHB received FDA approval for treating narcolepsy-related cataplexy, it failed to receive approval for treatment of

excessive daytime sleepiness. Therefore, GHB is presently undergoing clinical reevaluation for this narcolepsy indication. Pilot studies have shown promising results, since the nocturnal administration of sodium oxybate in narcoleptic patients recently produced significant improvements in sleep architecture, which coincided with significant improvements in daytime functioning.¹⁸⁹ GHB is also presently being evaluated as a treatment for fibromyalgia, with several recent clinical studies reporting GHB capable of effectively reducing the symptoms of pain, fatigue, and sleep abnormalities characteristic of this disorder.^{190,191} Preclinically, interesting and compelling data recently have been generated to demonstrate the potential use of GHB as a neuroprotective agent in stroke¹⁹²⁻¹⁹⁵ and traumatic brain¹⁹⁶ and spinal cord injury,¹⁹⁷ as well as an angiogenesis inhibitor in tumors.^{198,199}

DRUG INTERACTIONS

The potential for drug interactions by an inhibitory effect of GHB on human hepatic microsomal cytochrome P-450 (CYP) isozymes has been assessed in vitro with pooled human liver microsomal fractions. In these studies, the activities of CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A were not inhibited by GHB at concentrations of 3 to 300 $\mu\text{mol/L}$. Therefore, metabolic interactions of GHB with drugs metabolized through these pathways are not anticipated.²⁰⁰

TOXICOLOGY

Clinical Manifestations

Toxicity from GHB and its analogs have occurred in the settings of acute overdose/poisoning, withdrawal after abrupt cessation from chronic misuse, and human inborn error of SSADH expression.

ACUTE OVERDOSE

Clinical experience accumulated during the past 15 years with acute toxicity from GHB overdose has resulted in a fairly homogeneous and easily recognized pattern of symptoms and signs. The hallmark of this “GHB toxidrome” is CNS and respiratory depression of relatively short duration.^{5,6,7,8,24-42} There is a dose-response relationship such that the level of CNS and respiratory depression progressively worsens with increasing doses, with doses of greater than 50 mg/kg leading to coma, apnea, and death. These dose-response relationships are summarized in Table 46-4. Respiratory depression is particularly prominent in the published cases of pediatric GHB/GBL poisonings. Among the seven published case reports of pediatric GHB/GBL poisonings, apnea occurred in six patients.^{31-33,201} Other adverse clinical effects from acute GHB overdose are summarized by systems in Box 46-1. The occurrence of generalized clonic seizures is controversial because they have been inconsistently reported in acute GHB, GBL, and 1,4-BD overdoses. It is possible that such motor

activity may actually represent myoclonic movements mistaken for seizure activity. Such myoclonic activity has been clearly documented during anesthesia induction with GHB and occurs without epileptiform EEG patterns. It is further possible that such seizures may be attributable to hypoxia, co-ingestion with a stimulant drug, or withdrawal. Nevertheless, GHB has been clearly established to produce absence seizures in laboratory animals so that seizures may be a plausible adverse effect from acute GHB overdose. Deaths from GHB ingestion

TABLE 46-4 In Vivo and In Vitro Dose-Response Effects of GHB

DOSE OR CONCENTRATION OF GHB	CLINICAL OR PHYSIOLOGIC EFFECT
Oral Dose (Humans)	
10 mg/kg	Short-term amnesia
20–30 mg/kg	Sleep and drowsiness
50–60 mg/kg	Coma, cardiorespiratory depression, seizures
Systemic Dose (Rodents)	
10–50 mg/kg	Memory impairment
75–200 mg/kg	Absence seizures, EEG spike-and-wave discharges
200–300 mg/kg	Stupor, EEG slowing
>300 mg/kg	Coma, EEG burst suppression
1.7 g/kg	LD ₅₀
In Vitro Concentration	
Nanomolar to low micromolar	Activation of GHB receptor
Low micromolar	Alter GABA and glutamate release
Millimolar	Activation of GABA(B) receptor, possible conversion to physiologically active concentrations of GABA

EEG, electroencephalographic; GABA, γ -aminobutyric acid.

have occurred, with the majority of these incidents involving polysubstance ingestion with either alcohol or a narcotic. Co-ingestion of 1,4-BD with alcohol is particularly dangerous because both substances are competitive substrates for the metabolizing enzyme ADH. Because ADH has a greater substrate affinity for alcohol than 1,4-BD, the adverse effects from ADH-mediated biotransformation of 1,4-BD to GHB will be delayed in this co-ingestion.⁴⁰ When co-ingested with GHB or GBL, alcohol has been shown to produce additive or potentiated toxicity as well. Lastly, given the proscriptive status of GHB and its analogs, improperly performed “kitchen synthesis” of GHB has resulted in caustic oral burns and subsequent esophageal strictures when the neutralization process for potassium hydroxide (a key ingredient for home synthesis of GHB from GBL) was inadequately performed.²⁰²

WITHDRAWAL SYNDROME

The GHB withdrawal syndrome, which occurs after the abrupt cessation of chronic, high-dose abuse, is a rapidly emerging clinical disorder.^{42,203-233} As of this writing, there are 87 published case reports of GHB withdrawal in the clinical literature. Eight of these cases predated 2000,²⁰³⁻²¹¹ with the first case report published in 1994.²⁰³ The remaining 79 case reports of GHB withdrawal were published after 2000, which represents nearly a 10-fold increase in incidence during the past 5 years.^{42,211-233} The clinical experience derived from the sum of case reports has begun to yield a preliminary characterization of the GHB withdrawal state. Most of the patients experiencing the GHB withdrawal state have been males, with a mean age in the early thirties. Among these 87 case reports of withdrawal, GHB, GBL, and 1,4-BD were responsible for 72 (82.8%), 11 (12.6%), and 4 (4.6%) cases, respectively. While most individuals did not know their exact daily dose, they were estimated to be about 48 g and 27 g for GHB and GBL, respectively, with an average daily dosing interval of 4 to 5 hours. The mean duration of misuse was just over 1 year. The onset of withdrawal symptoms occurred within a mean of 46 hours after the last dose of GHB, and the mean duration of the withdrawal syndrome was 9 days. The clinical features of the GHB withdrawal syndrome were similar to ethanol withdrawal and included, in the relative order of frequency of occurrence, tremor, tachycardia, anxiety, restlessness, hallucinations (primarily visual and auditory), delirium, insomnia, delusions, paranoia, diaphoresis, hypertension, nausea or vomiting, and psychosis. Two seizures have been reported in GHB withdrawal, one of which was associated with death.^{223,233}

HUMAN INBORN ERROR OF METABOLISM (4-HYDROXYBUTYRIC ACIDURIA/SUCCINIC SEMIALDEHYDE DEHYDROGENASE DEFICIENCY)

Although acute poisoning from illicit GHB use has been seen by clinicians only in the past 15 years, chronic GHB poisoning from an inherited defect of GABA metabolism has been recognized by molecular biologists and geneticists for nearly 25 years. In 1981, Jakobs and

colleagues were the first to describe a 20-month-old boy of related Turkish parents with developmental delay (absent speech), motor retardation, hypotonia, and ataxia, in association with elevated concentrations of GHB in urine, serum, and cerebrospinal fluid.¹³⁵ Based on the well-defined metabolic pathway of GABA, Jakobs and colleagues postulated that an enzyme defect of SSADH was responsible. Subsequent investigators verified this theory by demonstrating that the conversion of radiolabeled SSA to CO₂ (via the tricarboxylic acid [TCA] cycle) in intact cultured lymphoblasts of patients was only 2.4% to 6.2% of control values.^{234,235} In patients with 4-hydroxybutyric aciduria, SSADH residual activity in these cells was significantly reduced or absent compared with controls.²³⁶⁻²⁴⁴ Parental and sibling white blood cell extracts demonstrated a “gene-dose effect,” with reduction of SSADH activity to approximately 50% of controls. These patterns of patient and parent SSADH activity were consistent with an autosomal-recessive mode of inheritance. As a result of this error of GABA catabolism, Gibson and colleagues reported urine GHB concentrations of 130 to 7600 mmol/mol creatinine (normal less than 2), plasma GHB concentrations of 98 to 1500 μmol/L (normal less than 3), and cerebrospinal fluid GHB concentrations of 263 to 830 μmol/L (normal less than 3) in their large case series. Presently, more than 350 patients have been diagnosed with 4-hydroxybutyric aciduria or SSADH deficiency.²⁴⁵ Recently, Trettel and colleagues mapped the gene encoding for SSADH to chromosome 6p22.²⁴⁶ Shortly thereafter, Chambliss and colleagues identified two exon-skipping point mutations in the SSADH genes of four patients. These genetic defects alter highly conserved sequences at intron/exon boundaries, preventing the RNA splicing apparatus from recognizing the normal splice junction. These RNA splicing errors consequently result in SSADH deficiency.²⁴⁷ Clinical diagnosis can be rather challenging due to some variability of the phenotypic expression of this disease, but in general, clinical findings in patients include psychomotor retardation, absent/delayed speech, mental delay, hypotonia, ataxia, hyporeflexia, seizures/EEG abnormalities, oculomotor apraxia, hyperkinesia, choreoathetosis, aggressive behavior, and somnolence.^{248,249}

DIAGNOSIS

Laboratory Testing

GENERAL CONSIDERATIONS

GHB poisoning is generally diagnosed based on clinical history and presentation and confirmed by laboratory testing. Laboratory testing for GHB and its analogs is confounded by several limiting considerations. First, there is a relatively small window of opportunity to recover GHB from biologic fluids. Following oral administration of GHB at toxic doses (12.5 to 50 mg/kg), GHB is almost completely eliminated from blood and urine within 2 to 8 and 8 to 12 hours of administration, respectively.¹⁵⁸⁻¹⁶⁷ Second, immunoassay urine drug screens generally

employed by hospitals do not detect GHB and its analogs. Third, while numerous qualitative and quantitative analytical methods have been developed to detect GHB in recent years, they are not routinely available at most hospitals. Fourth, even when these analytical methods are available to the clinician, they are presently incapable of distinguishing between GHB and its numerous analogs. Fifth, even if a laboratory test is available to confirm and/or quantify the presence of GHB or its analogs, this information is unlikely to alter management or disposition of the GHB-intoxicated patient. Lastly, accurate interpretation of quantitative GHB analysis must also take into consideration complex confounding factors such as specimen collection and storage, spontaneous GHB and GBL chemical interconversion, and endogenous GHB production.

SPECIMEN COLLECTION AND STORAGE

GHB concentrations from collected biologic fluids can be spuriously elevated if improperly collected and stored. Whole blood specimens undergoing laboratory analysis for GHB should be collected and stored in purple-top anticoagulant ethylenediaminetetraacetic acid (EDTA) tubes, avoiding yellow-top anticoagulant-citrate buffer tubes, which artificially generate GHB.²⁵⁰ Cold storage and use of sodium fluoride or sodium azide preservatives in urine specimens have been shown to minimize spurious GHB concentrations.^{251,252}

Spontaneous Chemical Interconversion

The proper identification of GHB versus one of its many analogs, especially GBL, is also complicated by a spontaneous chemical interconversion of GHB and GBL that can occur in aqueous solutions. Generally, this GHB-GBL interconversion is pH dependent, with GHB exhibiting greater stability than GBL in a variety of aqueous solutions. In aqueous solution with water, spontaneous interconversion of GBL to GHB occurs at a ratio of 2:1 within 202 days in pure water, within 9 days in acidic solution (pH 2.0), and within 15 minutes in alkaline solution (pH 12.0). Conversely, spontaneous interconversion of GHB to GBL occurred at a ratio of 1:2 only in acidic solution (pH 2.0) and did not occur at all in pure water or in alkaline solution (pH 12.0).²⁵³ Thus, aqueous solutions of alkaline pH 7.0 favor the spontaneous hydrolysis of GBL to GHB and true equilibrium between GHB and GBL occurring at approximately pH 2.0.

ENDOGENOUS GHB PRODUCTION

In clinical cases that have forensic implications (determination of cause of death) or medicolegal allegations (GHB use for chemical submission/date rape), the endogenous production of GHB must be carefully considered and an analytical chemist/toxicologist consulted. Endogenous production of GHB can occur spontaneously in postmortem biologic specimens and is dependent on both preservative use and storage temperature.²⁵⁴ Little to no endogenous production of

GHB will occur in postmortem blood preserved with sodium fluoride 10 mg/mL and stored at either room temperature or refrigeration at 4° C. Conversely, 50% higher endogenous GHB formation can occur when postmortem blood was not preserved but stored under refrigeration. Furthermore, when stored at room temperature, endogenous GHB production nearly doubled the value of those unpreserved specimens stored under refrigeration. Therefore, both preservative use and refrigeration of blood specimens will reduce the confounding influence of endogenous GHB production. While virtually all studies do not show elevation of endogenous GHB in postmortem urine, one investigator has reported elevations of endogenous GHB in both postmortem blood and urine specimens.²⁵⁵

In clinical cases when there is a medicolegal allegation of sexual assault facilitated by surreptitious placement of GHB into a beverage, it is important to consider that GBL has been discovered to be a natural constituent of a variety of wines. GBL has been detected in extracts from samples of unadulterated red and white wines at concentrations of 5 µg/mL and was easily quantified using a simple chloroform extraction technique followed by gas chromatography/mass spectrometry (GC/MS) analysis.²⁵⁶ It was additionally demonstrated that grape juice did not contain GBL, suggesting that GBL may be a natural by-product of the wine fermentation process. The observation that many varieties of wine may contain GBL reinforces the need to run proper controls in the forensic analysis of GBL. Hence, during the analysis of allegedly adulterated wine samples, it is important to conduct appropriate comparative quantitative analyses to assess accurately whether the amount of GBL present is at a naturally occurring or elevated level before rendering a decision that the material has been tainted.

QUALITATIVE SCREENING METHODS AND QUANTITATIVE CONFIRMATION METHODS

The dramatic surge in GHB abuse during the 1990s led to rapid advances in the laboratory detection of GHB, which can be useful to the clinician despite the myriad complexities associated with accurate GHB laboratory analysis and interpretation. Presently, at least two rapid colorimetric assays have been commercially developed for rapid screening of the presence of GHB.^{257,258} Both rely on the chemical conversion of GHB to GBL and are reported to be capable of producing qualitative results with 0.25 to 1.0 mL of urine within 5 to 10 minutes and with a sensitivity of 0.1 to 0.5 mg/mL. Such qualitative screening methods require confirmation by quantitative methods, which are the most sensitive and reliable methods.

Typically, this quantitative confirmation analysis is performed commercially using a GC/MS technique, for which over two dozen methods have been developed for analysis of GHB.²⁵⁹ A GC/MS technique was recently used in a clinical study examining the correlation of serum and urine GHB concentrations in 16 patients with a clinical suspicion of GHB-like drug overdose and a Glasgow Coma Scale (GCS) score of 8 or lower.²⁶⁰ All 16

suspected severe GHB overdose patients had significant serum and urine GHB concentrations, which ranged from 45 to 295 mg/L (median 180 mg/L) and 432 to 2407 mg/L (median 1263 mg/L), respectively. Patients who developed a GCS score of 3 had serum concentrations that ranged from 72 to 300 mg/L (median 193 mg/L). Although these GC/MS serum GHB concentrations correlated well with the occurrence of GHB toxicity, they did not correlate with the degree of coma or the time to awakening. Lastly, routine urine organic acid analysis may also accurately detect GHB in the overdose setting when available at a hospital.²⁶¹

Other Diagnostic Testing

Additional diagnostic laboratory testing should be performed as clinically indicated, particularly when the clinician is confronted with a conflicting or complicated clinical picture due to polysubstance ingestion. Because GHB is commonly ingested with ethanol, which exacerbates and/or prolongs the clinical toxicity of GHB, a serum ethanol concentration should be checked in all patients with suspected GHB poisoning. Also, MDMA is a relatively common co-ingestant, which is detectable in routine immunoassay urine drug screens. A 12-lead electrocardiogram is indicated, because GHB may produce cardiac effects (see Table 46-4), but primarily to rule out co-ingestion or intoxication with another potential cardiotoxic agents. A chest x-ray is indicated if there is clinical evidence of aspiration, which the severely GHB-intoxicated patient is at risk for, and which can increase the risk for morbidity and mortality. In cases of prolonged unconsciousness, a serum creatine phosphokinase and basic metabolic panel should be obtained and renal function monitored due to the risk for development of rhabdomyolysis. Other adjunct diagnostic studies for the comatose patient, such as a head computed tomography scan and lumbar puncture, may be deferred if there is a strong clinical index of suspicion for GHB poisoning.

Differential Diagnosis

The differential diagnosis for diminished mental status/coma and respiratory depression, the hallmarks of GHB poisoning, is exhaustive and includes trauma, medical conditions (such as CNS infection or masses, stroke, and hypoglycemia), and other medication overdoses (such as benzodiazepines, barbiturates, opioids, central α_2 -adrenergic agonists, anticonvulsants, and ethanol or toxic alcohols). However, while no true pathognomonic sign exists for GHB poisoning, the occurrence of extreme combativeness or agitation during noxious stimuli (such as an attempt on oroendotracheal intubation), followed by relapse into coma, may aid the clinician in differentiating this overdose from other sedative-hypnotic agents. Often, there is a history of GHB ingestion offered by friends, bystanders, or emergency services personnel at the scene, or the patient may be found in possession with containers or products whose label verifies the ingestion of GHB or one of its analogs.

MANAGEMENT

Supportive Measures

The medical management of symptomatic acute overdoses with GHB and its analogs, as well as their withdrawal syndrome, generally only requires vigilant monitoring and anticipatory supportive care. With supportive measures, 54% of patients were treated and released in the majority of episodes involving GHB according to 2002 ED trends reported by DAWN.⁴⁸ Recovery with supportive care is often spontaneous and abrupt, since patients have regained consciousness within 1 to 6 hours and without adverse sequelae. At present, there are less data and experience available for the management of the GHB withdrawal syndrome.

ACUTE OVERDOSE

Box 46-2 summarizes the medical management principles for the patient with symptomatic acute overdose with GHB and its analogs. Airway assessment and support is the first priority. A patent airway should be ensured, initially with proper positioning, suctioning of oral secretions, and placement of a temporizing oropharyngeal or nasopharyngeal airway if needed, and supplemental O₂ delivered. Bag-valve mask ventilation followed by endotracheal intubation and mechanical ventilation will be required for patients with loss of airway protective reflexes (coma or severe obtundation), respiratory distress (aspiration pneumonitis), or apnea. When invasive airway management is required, rapid sequence intubation protocols should be applied in order to facilitate a prompt intubation and minimize the occurrence of complications. Intravenous access should be secured and a crystalloid solution administered if hypotensive. Atropine and benzodiazepines are clinically indicated if bradycardia and seizures occur, respectively. As with any patient presenting with coma, dextrose,

BOX 46-2

MEDICAL MANAGEMENT AND DISPOSITION OF OVERDOSES FROM GHB AND ITS PRODRUGS AND ANALOGS

Airway support
Suction airway
Supplemental oxygen
Endotracheal intubation
Mechanical ventilation
Activated charcoal
Intravenous access
Cardiorespiratory monitoring
Atropine for symptomatic bradycardia
Benzodiazepines for seizures
Discharge if clinically stable after 6 hours of observation
Admit if initially presented comatose or if clinically intoxicated after 6 hours of observation

From Shannon M, Quang LS: Gamma-hydroxybutyrate, gamma-butyrolactone, and 1,4-butanediol: a case report and review of the literature. *Pediatr Emerg Care* 2000;16(6):435-440.

naloxone, and thiamine may be administered as clinically warranted.

WITHDRAWAL SYNDROME

Because the withdrawal syndrome from GHB and its analogs has been reported to be clinically similar to the ethanol withdrawal syndrome, it is managed in much the same manner. In general, high doses of benzodiazepines are used to manage the common withdrawal symptoms of dysautonomia (tachycardia, hypertension), anxiety, agitation, hallucinations, and psychosis. The limited clinical literature on the GHB withdrawal syndrome also reports cases that are refractory to high-dose benzodiazepines. In such case reports, benzodiazepines have been augmented with and/or substituted by barbiturates (pento-barbital or phenobarbital), anticonvulsants (valproic acid, carbamazepine, gabapentin), chloral hydrate, baclofen, clonidine, β -blockers (propranolol or labetalol), propofol, bromocriptine, trazadone, or antipsychotics.²⁰³⁻²³³ At present, no GHB withdrawal treatment regimen has undergone rigorous prospective clinical study.

Decontamination

Induced emesis with syrup of ipecac is contraindicated due to the high likelihood for rapid onset of CNS depression. Although there are no studies demonstrating adsorption of GHB or its analogs to oral activated charcoal (AC), gastrointestinal decontamination with single-dose oral AC may be beneficial if it can be administered in a timely manner. Given the rapid absorption of liquid preparations of GHB and its analogs, decontamination with AC should be initiated within 30 minutes of most ingestions or within 60 minutes of a polydrug ingestion. Accurate assessment for airway integrity and provision of an invasive airway, if clinically indicated, should precede the administration of oral AC.

Laboratory Monitoring

Continuous cardiorespiratory, pulse oximetry, and blood pressure monitoring are required for the patient with a symptomatic acute overdose or the withdrawal syndrome from GHB and its analogs.

Antidotes

Two pharmacologic antidotes, physostigmine and 4-methylpyrazole (4-MP, fomepizole), have been reported to reverse the clinical effects of acute GHB and 1,4-BD overdose, respectively. At present, the administration of these antidotal agents has not been validated with rigorous prospective clinical trials.

PHYSOSTIGMINE

There are several case reports of the successful administration of physostigmine, a carbamate inhibitor of acetylcholinesterase, to reverse GHB-induced sedation in the ED setting. Caldicott and Kuhn reported the reversal of GHB intoxication with physostigmine.²⁶² Their notion that GHB may be reversed with physostigmine

was based on two studies where “GHB reversal” was produced in surgical patients receiving GHB as an anesthetic adjuvant.^{263,264} In the two anesthesia case series and in the Caldicott and Kuhn case series, it is likely that investigators may have confused physostigmine “reversal” with the clinical course of GHB, since physostigmine was administered to patients at a time when GHB clinical effects can be expected to wane. Furthermore, pharmacologic studies have found no relationship between GHB and acetylcholine-mediated neurotransmission in the CNS.²⁶⁵ Therefore, at present, there is a lack of sufficient data to recommend empirical administration of physostigmine as an antidote in the setting of symptomatic acute overdose with GHB or its analogs.

4-METHYLPYRAZOLE

4-Methylpyrazole (4-MP) is a pharmacologically plausible antidotal agent for 1,4-BD overdose. A potent competitive antagonist for ADH, 4-MP would be expected to block the biotransformation of 1,4-BD to GHB, and there are many *in vitro* and *in vivo* experimental data to support the use of 4-MP to block 1,4-BD toxicity.²⁶⁶⁻²⁷¹ Furthermore, there is a case report of the successful administration of 4-MP to treat 1,4-BD poisoning.²⁷² Following a 30-mL ingestion of a homemade 1,4-BD solution, a 43-year-old man developed generalized seizures and coma. This patient awoke shortly after the administration of the initial 4-MP dose of intravenous 10 mg/kg. However, initial GC/MS plasma 1,4-BD and GHB concentrations were 24 and 222 mg/L, respectively. These analytical data are inconsistent with the proposed pharmacologic antidotal mechanism of 4-MP, which is to block 1,4-BD biotransformation to the toxic compound GHB. Although basic investigations support the use of 4-MP in the setting of early 1,4-BD acute overdose,^{150,272-274} the empirical administration of 4-MP as an antidote cannot be recommended until more rigorous clinically derived data are available.

Elimination

Given the known pharmacokinetic profile of GHB, it is unlikely that gastric lavage, whole bowel irrigation, or other extracorporeal methods of enhanced elimination will be useful in the management of acute overdoses with GHB or its analogs.

Disposition

Box 46-2 summarizes the disposition of a patient with an acute overdose of GHB or its analogs. Patients should be observed in the ED for 6 hours and may be discharged if they remain asymptomatic. If a patient arrives at the ED with a clinical presentation consistent with an acute overdose of GHB or its analogs, or develops these symptoms during ED observation, inpatient admission is indicated. Disposition of a patient with a GHB polydrug ingestion, particularly when a narcotic or ethanol is involved, requires caution because most GHB-related deaths have been associated with these co-ingestions. In the case of ethanol, animal studies and clinical case

reports have documented potentiated toxicity, prolonged toxicity, and in the case of 1,4-BD, delayed GHB toxicity.

ACKNOWLEDGMENTS

I wish to thank Hai Thong Nguyen, MD, attending physician, Ste. Anne Hospital, Montreal, Quebec (Veterans Affairs, Canada), for his valuable assistance in translating the French-written GHB papers cited in this manuscript (references 12 through 14). Preparation of this chapter was supported in part by National Institutes of Health/National Institute on Drug Abuse Grant 1RO3 DA14951.

Acetaminophen

STEVEN D. SALHANICK, MD ■ MICHAEL W. SHANNON, MD, MPH

At a Glance...

- Acetaminophen toxicity is a frequent cause of hepatic toxicity and should be considered in the differential diagnosis of any patient presenting with acute hepatic failure.
- Toxicity is resultant of the metabolism of the drug in overdose.
- Onset of hepatic toxicity is delayed 12 to 36 hours after acute overdose.
- Therapy after acute overdose is based on the level of drug if this can be measured 4 to 24 hours after overdose, according to the Rumack-Mathews nomogram.
- Subacute and late-presenting cases cannot be managed according to the nomogram.
- Acute overdose that is thought to put the patient at high risk for developing hepatic toxicity is treated with *N*-acetylcysteine administered as a loading dose of 140 mg/kg followed by 17 maintenance doses at 70 mg/kg. Shorter courses of therapy are routine in Europe, Canada, Australia, and elsewhere, and have been administered in the United States as well.
- The efficacy of *N*-acetylcysteine therapy declines beginning 8 hours after acute overdose; therefore, therapy should be started within 8 hours of overdose.
- Patients with acute ingestion and nontoxic levels do not require therapy. Short courses of therapy in other cases may be required if potential toxicity is unclear.

Acetaminophen (paracetamol, APAP) is a widely used analgesic and antipyretic agent. Use of APAP as an antipyretic was first reported by von Mehring in 1893, in fact preceding the medicinal use of salicylates.¹ Despite its effectiveness, an undesirable side effect profile led to discouragement of its use. It is likely that an impure preparation was used, accounting for the adverse effects.² Related compounds including acetanilide (marketed as Antifebrin) were in use since the late 1880s. APAP was subsequently abandoned until the late

1940s, when Brodie and Axelrod published their data indicating that APAP was in fact a metabolite of acetanilide and was responsible for the analgesic and antipyretic effects.² Subsequent to these investigations, APAP was substituted for phenacetin in the combination product Trigesic in 1950. Trigesic was withdrawn from the market in 1951 after reports of agranulocytosis associated with its use. APAP was never clearly implicated as causal. APAP use was essentially abandoned in the United States until the advent of Tylenol in 1955. However, aspirin was more widely prescribed until the early 1970s.² APAP, marketed as Panadol in the United Kingdom in 1956, increased in popularity throughout the 1960s and 1970s in a fashion parallel to that in the United States.²

Currently, APAP poisoning represents the most frequent poisoning reported to U.S. poison centers, is the cause of the majority of poisoning deaths reported to U.S. poison centers, and is the most frequent cause of acute hepatic failure in the United States.³⁻⁵

PHARMACOLOGY

Despite its widespread use, APAP's mechanism of action remains elusive. Cyclooxygenase inhibition has been long postulated, but APAP has been shown to be a poor inhibitor of COX-1 and COX-2, the two well-described cyclooxygenases involved in the early inflammatory response. Furthermore, unlike nonsteroidal anti-inflammatory drugs, APAP has not shown antiplatelet activity.⁶⁻⁸ Chandrasekharan and colleagues recently demonstrated the presence of a COX-3 enzyme that is inhibited by APAP. The COX-3 enzyme is primarily expressed in the central nervous system, implying a central location of action for APAP.⁶ COX-3 inhibition by APAP is weak, however; therefore, that COX-3 inhibition does not fully explain the analgesic and antipyretic actions of APAP.⁸

PHARMACOKINETICS

APAP in therapeutic doses is rapidly and nearly completely absorbed. Absorption occurs primarily in the small bowel with the rate of absorption consequently dependent on the rate of gastric emptying. APAP is distributed throughout the body, having a volume of distribution of 0.95 L/kg. Half-life is approximately 1.5 to 2 hours.⁹ Hepatic metabolism produces two major metabolites, the sulfate conjugate and the glucuronide conjugate. Approximately 5% of APAP is excreted unchanged, while approximately 4% to 5% undergoes reductive metabolism by the cytochrome P-450 (CYP) system, principally CYP2E1 and CYP1A2 to *N*-acetyl-*para*-benzoquinone-imine (NAPQI). NAPQI is subsequently bound to intracellular thiols, principally glutathione, and is excreted as the cysteine and mercapturic acid conjugates in urine⁹ (Fig. 47-1). This reductive metabolism and its products are implicated in the toxicity of APAP.

Glucuronide conjugation occurs to a much lesser degree in young children and neonates than in adults, and sulfate conjugation predominates; the plasma half-life may also be prolonged in young children.¹⁰ Patients with severe liver dysfunction may have decreased excretion of APAP as well.¹¹

The urinary excretion of APAP is via glomerular filtration with a significant fraction of tubular reabsorption. The glucuronide and sulfate conjugates are actively secreted by the tubules, with renal clearance rates of 130 and 170 mL/min, respectively.¹² Patients with renal failure accumulate metabolites, although the plasma half-life of APAP is unaffected.¹¹

APAP readily crosses the placenta and is risk category B in pregnancy, meaning that safety is presumed based on animal studies.¹³ Maternal pharmacokinetics are similar to those of humans in the nonpregnant state.^{14,15} Several studies have investigated the effects of APAP in therapeutic doses and overdose in all trimesters.¹⁶⁻²² APAP toxicity appears to occur in utero. One report describes plasma levels in an infant delivered by cesarean section similar to maternal levels following maternal APAP overdose.²³ Therapeutic dosing has not been shown to have any negative effects on pregnancy or the fetus. APAP is excreted in breast milk; plasma ratios reported to range from 1:0.50 to 1:1.42.²⁴

Pharmacologic agents that can theoretically affect APAP pharmacokinetics include those that delay gastric emptying, notably the anticholinergic agents. Several case reports describe delay in absorption following APAP overdose with co-ingestants that delay gastric emptying.²⁵⁻²⁷ Absorption of liquid preparations is slightly more rapid.⁹ No significant drug interactions are known to occur with APAP following therapeutic dosing.

TOXICOLOGY

Death due to hepatic failure following APAP overdose was first reported in 1966.^{28,29} Research into the cause of toxicity ensued, and in 1974 Mitchell and Jollow published their work that provided the basis for the widely

accepted theory of free radical arylation of hepatic proteins as causative.³⁰⁻³³ These investigators demonstrated in vivo and in vitro that radiolabeled acetaminophen was recovered bound to proteins in the hepatocyte following administration of high doses of acetaminophen. Furthermore, they found that glutathione depletion preceded other signs of hepatic injury and that glutathione precursors administered prior to experimental poisoning were hepatoprotective. This work formed the basis for *N*-acetylcysteine (NAC) antidotal therapy. Later studies identified the metabolite responsible for binding to be NAPQI.^{34,35} Further work has gone into determining the critical protein or proteins responsible for hepatic failure. At present, approximately 28 proteins subject to arylation have been identified.^{36,37} Binding is highly selective, however. Several specific proteins account for the majority of binding, specifically the cytosolic 56- to 58-kD acetaminophen binding protein, the 100-kD *N*-10-formyl-tetrahydrofolate dehydrogenase, and 50- and 54-kD mitochondrial dehydrogenases.³⁸ Several investigators have worked extensively to determine the critical protein or proteins that, when arylated, result in cell death. No decrease in protein function has been determined that could likely account for the cell death. Most enzymes show only modest reduction in function postpoisoning, with the most prominent being glutamine synthetase, which has a 50% reduction in activity.³⁷

These and other inconsistencies of the NAPQI binding hypothesis have led to consistent challenges to this hypothesis.^{37,39} Covalent binding does not always correlate with severity of injury.³⁷ Inhibition of Kupffer cell activity alters or abolishes toxicity despite a high degree of covalent binding.^{40,41} High levels of covalent binding will occur in young female rats with no detectable hepatic injury.⁴² 3'-Hydroxyacetanilide, a regioisomer of APAP administered in similar doses, results in a high degree of protein covalent binding without toxicity as well.^{43,44} Also, the critical protein or proteins have never been identified in nearly 30 years of investigation. A complete review of the criticism of the NAPQI theory is beyond the scope of this chapter; however, these and other inconsistencies have led to the investigation of several other causes of toxicity.

Wendel and co-workers proposed the hypothesis that reactive oxygen species formed during the CYP metabolism of APAP produce massive lipid peroxidation, and they produced data to strongly support this contention.⁴⁵⁻⁴⁷ The data were challenged on the basis that due to technical difficulties in the measurement of products of lipid peroxidation, the animal model used by Wendel's group was particularly susceptible to lipid peroxidation and that it was not therefore relevant.⁴⁸ Other investigators have not reproduced the work using other models.³⁷

Oxidant stress due to the action of reactive oxygen species has been proposed due to the generation of these species from a variety of sources, including injured mitochondria, activated Kupffer cells, infiltrating neutrophils, and xanthine oxidase.³⁷ Evidence supporting each of these mechanisms exists, but the question

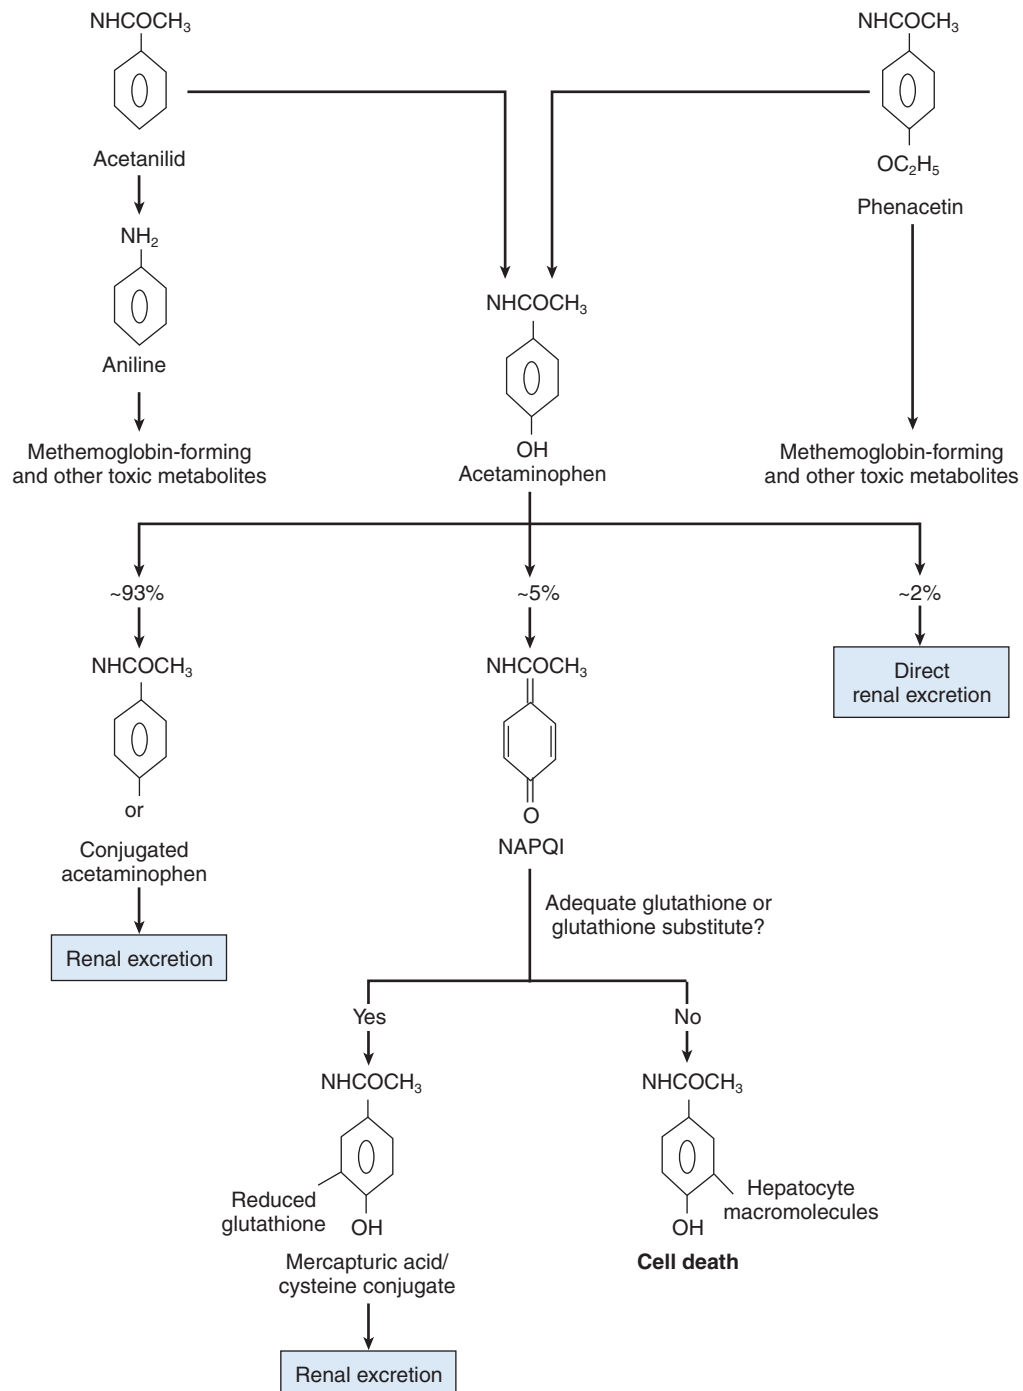

FIGURE 47-1 Metabolism of acetaminophen and other coal tar analgesics. NAPQI, *N*-acetyl-*p*-benzoquinoneimine; R, glucuronide or sulfate.

remains as to whether oxidant stress is a cause of hepatocyte injury or occurs as a result of hepatocyte injury.

Peroxynitrate formation occurs when nitric oxide is formed in the presence of superoxide anions, a reactive oxygen species.⁴⁹ Peroxynitrate is a powerful oxidant and produces nitrotyrosine adducts in tissue, which have been demonstrated by immunohistochemistry in hepatic tissue following experimental APAP overdose. Time course of nitrotyrosine adducts indicates that they bind concurrently or immediately preceding hepatocyte

injury. Furthermore, peroxynitrate can deplete cellular glutathione stores.³⁷

Finally, early mitochondrial dysfunction is an important early finding in all models of APAP overdose and may occur as soon as 15 minutes after APAP exposure.⁵⁰⁻⁵⁵ Mitochondrial dysfunction is implicated as playing a role in nearly every aspect of the pathogenesis of APAP toxicity, including failure of energy substrate, increase in reactive oxygen species, and increased cytosolic calcium concentrations. The cause of this early failure is not

known. Reactive metabolite arylation of mitochondrial proteins has not been demonstrated to have a significant enough effect to be accepted as causal.³⁷ Early mitochondrial failure remains a crucial missing piece of the puzzle of APAP-induced hepatic injury. One mechanism that has been proposed in the past and is currently undergoing investigation is the concept of hypoxia as causal regarding the early mitochondrial failure.^{56,57} Centrilobular hepatocytes are relatively hypoxic at baseline. Mitochondria are susceptible to a lack of available oxygen due to the use of oxygen for drug metabolism. Early work has shown promise but mixed results with regard to APAP poisoning.⁵⁷ Hypoxia has been demonstrated in a more convincing fashion in relation to other centrilobular toxins, including ethanol and carbon tetrachloride.⁵⁸⁻⁶² Another proposed mechanism of mitochondrial failure involves mitochondrial permeability transition (MPT), a state where the inner mitochondrial membrane becomes depolarized due to increased ion permeability. The proposed mechanism involves NAPQI binding to vicinal thiols in the membrane pore responsible for MPT. Other quinones known to bind vicinal thiols have been demonstrated to induce MPT. NAPQI has not been demonstrated to have this effect, however.⁶³

Recently, attention has been turned to the delay in fulminant hepatic failure following overdose. Humans and animals typically will have a delay following metabolism of APAP before the rise in transaminases occurs. This phenomenon has been referred to as stage 1 and stage 2 of toxicity.⁶⁴ Stage 1 is the metabolism phase of poisoning, where plasma drug level declines and serologic and clinical evidence for hepatotoxicity is absent. Stage 2 refers to the hepatic injury phase that occurs 12 to 36 hours after drug metabolism is complete. Current investigation is focused on the identification of inflammatory mediators that may be responsible for the second stage.³⁷ It is important to note that the exact cause of the initiating events, while clearly related to metabolism, remains in question. An immune response to arylated proteins has not been demonstrated. Kupffer cell involvement is thought to be imperative in toxicity.

CLINICAL MANIFESTATIONS

Acute human toxicity has traditionally been divided into four clinical phases (Box 47-1). Initially, patients may be asymptomatic or may develop nausea and vomiting. Transaminases may begin to rise by 16 hours after overdose.⁶⁵ Between 24 and 72 hours, signs of hepatic insult become prominent. Transaminases begin or continue to rise, the patient may develop right upper quadrant pain, and signs of hepatic synthetic failure (i.e., elevated prothrombin time) may appear, as may evidence of cholestasis with elevated bilirubin. Renal injury will become evident in a small fraction of patients at this point.⁶⁶ A few reports of renal injury without hepatic failure exist, but these are exceedingly rare and not well documented.⁶⁷ Most cases include some degree of hepatic injury. Between 72 and 96 hours, hepatic and

BOX 47-1

PHASES OF ACETAMINOPHEN POISONING

Phase I (0.5–24 hr)

Anorexia, nausea, and vomiting are frequently present. Malaise and diaphoresis may be present. Transaminases may be elevated. Patients may appear normal.

Phase II (24–72 hr)

Anorexia, nausea, and vomiting become less pronounced. Right upper quadrant pain may be present. Transaminase levels continue to increase. Bilirubin level may be elevated. Prothrombin time may be prolonged. Renal function may deteriorate.

Phase III (72–96 hr)

Characterized by the sequelae of hepatic necrosis: jaundice, coagulation defects, renal failure, and hepatic encephalopathy. Liver biopsy reveals centrilobular necrosis. Death due to multiorgan failure may result.

Phase IV (4–14 days)

If patients survive, complete resolution of hepatic dysfunction occurs and the liver heals without evidence of fibrosis.

renal failure may worsen. Death occurs due to hepatic failure. Early hepatic transplant may allow survival at this point. Alternatively, hepatic injury may resolve and transaminases may return to normal over the ensuing 4 to 14 days. Complete regeneration of the liver is the rule. Renal insult will resolve as well.⁶⁷

APAP toxicity following supratherapeutic administration, often referred to as chronic toxicity, has been observed in both children and adults. The patients manifest essentially the same course of toxicity. One case of hepatic fibrosis following chronic administration of supratherapeutic doses has been reported.⁶⁸

More recently, chronic administration of therapeutic amounts of acetaminophen has been shown to cause hepatocellular injury. Injury was relatively mild and resolved with discontinuation of the drug.⁶⁹ Case reports exist implicating APAP in analgesic nephropathy.¹¹ However, epidemiologic data do not support the contention that chronic therapeutic administration leads to renal injury.⁷⁰⁻⁷² APAP hypersensitivity is exceedingly rare.¹¹

DIAGNOSIS

The diagnosis of APAP poisoning is based primarily on history and laboratory screening, given the nonspecific nature of the initial presentation and the delay in manifestations of hepatotoxicity. Nausea and vomiting are consistent with early toxicity. A serum APAP concentration should be sent when any patient presents with a history of intentional overdose of any substance due to the wide availability of the drug and the 5% incidence of undeclared ingestion. Because the manifestations of hepatic injury are delayed, the decision to initiate

therapy is based on the risk of developing hepatotoxicity. In the setting of the acute ingestion at a single point in time, the decision to treat is relatively straightforward. An accurate time of ingestion must first be established. Establishment of the risk for toxicity is based on the Rumack-Matthews nomogram (Fig. 47-2). The nomogram was developed in 1975 by retrospective review of 64 patients following acute APAP overdose. Patients were found to have a 60% chance of developing severe hepatotoxicity if the plasma level was above the line drawn from the 200 $\mu\text{g}/\text{mL}$ level at 4 hours to the 50 $\mu\text{g}/\text{mL}$ level at 12 hours. Severe hepatotoxicity was defined as an aspartate aminotransferase (AST) level of greater than 1000 IU/L.⁷³ It is important to recognize that the nomogram is not applicable to modes of ingestion other than the acute single overdose. Furthermore, the nomogram is not applicable prior to 4 hours or after 24 hours. Levels prior to 4 hours may be markedly elevated because APAP may not have distributed from the vascular compartment to the tissues. It is also important to recognize that the nomogram comprises a series of data points rather than representing the elimination half-life of APAP in overdose.

Rarely, patients following a massive overdose causing levels in the range of 800 to 1000 $\mu\text{g}/\text{mL}$ will present with severe acidosis and coma.⁷⁴ The mechanism of this presentation is not understood. Animal and in vitro data indicate reversible binding of APAP to mitochondrial proteins inhibiting respiration, and this mechanism has been suggested to be the cause of the acidosis seen in these massive overdoses.^{56,75}

Patients presenting late or following ingestion over a prolonged period of time present a more difficult diagnosis because the nomogram cannot be used. A

FIGURE 47-2 Acetaminophen (APAP) overdose treatment nomogram. (Adapted from Smilkstein MJ, Knapp GL, Kully KW, et al: Efficacy of oral *N*-acetylcysteine in the treatment of acetaminophen overdose: analysis of the National Multicenter Study [1976 to 1985]. *N Engl J Med* 1988;319:1557.)

careful history of ingestion should be sought. APAP level should be measured to confirm ingestion, but the level cannot be used to determine risk for resultant hepatotoxicity. Transaminase values should be obtained and elevation should be assumed due to APAP poisoning unless proven otherwise.

The differential diagnosis includes all causes of hepatic centrilobular necrosis. Principal are other toxic causes, including hepatotoxic mushrooms, carbon tetrachloride, halothane and other inhaled anesthetics, brominated and chlorinated benzenes, and dioxane. Shock, vascular obstruction, and other causes of acute hepatic ischemia will also produce a centrilobular necrosis with the resultant clinical picture consistent with acute APAP poisoning. APAP poisoning may be worsened in patients with cardiac insufficiency.⁷⁶

MANAGEMENT

Supportive Measures

Initial supportive measures should be those applicable to any poisoned patient. If the patient presents late in the course of poisoning, then resuscitative measures may be necessary. These should include standard measures to control airway, ventilation, and hemodynamic status. Supportive care for the patient with hepatic failure from APAP poisoning does not differ from that due to any other cause of hepatic failure. Acute renal failure may require dialysis.

Decontamination

Activated charcoal should be given unless the clinician is certain that the time of ingestion is so remote that there is no chance that any APAP remains in the gut. Every patient who presents within 6 hours of ingestion, or for whom the time of ingestion is in question, should therefore be treated with activated charcoal. Multiple-dose charcoal is not indicated following APAP ingestion.

Activated charcoal will bind and reduce the absorption of NAC if given simultaneously; however, no clinical detriment has been shown by this practice.⁷⁷⁻⁷⁹ NAC should never be delayed beyond 8 hours following ingestion to facilitate decontamination, and concurrent administration of charcoal likely will not be detrimental.

Laboratory Monitoring

Initial management should include obtaining baseline serum transaminase levels, blood urea nitrogen, creatinine, and prothrombin time along with the APAP level. Appropriate screening for co-ingestants should be dictated by the clinical situation. If there is no laboratory evidence of hepatic injury, then daily transaminase levels should suffice for laboratory monitoring. Should any abnormalities in transaminase levels appear at any time, then evidence of synthetic failure should be sought. Serial prothrombin time should be added to the serial transaminases. The frequency of laboratory evaluation

should be dictated by the clinical situation. A modest rise in transaminase levels (less than 500 IU/L) does not warrant more than daily monitoring. As levels approach 1000 IU/L, more frequent (i.e., every 6 to 12 hours) laboratory monitoring should be instituted. With any signs of synthetic failure the evaluation should be expanded to include data with prognostic value. Renal function tests should be followed due to the renal dysfunction that occurs infrequently. Should the patient develop signs of hepatic failure, he or she should be admitted to an intensive care unit and monitored closely for developing acidosis and renal and hepatic failure. This is important because the prognostic factors associated with death include a metabolic acidosis (arterial pH less than 7.3), renal insufficiency (serum creatinine greater than 3.3), or hepatic synthetic failure (International Normalized Ratio [INR] greater than 2 at 24 hours, 4 at 48 hours, or 6 at 72 hours).⁸⁰ Recently, attention has been drawn to the use of blood lactate as an early predictor of hepatic failure. Blood lactate greater than 3.5 mmol/L or 3.0 mmol/L after fluid resuscitation was predictive of mortality and has been suggested as criteria to list for transplantation.⁸¹

Prothrombin time and INR may be elevated following APAP ingestion without evidence of hepatocellular injury. Inhibition of factor VII by high levels of APAP and the anticoagulant effects of NAC have been proposed as mechanisms.^{82,83} This early elevation in INR has no prognostic value.

Antidotes

NAC is the current antidote employed worldwide for the treatment of APAP toxicity. The rationale for NAC therapy is based on the theory that glutathione depletion leads to a state where the toxic free radical NAPQI can injure cellular macromolecules. NAC is given as both a glutathione precursor to provide substrate for NAPQI binding as well as a sulfate precursor to help drive the metabolism of APAP down the sulfonation pathway.⁷³

Dosing

The standard course of NAC therapy in the United States is to administer a loading dose of 140 mg/kg followed by 17 maintenance doses of 70 mg/kg every 4 hours. This regimen was developed in the 1970s by Rumack and colleagues based on their observations of patients suffering from APAP overdose and applying the theory of NAC as a binding substrate for NAPQI.⁷³ The amount of NAC administered is based on the theoretical molar amount of NAPQI formation. The duration of therapy is based on the period of time required to metabolize APAP. The duration is purposefully long because some patients display a markedly extended half-life. Standard practice in Europe, Canada, Australia, and other countries is to administer NAC for 20 to 36 hours. Rates of fulminant hepatic failure, death, and transplantation are not significantly different, prompting several investigators in the United States to begin trials of shorter courses of NAC following the acute single overdose.^{84,85}

NAC therapy is typically given orally in the United States, while in other countries, intravenous (IV) administration is the preferred route. There are several reasons for this discrepancy. Proponents of oral administration cite the theoretical advantage that oral NAC is presented to the liver in high concentration because it is initially circulated via the portal system. No data exist to support this contention, however. IV NAC can and should be given to patients in the United States, however, if the patient is unable to tolerate the medication orally. The oral preparation sold in the United States is sterile and can be given by the IV route. As with oral administration, NAC should be given as a 5% solution in saline. A 22- μ m filter typically used for blood administration should be used. NAC dosing is identical to the oral protocol: 140 mg/kg loading dose followed by 17 maintenance doses of 70 mg/kg. The rate of administration is related to complications. Anaphylactoid reactions are reported in approximately 6% of patients when the loading dose is administered over 15 to 30 minutes.^{86,87} Typically, these resolve with cessation of administration.⁸⁶ Restarting administration at a lower rate following the administration of diphenhydramine is sufficient treatment. Administration at slower rates reduces the rate of anaphylactoid reaction. Consequently, administering IV NAC over the course of 1 hour is a reasonably conservative practice. More recently, an intravenous form of NAC was approved by the U.S. Food and Drug Administration. The approved dosing protocol applies only to acute ingestion and is given over 21 hours. A loading dose of 150 mg/kg is given over 1 hour, followed by 50 mg/kg over 4 hours, followed by 100 mg/kg over 16 hours.

Patients who ingest APAP over a period greater than several hours due to repeat attempts or therapeutic misadventure and patients who present greater than 24 hours after ingestion present a more difficult decision with regard to initiating treatment. Generally, if the patient gives a history of overdose, has a measurable APAP level, and/or has a rise in AST or alanine transaminase, then NAC should be initiated. If the patient remains without biochemical evidence of toxicity by 24 hours, it is reasonable to discontinue therapy. Therapy should continue if there is evidence of toxicity.

The decision to treat patients who have ingested an overdose at one time point is aided by the use of the Rumack-Matthews nomogram (see Fig. 47-2). It is important to note that this is the only clinical scenario in which the nomogram is applicable. The nomogram was constructed using a series of data points, which represent the presenting plasma level of APAP versus time. A line is drawn through those points representing patients with a greater than 60% likelihood of developing an AST greater than 1000 IU/L. A second line was arbitrarily lowered in order to allow for error in history of the time of ingestion and is the treatment level most commonly in use in the United States. Most physicians outside the United States use the first line as indication for therapy. The lines are drawn from a time point of 4 hours after ingestion. This is because levels during the absorptive phase following ingestion are not reliable in terms of

prognosis. APAP levels obtained prior to 4 hours after ingestion should not be used to base treatment decisions. Furthermore, levels obtained after 24 hours similarly have not been determined to have prognostic value. Patients presenting following ingestion should have a level checked as close to 4 hours after the ingestion as possible. Treatment should be based on that level. If the level is above the lowest treatment line, a course of NAC therapy is indicated. If it is below the line, no therapy is needed. A caveat to this rule occurs following co-ingestion of drugs that slow gastric motility, particularly anticholinergics such as diphenhydramine. Case reports indicate that delayed absorption may result in a 4-hour level that is not considered treatable followed by a 6- or 8-hour level that is toxic.⁸⁸ In this case a second level should be determined at 6 hours to ensure that the level is trending down and that levels subsequent to the initial 4-hour level will be unlikely to be in the treatable range. If the patient presents 8 or more hours after the ingestion or if a level will not be available before that time, treatment based on history of ingestion alone while awaiting an APAP level is indicated due to the decreasing efficacy of NAC therapy following delay to treatment greater than 8 hours.⁸⁹ Patients who present greater than 24 hours after the ingestion pose a more difficult decision to treat because the nomogram is not directly applicable to their treatment. It is reasonable practice to treat patients with persistently elevated APAP levels who present later than 24 hours after ingestion because it is reasonable to assume that the level was in a toxic range at prior to the 24-hour mark. Notably, this is an assumption only, and such levels have no prognostic significance. Patients who present greater than 24 hours after ingestion without an elevated APAP level pose a more difficult treatment decision because it is impossible to know if they had a level placing them at risk for hepatic injury during first 24 hours. Consequently, a reasonable practice is to administer a course of therapy for 24 hours and to follow transaminase levels. Patients will likely begin to display elevated transaminase levels by 36 hours after ingestion.^{65,90} If they show no signs of hepatic injury, therapy may be discontinued. Also, any patients with evidence of hepatic injury at the time of presentation warrant therapy. Patients whose evidence of liver injury can clearly be attributed to a cause other than APAP toxicity who do not show progression of liver injury after 24 hours may have NAC therapy discontinued.

It is important to note that NAC therapy is effective at any point after poisoning and that if hepatic injury occurs, therapy is continued until evidence of hepatic dysfunction has resolved and transaminase values are declining and near normal. Therapy should never be stopped following the prescribed 18 doses when evidence of hepatic injury is still present. The reason for this apparent discrepancy is that NAC therapy is proven effective in reducing mortality when started and continued during any point in the course of APAP-induced hepatic injury.⁹¹ Lack of a measurable APAP level is not an indication to withhold NAC therapy because late-presenting patients without measurable APAP levels are clearly benefited by NAC therapy. The

reasons for this are unclear. Several theories have been advanced. “Extrahepatic” effects such as free radical scavenging have been suggested, but experimental evidence is lacking. NAC has been shown to increase hepatic blood flow and oxygen extraction.^{92,94} It is following these observations that have led to the advent of NAC therapy for other causes of hepatic failure.

Other suggested antidotes include the CYP inhibitor cimetidine. Cimetidine was recognized early on as an inhibitor of the CYP system, and its use as an antidote for APAP poisoning was considered. Early animal data showed promise.⁹⁵ Human experience was less promising and met with little enthusiasm.⁹⁶ One argument against cimetidine is that it does not affect the specific CYP isoforms involved in the metabolism of APAP. Specific CYP2E1 inhibitors such as 4-methyl-pyrrazole and disulfiram have been investigated in animals with positive results.^{97,98} Human data do not yet exist.

Elimination

Dialysis has been used to enhance elimination following APAP poisoning. Its use has largely been abandoned following the advent of NAC therapy due to the effectiveness of this treatment. However, a role for dialysis has been suggested in cases of massive overdose where the patient presents with coma, acidosis, and levels near 1000 µg/mL, at which point the risk for mortality is very high. There are no data addressing the effectiveness of this intervention. Liver dialysis has been reported to be of benefit in an uncontrolled case series of four patients.⁹⁹ More data will be needed to determine benefit of liver dialysis.

DISPOSITION

Patients presenting with a history of APAP ingestion should be screened for co-ingestants in the usual fashion. A careful physical examination aimed at identifying a toxidrome suggestive of co-ingestants should be performed. Serum APAP level should be determined at 4 hours postingestion or as soon as possible after the 4-hour mark. Levels prior to 4 hours are of no prognostic significance. Patients with a single time of ingestion between 4 and 24 hours prior to presentation may be treated according to the Rumack-Matthews nomogram. Patients ingesting APAP at more than one time point warrant an abbreviated course of therapy while monitoring transaminase levels. Any patient with evidence of hepatic injury should have therapy continued until evidence of hepatic injury is resolved. Patients not meeting these criteria do not warrant therapy. As with any ingestion, a careful investigation of the circumstances surrounding the ingestion should be performed. It is important to educate any patient who has overdosed due to misuse of APAP. Intentional overdoses warrant psychiatric evaluation before the patient is discharged from medical care. Patients who suffer hepatic injury and recover may be safely discharged from care because no sequelae will occur once the injury is resolved.

The question of referral to a center capable of transplantation often arises. Given the rapidity of demise in patients who suffer hepatic injury, referral should be discussed with the appropriate personnel at the referral center when the patient begins to display evidence of hepatic functional impairment in order to allow the transplant service adequate time to assess the patient and place him or her on a transplant list. Patients who have only elevation in transaminase levels and a transient, slight elevation in prothrombin time and INR can be managed expectantly with NAC therapy alone. Patients who undergo transplantation will need careful follow-up care as with any transplant patient.

At a Glance...

- Salicylate poisoning may be a difficult diagnosis to make, particularly in the chronic setting, where salicylism is often unrecognized or mistaken for other illnesses.
- Serial assessments of a patient's physical examination, acid-base state, and serum salicylate concentrations are essential to guide appropriate treatment.
- Activated charcoal is the preferred method of gastrointestinal decontamination.
- Fluid, electrolyte, and metabolic abnormalities occur commonly and should be treated promptly.
- Urinary alkalization enhances salicylate elimination and should be instituted in all symptomatic patients and those with serum salicylate concentrations greater than or equal to 30 mg/dL.
- Hemodialysis is recommended for seriously poisoned patients.

INTRODUCTION AND RELEVANT HISTORY

Salicylates have been used since ancient times. Hippocrates, Galen, and medieval herbalists relied on salicylate-containing plants for their palliative properties. The medicinal properties of willow bark (*Salix alba vulgaris*) have been appreciated by native peoples for centuries. In the mid-19th century, the active ingredient of willow bark, salicylic acid, was isolated and subsequently synthesized from phenol. It gained widespread use in compounded pharmaceuticals as a pain reliever, anti-inflammatory, and antipyretic. In the latter portion of the 19th century, the Bayer company in Germany developed a salicylic acid derivative, aspirin (or acetylsalicylic acid), for commercial use. Aspirin and its chemically related analogs (all known as salicylates) have since been prescribed widely by the medical profession and used extensively in numerous pharmaceuticals for nonprescription use by the public. Since the 1960s, the development of analgesic, antipyretic, and anti-inflammatory alternatives (e.g., acetaminophen, ibuprofen) to salicylates has curtailed their use for these purposes. More recently, aspirin has become widely used as an antiplatelet agent in the treatment of cardio- and cerebrovascular disease. Because of its ubiquitous use and availability, aspirin continues to result in a significant number of acute and chronic poisonings.

EPIDEMIOLOGY

Salicylate poisoning (salicylism) can be accidental or intentional and acute or chronic. Salicylate poisoning occurs largely as an accidental overdose in the pediatric

age group or intentional overdose with suicidal intent in the adult and teenage population. Therapeutic misadventure (misuse or error) can result in poisoning at any age. Although acute intoxication is more common, chronic salicylism also occurs with regularity. Untreated, both forms of poisoning can result in significant morbidity and mortality, particularly in the elderly population.

A review of salicylate exposures reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System (AAPCC TESS) for the 10-year period of 1993 through 2002 reveals that 26.3% of all salicylate exposures occurred in children younger than 6 years (Fig. 48-1). Although a significant number of exposures occurred in the pediatric age group (birth–19 years of age), only five fatalities related to accidental overdose were reported—0.003% of all salicylate exposures reported to American poison centers. During this time period, 468 fatalities were attributed to salicylate poisoning. The mean age of those with fatal outcomes was 47.25 years. Most salicylate fatalities occur in older adults who intentionally ingest salicylates acutely in combination with other pharmaceuticals with suicidal intent.

Based on poison center data, the number of salicylate-related poisonings in children younger than 6 years has declined steadily from 1993 through 2002. This is especially noteworthy since the number of pediatric salicylate exposures decreased by nearly 10% since 1993

FIGURE 48-1 Age distribution: unintentional salicylate exposures, 1993 through 2002. Mean age, 47.25 years. The data were derived from the American Association of Poison Control Centers Toxic Exposure Surveillance System annual reports, 1993–2002 (retrieved September 16, 2003, from <http://www.aapcc.org/annual.htm>).

FIGURE 48-2 Aspirin-related fatalities in children younger than 5 years, 1972 through 1992. (From National Center for Health Statistics: Unpublished data.)

(9707 in 1993 versus 8753 in 2002), while the number of exposures reported to poison continued to increase (1,751,476 in 1993 versus 2,380,028 in 2002). Therefore, relative to all poisoning exposures, the incidence of reported pediatric salicylate exposures has dropped dramatically. A number of factors may account for this trend. Most important was the enactment of the 1970 Poison Prevention Packaging Act that mandated the use of child-resistant closures on aspirin-containing products. In addition, the enticingly flavored children's aspirin tablets were restricted to 81 mg per tablet and 36 tablets per bottle, thereby limiting the amount taken by children in accidental ingestions. The possible association between Reye's syndrome and the use of aspirin to treat viral diseases in children has led to a significant decline in the pediatric use of aspirin. As a result, the number of annual fatalities due to aspirin in children younger than 5 years dropped from 46 in 1972 to 0 in 1992 (Fig. 48-2). The introduction of alternatives to aspirin-containing products such as acetaminophen and ibuprofen, which have a considerably higher therapeutic index, have contributed to the decreased number of fatalities by decreasing the use of salicylates in this age group.

STRUCTURE/STRUCTURE-ACTIVITY RELATIONSHIPS

Salicylic acid (base salicylate) is also known as ortho-hydroxybenzoic acid (Fig. 48-3).¹ Aspirin is a salicylate ester of acetic acid. Substitutions on the carboxyl or hydroxyl groups alter the potency and toxicity of individual salicylates.¹ Although most salicylates have pharmacologic properties as a result of their salicylic acid component, some agents have additional pharmacologic

FIGURE 48-3 Chemical structures of salicylate.

activity from other substitutions. For instance, the acetyl group substitution of aspirin allows it to acetylate proteins, which is the basis for most of its antiplatelet effects.

PHARMACOKINETICS

A thorough understanding of salicylate pharmacokinetics and changes that occur with salicylate overdose (toxicokinetics) is essential to understanding the genesis of salicylism and its appropriate management.

Dosing

Salicylates are formulated in oral, rectal, and topical preparations. The therapeutic dose of salicylate depends on the condition being treated. In general, the recommended dose for antipyresis and analgesia is 10 to 20 mg/kg orally every 6 hours for children (up to 75 mg/kg or 3.6 g/day) and 325 to 650 mg every 4 hours for adults (following an initial dose of 1 g). Larger doses of salicylate (4 to 6 g/day) are sometimes recommended for its full anti-inflammatory effects in adults with chronic illnesses (e.g., rheumatoid arthritis).

Absorption

Most cases of salicylate poisoning involve the ingestion of a product that contains aspirin. As a weak acid (pKa 3.5), aspirin is largely nonionized in the stomach and absorbed passively as acetylsalicylic acid.² The majority of salicylate absorption, however, occurs as the ionized form in the jejunum due to its greater absorptive surface. In addition, the alkaline jejunum enhances salicylate solubility, and thus tablet dissolution.³ Absorption is rapid with therapeutic dosing; measurable levels are observed within 30 minutes, and peak serum concentrations of 10 to 20 mg/dL (0.7 to 1.4 mmol/L) usually occur within 1 to 2 hours of a single therapeutic dose. Chronic therapy with anti-inflammatory doses will produce peak serum salicylate concentrations of up to 30 mg/dL (2.2 mmol/L).

Absorption will be significantly influenced by the dose ingested, product formulation (different dissolution characteristics), mucosal pH, and gastric emptying time.^{1,2} The presence of food may delay absorption by retarding gastric emptying. Enteric-coated products are resistant to the acid environment of the stomach; tablet dissolution is delayed until the more alkaline medium of the distal intestines is reached. Buffered (alkaline) aspirin tablets have enhanced solubility and more rapid dissolution in the small intestine, which can result in greater bioavailability. Overdose of salicylates can produce pylorospasm, delaying gastric emptying and subsequent absorption. While not a common phenomenon, salicylates have the potential to form gastric concretions or bezoars, which retard the otherwise rapid absorption and result in slow, continuous absorption that simulates a sustained-release pharmaceutical. Salicylate absorption may be slowed when it is co-ingested with other agents that retard gastric emptying and intestinal motility (i.e., anticholinergic drugs, opioids). Peak blood concentrations are often not reached for 4 or more hours in overdose situations. In one reported overdose of enteric-coated aspirin, the peak serum salicylate concentration

did not occur until 24 hours after ingestion.⁴ Coexistent pathophysiology such as hypotension or decreased splanchnic circulation may also impede the absorption of salicylates. Liquid forms of salicylate, such as methyl salicylate, are more bioavailable and not subject to the rate-limiting process of dissolution; therefore, the absorption of liquid products may be more rapid and not retarded by physical or pathophysiologic factors. The route of administration will also affect absorption; rectal administration frequently results in delayed and erratic absorption.

Biliary secretion of salicylate is minimal.⁵ Therefore, reabsorption secondary to enterohepatic circulation does not occur.

Dermal absorption of salicylates is a reported but rarely encountered etiology of salicylism.^{6,7} Salicylate-containing liniments, keratolytics, and topical rubifacients are unlikely to represent a significant risk due to poor absorption through normal skin and use that is limited to the nonprescription treatment of minor musculoskeletal discomfort. The chronic use of highly concentrated products that are applied to large surface areas of compromised skin, however, may create a condition that allows sufficient salicylate absorption with resultant toxicity.

Chronic excessive use of salicylate suppositories has the potential to produce toxicity. However, it is rarely a cause of acute salicylism. The intentional use of a salicylate enema that contained 700 aspirin tablets produced profound salicylism.⁸

The natural source of salicylates (e.g., willow bark, herbals, etc.) or their pharmaceutical formulation, in conjunction with other variables, will affect salicylate absorption. Once absorption and metabolic conversion to salicylic acid occur, toxicokinetics are unaffected.

Distribution

Salicylates are distributed throughout body fluids and tissues. The low apparent volume of distribution ($V_d = 0.16$ to 0.35 L/kg) in salicylate overdose victims suggests that salicylate remains largely in the central compartment.⁹ The apparent V_d and, thus, tissue distribution increases with supratherapeutic salicylate concentrations (saturation of plasma protein binding sites), lower blood pH, and the presence of drugs that compete with serum protein binding.

Salicylates are amenable to enhanced extracorporeal clearance (e.g., hemodialysis) due to their low molecular weight, small V_d , high water solubility, and increased fraction of free salicylate at supratherapeutic concentrations.

At therapeutic concentrations, salicylates are largely protein bound (50% to 80%), predominantly to serum albumin.^{3,10} The degree of protein binding is a function of both the concentration of salicylic acid and the amount of albumin. As protein binding sites become saturated following salicylate overdose or with co-ingestion of other drugs that compete with albumin binding sites (e.g., phenytoin), the amount of free non-protein-bound salicylic acid increases and creates a climate for more significant toxicity. Any condition that

depletes albumin or competes with its available binding sites predisposes the patient to a disproportionate risk for severe salicylism at a given plasma concentration.

Under normal physiologic conditions (pH 7.4), salicylates are highly ionized (>99%), which significantly reduces their ability to diffuse across the blood-brain barrier and into the central nervous system (CNS). In advanced salicylate poisoning, the development of metabolic acidosis (acidemia) significantly increases the fraction of nonionized salicylate and results in greater CNS penetration and elevated cerebral spinal fluid (CSF) concentrations. High CSF concentrations are associated with CNS toxicity and greater morbidity.

Salicylates cross the placenta readily and pose a significant risk to the fetus after maternal overdose. Salicylates are also found in breast milk but present a threat to the breast-fed infant only when the mother is taking large daily doses. The infant is prone to toxicity due to immature metabolism and, thus, impaired ability to eliminate salicylates and their metabolites.

Metabolism and Excretion

After gastrointestinal absorption, aspirin is hydrolyzed rapidly by nonspecific plasma esterases to the pharmacologically and toxicologically active chemical salicylic acid. This is a first-order process with a half-life of 15 to 20 minutes.¹¹ At therapeutic doses, salicylic acid then undergoes hepatic biotransformation and renal elimination via first-order processes^{1,12,13}:

1. Glucuronidation → salicyl phenolic (10%) and salicyl acyl (5%) glucuronides
2. Oxidation → gentisic acid (<1%)
3. Microsomal oxidation or glycine conjugation → salicyluric acid (75%)
4. Salicylic acid → elimination via the urine (10%)

The major hepatic metabolic pathways (formation of salicyl phenolic glucuronide and salicyluric acid) become saturated when serum salicylate concentrations exceed 20 to 30 mg/dL.^{1,12,13} Biotransformation converts from a dose-dependent first-order process (rate proportional to the dose) to a zero-order process, which means that a fixed amount of salicylic acid is metabolized per unit of time, regardless of the dose. This is referred to as Michaelis-Menten kinetics (see Chapter 4).

Because salicyluric acid and salicyl phenolic glucuronide formation is a saturable process, the biotransformation of salicylic acid proceeds more slowly and creates more opportunity for toxicity to occur.^{12,13} The elimination half-life of salicylate is 2 to 3 hours after a single therapeutic dose, 6 to 12 hours with high therapeutic doses (20 to 30 mg/dL), and 20 to 40 hours after overdosage. Importantly, small increases in the dose can result in a significant increase in serum concentration.¹ Awareness of the accumulation kinetics of salicylic acid is essential to understanding the long half-life of salicylates in the overdose situation and the subsequent long duration of toxic manifestations. For the same reasons, the well-intentioned Done nomogram is not applicable in the determination of patient

prognosis and the management of either acute or chronic salicylism.¹⁴ Done considered that salicylates followed a first-order elimination process and developed the nomogram accordingly.¹⁵

SPECIAL POPULATIONS

Kinetics in Children

Neonates absorb salicylate as rapidly as any other age group but metabolize it more slowly than those with mature hepatic function. Renal elimination is slower in children, and they have reduced albumin concentrations that increase plasma salicylate concentrations. The Vd increases proportional to the dose, suggesting that children may have higher tissue concentrations than inferred by their plasma concentration.

Kinetics in the Elderly

Salicylate toxicokinetics in the elderly have not been well defined. However, the same accumulation kinetics apparent in younger adults apply to the elderly. It is likely that elderly patients are more predisposed to salicylate toxicity due to impaired hepatic and renal function that occurs with advanced age.

PHARMACOLOGIC AGENTS

Aspirin is the most common salicylate-containing preparation available. In addition, numerous over-the-counter and prescription products contain aspirin or salicylate analogs (e.g., bismuth subsalicylate, methyl salicylate) in combination with other pharmaceutical agents (Table 48-1). The salicylates are available in many different formulations (i.e., immediate-release, enteric-coated, and effervescent tablets; capsules; suppositories; powder papers; and liquids) for oral and rectal use. In addition, methyl salicylate is found commonly in liniments, lotions, creams, and ointments for the treatment of minor musculoskeletal complaints (concentration of methyl salicylate from 10% to 30%). Methyl salicylate is found in high concentration in oil of

wintergreen, a product that is used to flavor confections. One teaspoon of oil of wintergreen contains the equivalent of 5 g of salicylate. Bismuth subsalicylate is used in popular antidiarrheal agents (e.g., Kaopectate [Pfizer, Morris Plains, NJ] and Pepto-Bismol [Proctor & Gamble, Cincinnati, OH]) and often is not recognized as a possible cause of salicylate poisoning (especially when other salicylates are ingested concomitantly). Salicylic acid is present in corn and wart removers. The most common use of salicylates is as an oral analgesic, antipyretic, and anti-inflammatory. For this application, salicylates may be ingested as the sole pharmaceutical (e.g., salicylsalicylic acid in Disalcid [3M Pharmaceuticals, St. Paul, MN]) or in combination with synergistic pain relievers such as opioids (e.g., aspirin with oxycodone in Percodan [Endo Labs, Chadds Ford, PA]). Salicylates may also be found in certain herbal preparations that contain willow bark (*Salix* species) or wintergreen leaf (see Chapter 68).

TOXICOLOGY

Clinical Manifestations

Acute salicylate poisoning produces a diverse array of signs and symptoms. Common clinical findings include tachypnea and hyperpnea, nausea and vomiting, abdominal pain, dehydration, hyperpyrexia, diaphoresis, tachycardia, pallor, and a variety of CNS disturbances (Box 48-1). CNS effects include dizziness, ataxia, tinnitus, deafness, confusion, psychosis, agitation, delirium, stupor, coma, and seizures. More uncommon clinical features may include bleeding, pulmonary edema, acute renal failure, and anaphylaxis. Chronic salicylate poisoning is often misdiagnosed initially due to an insidious onset, lack of history of an overdose, and the presence of nonspecific clinical findings. This category of poisoned patients is discussed in more detail at the end of this chapter.

The mechanisms by which salicylates exert their toxic effects are complex and not completely understood (Table 48-2). However, the pathophysiology includes direct and indirect respiratory center stimulation, uncoupling of oxidative phosphorylation, inhibition of the tricarboxylic acid (TCA) cycle, inhibition of amino acid metabolism, and stimulation of glycolysis, gluconeogenesis, and catabolism of proteins and fats. In addition, there is an interference with hemostatic mechanisms.

TABLE 48-1 Common Salicylate Preparations

COMPOUND	TRADE/Common Name
Acetylsalicylic acid	Aspirin
Bismuth subsalicylate	Pepto-Bismol, Kaopectate
Choline magnesium trisalicylate	Trilisate
Choline salicylate	Arthropan
Magnesium salicylate	Doan's pills, Magan
Homomenthyl salicylate	Sunscreens
Methylsalicylate	Oil of wintergreen
Salicylic acid	Topical ketatolytics
Salicylsalicylic acid	Salsalate, Disalcid, Salsitab
Sodium salicylate	Analgesic
Trolamine salicylate	Aspercreme

BOX 48-1

COMMON CLINICAL FINDINGS IN SALICYLISM

Nausea and vomiting
Dehydration
Tachypnea and hyperpnea
Hyperpyrexia
Confusion
Coma
Tinnitus
Abdominal pain
Diaphoresis

**TABLE 48-2** Mechanisms and Manifestations in Salicylate Poisoning

MECHANISM	MANIFESTATION
Respiratory center stimulation	Respiratory alkalosis Renal HCO ₃ elimination increased osmotic diuresis Increased insensible fluid loss
Oxidative-phosphorylation uncoupling	Metabolic acidosis Increased heat production and fluid loss Hypoglycemia
Inhibition of tricarboxylic acid cycle Enhancement of protein metabolism and inhibition of amino acid metabolism Stimulation of gluconeogenesis	Metabolic acidosis Metabolic acidosis Aminoaciduria — osmotic diuresis Hyperglycemia
Stimulation of lipid metabolism	Glycosuria — osmotic diuresis Metabolic acidosis (ketoacidosis) Ketonuria — osmotic diuresis
Increased pulmonary capillary permeability	Pulmonary edema

Acid–Base Disturbances

Acid–base disturbances are one of the most common manifestations of salicylate toxicity. Respiratory alkalosis and a high anion gap metabolic acidosis may occur alone or together. Generally, one will observe an initial respiratory alkalosis. However, metabolic acidosis may supervene in sensitive or severely poisoned patients. The coingestion of other drugs may influence acid–base balance. For example, Gabow and colleagues found that 40% of the patients in their series who ingested other drugs had a normal anion gap metabolic acidosis.¹⁶ In children younger than 4 years, the metabolic component is usually more prominent, and these patients invariably demonstrate metabolic acidosis.¹⁷ In contrast, older children and adults tend to have a predominating respiratory component.¹⁸ In a review of 97 adults patients with high salicylate levels, Chapman and Proudfoot recorded patients in four categories of acid–base disturbance, with mixed respiratory alkalosis and metabolic acidosis or respiratory alkalosis alone predominating in 61% and 19% of patients, respectively. The arterial pH, rather than the type of acid–base disturbance, was of greater value in determining clinical severity and mortality.¹⁹ The concomitant ingestion of respiratory depressant drugs may manifest as a mixed or isolated respiratory acidosis.¹⁶

It is commonly held that in adult salicylate poisoning a dominant metabolic acidosis follows an initial respiratory alkalosis. This latter phase may be very brief.¹⁷ Adults may develop severe acidemia within as little as 3 to 4 hours of a massive aspirin overdose.

The underlying pathophysiology of the acid–base disturbances in salicylate intoxication is complex and not fully elucidated. Salicylates have been shown to stimulate the central respiratory center directly.^{20,21} Respiratory alkalosis occurs due to hyperventilation, with an increase in the depth and rate of respirations. As a result there is a low partial pressure of CO₂ in arterial blood (Paco₂), an increased plasma pH, and an elevated serum [HCO₃⁻]. As a compensatory measure, [HCO₃⁻] is then excreted vigorously in the urine. There are animal data that suggest a role for peripheral arterial chemoreceptors in the development of hyperventilation.²² The respiratory

stimulant effects of salicylates also occur indirectly from an increased production of tissue CO₂. Tissue CO₂ stimulates the respiratory center in the medulla oblongata.

Metabolic acidosis occurs after the inhibition of TCA cycle enzymes and of mitochondrial oxidative phosphorylation.^{23,24} The uncoupling of oxidative phosphorylation reduces the production of cellular adenosine triphosphate and hence increases the production of pyruvic and lactic acid. Bartels and Lund-Jacobsen cast doubt on the significance of excessive lactate production due to salicylate-induced uncoupling of oxidative phosphorylation.²⁵ They postulated that observed elevations in lactate may be due to decreased hepatic elimination of lactate. The inhibition of key TCA cycle enzymes (e.g., α -ketoglutaric dehydrogenase and succinic acid dehydrogenase) further increase pyruvic and lactic acid levels.

The inability to produce cellular energy from oxidative phosphorylation results in enhanced but inefficient cellular metabolism. Gluconeogenesis and glycolysis are stimulated, and protein and lipid catabolism occur. Increased lipid and protein metabolism lead to the production and accumulation of ketone bodies (e.g., β -hydroxybutyric acid, acetoacetic acid, and acetone) and amino acids. Concurrent aminotransferase inhibition by salicylate prevents amino acid (e.g., alanine) metabolism and further augments levels of circulating amino acids.²⁶ Accumulation of these organic acids leads to the increased anion gap metabolic acidosis associated with salicylate poisoning; only a small contribution occurs from salicylate itself.

Both salicylate in the CSF and acidemia are powerful stimuli to respiration, and the latter facilitates the former.²⁷ Together they might be expected to enhance hyperventilation in comparison to patients with normal or low arterial [H⁺]. Chapman and Proudfoot, however, found that the mean Paco₂ was higher in fatal cases (most of whom were acidemic) than in survivors (most of whom had normal or low arterial [H⁺]). This failure to hyperventilate appropriately in response to an acid stimulus may be a factor in the development of acidemia in these patients.¹⁹

A final contributing factor to the development of acidosis is the depletion of buffering capacity as a result of increased renal loss of $[\text{HCO}_3^-]$ through the compensatory mechanisms that are a consequence of the initial respiratory alkalosis.²⁸

Fluid and Electrolyte Abnormalities

Fluid and electrolyte aberrations are not uncommon in salicylate poisoning and are multifactorial. Fluid and electrolyte losses occur from vomiting, decreased oral intake, diaphoresis, hyperventilation, osmotic diuresis (from bicarbonate, glucose, organic acid loss in urine), and increased metabolism and heat production. Water losses may reach 4 to 6 L/m².²⁹ With increased bicarbonate excretion at the kidney in the early alkalotic stage, there is concomitant loss of sodium and potassium as the body attempts to conserve hydrogen ions. Robin and colleagues reported six severely poisoned patients who presented with hypokalemia manifesting as a low serum potassium concentration, electrocardiographic changes, and neuromuscular abnormalities.³⁰ All patients demonstrated respiratory alkalosis. It was postulated that the hypokalemia resulted from a subsequent shift of potassium into the cells and excessive renal loss. In a similar way, forced alkaline diuresis may also lead to significant hypokalemia.³¹ In both of the above situations, patients responded to potassium supplementation. Hypocalcemia may also complicate attempts to alkalinize the urine.³² Conversely, transient hypercalcemia has been reported after overdose with soluble aspirin, possibly due to the calcium content of the tablet.³³ Hyponatremia is common, presumably resulting from dehydration. Hyponatremia is less common but does occur, and may be associated with inappropriate fluid retention.³⁴

Pulmonary Edema

Pulmonary edema is an uncommon but well-recognized complication of acute salicylate intoxication, first being reported in 1950. More importantly, it is considered to be the most common cause of significant morbidity in chronic salicylate intoxication.³⁵ In the 1970s, the noncardiogenic origin of the edema was suspected by Zitnik and colleagues after pulmonary artery catheterization revealed a normal pulmonary artery wedge pressure, and by Bowers and colleagues in their studies on sheep.^{36,37} Since that time, a number of studies have suggested an increase in pulmonary capillary permeability as the underlying pathologic process. Three prominent theories attempt to explain this.³⁷ First, aspirin is known to inhibit prostacyclin, a chemical that acts to reduce capillary permeability. Second, mild cerebral edema may result in a catecholamine surge, leading to elevated pulmonary vascular pressures. And third, salicylates' effect on platelet-vessel interaction may result in increased capillary permeability.

Radiologic studies in salicylate intoxication indicate that pulmonary edema occurs in about 35% of patients over the age of 30 years.³⁷ Chronic ingestion of the drug, smoking, and the presence of metabolic acidosis and/or

neurologic features on admission were major risk factors for its development. In the same study, by Walters and colleagues, none of the patients younger than 16 years developed pulmonary edema, whereas Fisher and colleagues demonstrated that 2 out of 20 children developed the complication.³⁸

Central Nervous System Abnormalities

CNS toxicity is an important indicator of severe salicylate toxicity. Coma is rare, with patients more often agitated, confused, and restless before unconsciousness occurs. In children younger than 5 years, in whom acidemia is the usual acid-base disturbance, these neurologic features are more common.^{17,39}

Adults display CNS toxicity less often, but when they do, it is also associated with acidemia.^{16,19} The severity of CNS manifestations and salicylate mortality appears to have a direct relationship to brain salicylate concentrations.^{27,40} In a rat model, Hill demonstrated that the presence of acidemia facilitates the shift of salicylate from the extracellular fluid into the intracellular space, especially in the brain.^{27,40} With a pKa of 3.0 for salicylic acid, as the pH of the blood falls, a higher percentage of the compound will be found in the nonionized form. This results in enhanced lipid solubility and hence an increased ability to cross cell membranes and the blood-brain barrier. Some patients with significant CNS effects have been alkalemic, but in those cases the plasma salicylate concentrations were very high.

Cerebral edema has been reported, but is uncommon. Hyponatremia and fluid retention or overload may contribute to its development. Seizures may occur in patients with severe toxicity. Some animal studies indicate that they may result from hyperventilation or reduced brain glucose levels, which paradoxically can occur despite normoglycemia.

Concomitant ingestion of CNS depressants, such as alcohol and benzodiazepines, may enhance the toxicity from salicylate independent of the toxic effects that occur directly from these CNS depressants themselves. By reducing the central drive to hyperventilate in response to acidemia, these drugs will enhance the CNS distribution and morbidity from salicylate.¹⁶

Metabolic Derangement

The principal metabolic derangement in salicylate poisoning is a change in glucose metabolism, which may produce either hypoglycemia or hyperglycemia. In addition, hypoglycorrachia (low CSF glucose concentrations) may occur despite normal or even high serum glucose concentrations.⁴¹ Increased demand for glucose occurs simultaneously with a decreased ability of certain tissues to utilize the glucose substrate. Increased glucose demand results in glycogenolysis and gluconeogenesis. Initially, patients may present with a short-lived, or in some cases persistent, hyperglycemia, which may be of high enough magnitude to produce glycosuria.^{18,29} Sustained and persistent hyperglycemia reflects a failure of the tissues to utilize glucose adequately. Glucose stores

may also become exhausted and result in hypoglycemia. Contributing to the development of hypoglycemia is enhanced insulin secretion, which may result from the inhibition of prostaglandin synthesis.⁴²

Hyperpyrexia

Hyperpyrexia is more common in children than adults.¹⁹ It may result from the increased heat production that occurs following the uncoupling of oxidative phosphorylation. Additionally, toxic levels of salicylate impair the efficiency of the body's cooling mechanisms. This is compounded by the presence of dehydration.²⁹ Hyperpyrexia is uncommon in acute adult salicylate poisoning, and its presence is associated with a poor prognosis.¹⁹ Other causes of an elevated temperature should also be considered, for example, infection or concomitant drug ingestion.

Hematologic Abnormalities

Decreased production of prothrombin and factors V, VII and X, increased capillary fragility, decreased platelet adhesiveness, and thrombocytopenia have all been observed in salicylate intoxication.⁴³ Rarely do any of these changes become clinically significant. On occasion, transient petechial rashes may be observed over the face and neck. Significant hemorrhagic complications, however, are very uncommon in salicylate poisoning.

Gastrointestinal and Hepatic Abnormalities

As discussed above, gastrointestinal bleeding is rare in salicylate poisoned patients. Gastric perforation has been reported after an acute overdose with enteric-coated aspirin.⁴¹ Nausea, vomiting, and epigastric abdominal pain are the most common and consistent gastrointestinal tract findings in acute salicylate poisoning. Hemorrhagic gastritis, pylorospasm, and decreased gastric motility may also occur.

Direct hepatotoxicity, histologically similar to Reye's syndrome on biopsy, may occur with chronic salicylate use. Differentiating salicylate poisoning from Reye's syndrome is the presence of larger fatty droplets and a lack of mitochondrial changes.^{44,45} Salicylate-associated hepatotoxicity is usually mild and resolves with discontinuation of salicylates.

Renal Abnormalities

Kimberly and Plotz have reported a reduced creatinine clearance, an elevated urea, and an increase in celluria as adverse effects of aspirin.⁴⁶ This acute renal impairment may possibly be explained by either a reduction in renal blood flow or as a result of direct nephrotoxicity. The renal abnormalities may result from the anti-prostaglandin effects of salicylates. It is thought that salicylates acutely inhibit prostaglandin synthesis, which results in vasoconstriction, reduced renal blood flow, and reduced glomerular filtration.⁴⁷ The resultant oliguria is

exacerbated by the presence of dehydration. Preexisting renal disease may predispose patients to the development of renal impairment.

Other

Tinnitus is well-described with salicylate intoxication, and frequently precedes the onset of deafness. Both effects are reversible. Mongan and colleagues reported tinnitus beginning at levels from 20 to 45 mg/dL.⁴⁸ It has been postulated that salicylates increase intralabyrinthine pressure, but Ramsden and colleagues suggested that salicylates cause their effect by acting at the hair cell–neural interface, causing a transient metabolic blockade.⁴⁹ Alternatively, tinnitus and deafness may result from vasoconstriction of the auditory microvasculature (serving cochlea and hair cells).¹

Ralston and colleagues reported on a 13-month-old boy with mild to moderate salicylate intoxication who experienced bradyarrhythmias and global myocardial dysfunction that they could not attribute to acidosis, hypoxia, ischemia, or metabolic or electrolyte abnormalities.⁵⁰ Therapeutic doses of salicylates have no significant cardiovascular effects.

Fatal in utero salicylism has been reported following an aspirin overdose in an 8-month pregnant primigravida.⁵¹ Palatnick and Tenenbein described a 37-week pregnant 17-year-old girl who presented with fetal demise after ingesting 50 aspirin tablets a day for 1 month.⁵² A number of factors may explain the apparent increased fetal susceptibility to salicylate poisoning. First, the fetus has immature pathways to metabolize and excrete the drug; second, the fetal concentration of salicylate is higher; and third, the more acidotic fetal blood facilitates the movement of salicylate across the blood-brain barrier.^{53,54}

A number of investigators have reported on multiple-system organ failure following salicylate overdose, sometimes associated with rhabdomyolysis.^{55,56} Vadas and colleagues demonstrated increased phospholipase A₂ concentrations and postulated that this may result from an aspirin-induced intestinal permeability to endotoxin and that these elevated phospholipase A₂ levels may play a role in the development of multiple-system organ failure.⁵⁶

Hypersensitivity reactions to aspirin and salicylate-containing products have been well documented. Most patients develop a mild urticarial rash, but life-threatening anaphylaxis can occur. Botma and colleagues reported a case of an 18-month-old girl who ingested oil of wintergreen.⁵⁷ In addition to the typical features of salicylate poisoning, she also developed local laryngeal edema and stridor that necessitated endotracheal intubation.

DIAGNOSIS

Following an acute overdose of salicylate, the diagnosis is often straightforward. In the pediatric age group, a history of recent ingestion is usually present. The history in the adult population is more circumspect, but these

patients are seldom comatose and commonly admit to their actions. Where CNS depressant drugs have also been ingested, the history is more difficult, and a greater reliance should be placed on physical findings. If possible, the history should include the time and intent of ingestion, specific product and amount ingested, and the presence of co-ingestants and pertinent comorbid illnesses.

The severity of an acute salicylate overdose can be determined by history, physical findings, and laboratory data. Although potentially unreliable, the history may be used to predict the clinical severity of illness.¹⁸ Generally, acute ingestions of less than 150 mg/kg follow a benign course, with symptomatic salicylate toxicity unlikely to occur.⁵⁸ With ingestions above 150 mg/kg, toxicity is dose dependent and have been traditionally divided into mild (150 to 300 mg/kg), moderate (300 to 500 mg/kg), and severe (>500 mg/kg) poisoning.¹⁸ These categories are not absolute and should be utilized in conjunction with the patient's clinical condition.

Physical findings can also be used to grade the severity of salicylate poisoning.¹⁸ The physical examination should focus on the vital signs, neurologic and cardiovascular examinations, and state of hydration. Early in the course of an acute salicylate overdose, symptoms and signs may be mild and subtle. Hence, it is important to evaluate patients serially, rather than relying on a single initial assessment as an indicator of clinical severity. Traditionally, cases of mild poisoning are said to demonstrate hyperpnea and/or tachypnea, mild lethargy or ataxia, tinnitus, and mild nausea and/or vomiting. Moderate toxicity is characterized by more prominent tachypnea, tachycardia, orthostatic hypotension, and neurologic disturbances (e.g., slurred speech, disorientation, confusion). Severe poisoning is represented by stupor or coma, seizures, respiratory depression, and hyperpyrexia. It is vital to remember, however, that salicylate poisoning is a dynamic process, and regular assessments and management appraisals are required. It is unwise to rigidly categorize such patients.

Finally, the severity of salicylate poisoning can be assessed with various laboratory parameters. Historically, the use of serum salicylate concentrations alone was used by some to assess severity of salicylate poisoning. In 1960, Done studied 38 patients (29 of whom were children), who presented after an acute aspirin overdose.¹⁵ Based on their clinical symptoms and signs and their plasma levels, he created a nomogram that plots salicylate concentrations at differing times in an attempt to estimate the degree of intoxication— asymptomatic, mild, moderate, or severe—and hence predict expected symptoms. Measurements made before 6 hours were considered misleading since the drug may still be in the absorptive phase. In practice, plasma salicylate concentrations do not correlate well with features of acute toxicity, especially in those patients who are assessed as moderately or severely intoxicated.¹⁴ The nomogram has been demonstrated to be unrepresentative of toxicity.^{58,59} More specifically, the nomogram is not useful in the following circumstances: salicylate ingestion over a prolonged time (chronic ingestion), a sustained-release preparation or oil

of wintergreen ingestion, the presence of renal insufficiency, an unknown time of ingestion, and an academic patient.⁶⁰ Furthermore, the nomogram is based on the misconception that salicylates are eliminated via first-order kinetics.⁶⁰ Due to these limitations, most toxicologists do not utilize the nomogram to determine severity of salicylate poisoning.

For those with chronic salicylate poisoning, more severe toxicity is typically manifested at lower plasma salicylate concentrations as compared with acute intoxication. For these patients as well, clinical features correlate poorly with concentrations and the Done nomogram is of no use.

Use of laboratory data other than salicylate concentrations will allow a better assessment of the severity of salicylate poisoning. In particular, concurrent measurements of plasma (arterial or venous) and urine pH identify the presence of a systemic acid-base disturbance and allow for estimation of the phase and severity of salicylism.⁶¹ Early or mild poisoning is represented by alkalemia (plasma pH >7.4) and alkaluria (urine pH >6); intermediate or moderate poisoning by alkalemia and paradoxical aciduria (urine pH <6); and late or severe poisoning by acidemia (plasma pH <7.4) and aciduria. Simultaneous measurement of each of these two parameters helps to determine the severity and stage of poisoning and will facilitate treatment. Ultimately, assessment of salicylate severity, whether acute or chronic, is best determined by combining data obtained from history, clinical signs and symptoms, plasma salicylate concentration, and urine and plasma pH together.

Laboratory Testing

When a patient's clinical signs and symptoms suggest salicylism, a plasma salicylate concentration is essential to confirm diagnosis and guide management decisions. A concentration greater than 30 mg/dL is usually associated with toxicity. Chronic therapeutic plasma concentrations in rheumatoid arthritis sufferers range from 10 to 30 mg/dL. A single level drawn too early may not be representative. Therefore, repeated levels at 2- to 3-hourly intervals should be obtained until a downward trend is established. It is important not to rely on a single concentration because of the possibility of prolonged or delayed absorption following the ingestion of sustained-release products, enteric-coated tablets, or the formation of a pharmacologic bezoar. Concentrations should be interpreted in conjunction with the patient's overall clinical and acid-base status. The presence of significant acidemia may imply a more serious intoxication, since higher concentrations of nonionized salicylate can penetrate into the CNS.

Several methods are available through which to determine plasma salicylate concentrations,⁵⁹ the most common one being the colorimetric technique, which utilizes the reaction between salicylate and ferric ion, and gives an estimate of the total plasma salicylate concentration. High-performance liquid chromatography and gas chromatography can distinguish acetylsalicylic acid (aspirin) from salicylic acid, something the color-

metric test cannot differentiate. Colorimetric testing is, however, easy and fast. So-called “routine” toxicologic screening for salicylate poisoning has a low positive yield.⁶² Spot tests performed in the emergency department have little prognostic value and are fraught with problems due to misinterpretation by inexperienced individuals.

In all symptomatic patients and those with intentional salicylate overdose, measurements of serum electrolytes, glucose, BUN, creatinine, and calcium should be obtained and an anion gap calculated. Other tests should include a venous or arterial blood gas, urinalysis (including urine pH), and toxic screening for co-ingestants and qualitative pregnancy testing, as indicated. A complete blood count, coagulation profile, and liver function tests are appropriate in moderate to severe poisonings. A chest x-ray should be performed if pulmonary edema is suggested on examination or if arterial blood gases demonstrate a widened arterial-alveolar gradient.³⁸

The concentration of salicylate in the CSF reflects the concentration of unbound drug in the plasma, and studies in children and animals have shown that the severity of intoxication is closely related to the CSF salicylate concentrations. These in turn are related to the total plasma concentration and the $[H^+]$. High $[H^+]$ reduces ionization and thereby facilitates the shift of salicylate into the cells. However, CSF levels are not used routinely to assess the magnitude of salicylism.

Differential Diagnosis

Salicylate toxicity should be considered in patients with unexplained acid–base disturbances, hyperventilation, tinnitus, or CNS disturbances. In severe cases, the presence of an altered mental status may prevent the disclosure of salicylate ingestion and erroneously lead to an involved neuropsychiatric evaluation, delaying the diagnosis and potentially increasing morbidity. Chronic salicylism is insidious and often mistaken for other illnesses, such as diabetic ketoacidosis, alcoholic ketoacidosis, metabolic encephalopathy, systemic infection or sepsis, dementia, organic psychosis, alcohol withdrawal, viral meningitis, Reye’s syndrome (in children), delirium, pancreatitis, and other causes of high anion gap acidemia.

MANAGEMENT

Supportive Measures

As with all poisoned patients, initial management should be directed toward establishing and maintaining an adequate airway, and then optimizing respiratory and cardiovascular function. Intravenous access should be established and supplemental oxygen applied when appropriate. Although endotracheal intubation can be life-saving when an airway is compromised, Greenberg and Hendrickson described a 58-year-old man who presented with a mixed metabolic acidosis/respiratory

alkalosis and marked tachypnea following an overdose of aspirin. After intubation, the pH fell and the patient deteriorated and subsequently died. They postulated that mechanical ventilation was an inadequate substitute for manual ventilation and could not provide the rates needed to prevent acid accumulation.⁶³ If endotracheal intubation becomes clinically necessary, it is critical to maintain or establish patient alkalemia (plasma pH 7.50 to 7.55) to minimize salicylate distribution into the CNS. Patient hyperventilation (to produce hypocarbia) before and after intubation, along with the adjunctive administration of sodium bicarbonate (see Urinary Manipulation) can minimize the entry of salicylates into the CNS.

It is absolutely essential that careful attention be directed to the fluid balance status of the patient. Patients with moderate to severe poisoning should have an indwelling bladder catheter placed to closely monitor urine output. Central venous or pulmonary artery catheter monitoring is recommended for severely poisoned patients. Most patients are dehydrated on presentation. Thus, Temple suggests that the initial amount of fluid given should be in the range of 10 to 15 mL/kg/hr, administered over the first 1 to 2 hours.¹⁸ This may be an important consideration in patients with chronic poisoning or in those who present several hours after the ingestion. Subsequent fluid therapy should be based on the clinical need for rehydration, the renal function, and the risks of inducing or complicating pulmonary edema. Ultimately the aim of fluid replacement is to replace fluid deficits and maintain a urine output of between 100 and 200 mL/hr.

Because hypoglycemia has been implicated in the pathophysiology of CNS injury in salicylate-poisoned patients, glucose should be added (50 to 100 g/L), despite the presence of normoglycemia or even mild hyperglycemia. The potential benefit of giving glucose supplementation is empiric, and there are no clinical data concerning the real glucose requirements.⁶²

Patients poisoned seriously by salicylates are at risk for developing pulmonary edema and/or fluid retention through an inappropriate antidiuretic hormone secretion. In these patients, particularly if at the extremes of age, aggressive fluid replacement may be counterproductive. Urine output, renal function, and central venous pressure readings will be helpful in assessing these persons.

Hyponatremia is common; hence, some clinicians recommend hypotonic solutions in the initial management phase. Hypokalemia should also be monitored for and treated. The presence of a significant acidemia may result in a normal serum K^+ level, but mask a true total body potassium deficiency.

As outlined previously, a low serum pH increases the tissue penetration of salicylate, and hence increases CNS concentrations. For this reason, acidemia should be corrected using sodium bicarbonate (see Urinary Manipulation). Hypokalemia should be corrected simultaneously. It should be understood that sodium bicarbonate therapy is often indicated in mild/early and intermediate/moderate poisoning despite the

presence of alkalemia. Alkalemia rarely requires specific treatment.

Pulmonary edema in salicylate-poisoned patients is noncardiogenic. Therefore, therapy should begin with oxygen and progress to continuous positive airway pressure ventilation (CPAP), and finally may require intubation with positive end-expiratory pressure ventilation (PEEP). Pulmonary edema will improve as salicylate concentrations fall.^{35,62}

All patients with an altered mental status should receive intravenous dextrose (or have a fingerstick blood glucose analysis), naloxone (as indicated), and thiamine. As described above, normoglycemia, or even a slightly elevated blood glucose concentration, may be present in the face of depressed CNS glucose concentrations. The presence of CNS symptoms or signs or hypoglycemia should be treated with an intravenous bolus of 50% glucose, approximately 1 mL/kg.

Seizures are not common in salicylate intoxication. Those that occur should be treated in standard fashion (e.g., dextrose, lorazepam or diazepam, and phenobarbital). Other causes for seizures should also be considered, including electrolyte abnormalities (e.g., hypocalcemia) and hypoglycemia. For those patients with suspected cerebral edema, the head of the bed should be elevated, hyperventilation should be performed, and mannitol administration should be considered.

Hyperpyrexia is more common in children than adults. The possibilities of other causes should be considered, including infection or other drug ingestions. If severe, evaporative cooling (tepid water spray and fans), cooling blankets, and neuromuscular paralysis should be considered (for those with associated neuromuscular agitation).

Decontamination

In recent years the role of syrup of ipecac has been significantly curtailed and most toxicologists do not recommend it in the setting of salicylate poisoning.⁶⁴ Gastric lavage has also been the focus of considerable attention. The joint position statement from the American Academy of Clinical Toxicology and the European Association of Poisons Centers and Clinical Toxicologists recommends gastric lavage only for those patients presenting within 1 hour of ingesting a potentially life-threatening amount of poison.⁶⁵ Gut decontamination following aspirin ingestion is controversial and can raise considerable debate.⁶⁶ Contemporary practices dictate the sole and expeditious use of oral activated charcoal in most acute salicylate overdoses, especially if it can be administered within 1 hour of the ingestion.^{67,68} Although uncommon, pharmacologic bezoars may form after very large overdoses. Their presence, as indicated by sustained or rising salicylate concentrations, may necessitate gastric lavage and/or multiple-dose activated charcoal administration or even endoscopic procedures to break up the concretions if there is evidence of continued gut absorption. Comatose patients who undergo gastric lavage should be intubated endotracheally.

Activated charcoal is effective in reducing the gut absorption of salicylates.^{12,69} An initial oral bolus of 50 g

(adults) or 1 g/kg (children) should be administered as soon as possible, but preferably within 1 hour of ingestion.⁷⁰ Charcoal should not be withheld for patients who present late after oral salicylate overdose; pylorospasm and decreased gut motility associated with overdose may provide continued efficacy with late charcoal administration. Subsequent doses should be considered at 2- to 6-hour intervals if there is evidence that continued absorption is occurring. Given that absorption has already occurred in most patients, the use of activated charcoal in those with chronic poisoning is probably of no benefit. Conceptually, as enteric-coated salicylates dissolve in the distal gastrointestinal tract, activated charcoal should be effective. However, whole bowel irrigation (WBI) may be a more effective means of eliminating enteric-coated products. Kirshenbaum and colleagues studied the effectiveness of WBI, compared with single-dose activated charcoal with sorbitol, in preventing salicylate absorption following the ingestion of enteric-coated aspirin in volunteers.⁷¹ They concluded that WBI was more effective in reducing absorption. Generally, the use of WBI in the prevention of salicylate absorption has not been validated, and it cannot be recommended routinely in the management of salicylate overdoses.⁷²

Antidotes

There are no specific antidotes for salicylate poisoning.

Elimination

MULTIDOSE ACTIVATED CHARCOAL

The use of multidose activated charcoal (MDAC) to enhance the elimination of salicylates is controversial.⁷³⁻⁷⁵ Hillman and Prescott demonstrated that MDAC was effective for enhancing elimination in patients with mild to moderate toxicity. Most subsequent studies, however, have failed to demonstrate efficacy of MDAC for elimination enhancement. MDAC should not be used as a means of enhancing elimination, but rather as an intervention to prevent the ongoing absorption of salicylates.⁷⁶

URINARY MANIPULATION

Normally, salicylate undergoes both glomerular filtration and tubular secretion. At high therapeutic doses, the hepatic metabolic pathways for salicylates become saturated. Renal excretion, therefore, becomes very important for the total body elimination of salicylate at high therapeutic and toxic levels. Although only the unbound fraction of salicylate is available for glomerular filtration, this fraction increases with supratherapeutic salicylate concentrations. Salicylate is also reabsorbed at the proximal convoluted tubules (PCTs). This latter process depends on both urine flow rate and urine pH. As explained previously, in an acid environment, salicylate is maximally nonionized, facilitating transfer across cell membranes, and hence PCT reabsorption. During periods of high urine output, the urinary concentration of salicylate falls, which reduces the urine:tubular cell concentration gradient and, thus, PCT

reabsorption. Overall, urinary salicylate clearance is directly proportional to urinary flow rate but logarithmically proportional to urine pH.⁷⁷ Forced diuresis, forced alkaline diuresis, and urinary alkalization are methods that apply these principles to enhance the urinary elimination of salicylates.

Traditionally, to achieve a forced alkaline diuresis, crystalloid fluid with sodium bicarbonate was administered intravenously at a rate of approximately 2 L/hr for 3 hours.³¹ Forced diuresis requires the same volume of fluid at the same rate, without the concomitant use of sodium bicarbonate.⁷⁸ Urinary alkalization calls for the administration of sodium bicarbonate alone in an attempt to increase the urine pH above 7.5, while maintaining a normal urine output and avoiding the risks of fluid overload.⁷⁹

In 1982, Prescott and colleagues compared these three methods by studying 44 salicylate-poisoned adults.⁷⁸ They concluded that the administration of sodium bicarbonate alone was at least as effective as and, possibly, more effective than either forced diuresis or forced alkaline diuresis. Furthermore, unlike the other two regimens, fluid retention was not a problem with urinary alkalization alone. The large fluid load produced by regimens designed to force a diuresis are usually well tolerated by young adults with normal renal function; however, even in this age group pulmonary edema and cerebral edema have occurred. The addition of furosemide does reduce the risk of fluid retention, but it may decrease rather than increase renal salicylate elimination.⁷⁹ Utilizing urinary alkalization, the apparent elimination half-life of salicylate poisoning decreased to 6 to 12 hours. In the Prescott and colleagues study, the significant decreases in plasma salicylate seen with forced diuresis and forced alkaline diuresis were greater than expected based on the urinary salicylate excretion. It was felt that this was due in part to hemodilution, and that this phenomenon may give a false impression of efficacy. Patients treated with alkalization alone in this study, however, received 375 to 500 mL/hr of intravenous fluid during the treatment period, suggesting that fluid resuscitation and the initiation of a diuresis is also important to enhance the renal clearance of salicylate.

The effectiveness of urinary alkalization to enhance the clearance of salicylate was demonstrated in another human volunteer study. Vree and colleagues conducted a randomized study in six volunteers who received 1.5 g sodium salicylate orally before initiation of urine alkalization or urine acidification. The mean peak salicylate concentrations were 93.3 mg/L and 109.8 mg/L, respectively. As compared with urinary acidification, the mean elimination half-life was significantly less and the mean total clearance was significantly increased during urine alkalization.⁸⁰

In the care of poisoned salicylate patients, most patients are dehydrated on presentation, thus necessitating fluid resuscitation simultaneous with urinary alkalization. While urinary alkalization is more important to augment renal salicylate clearance than forced diuresis alone, aggressive fluid resuscitation until an adequate flow of urine (>2 mL/kg/hr) is achieved is also

important to competent patient care. The indications for urinary alkalization include the presence of signs or symptoms of salicylism (symptomatic poisoning), acid-base disturbances, or elevated salicylate levels (>30 mg/dL). The latest recommendations from the American Academy of Clinical Toxicology and the European Association of Poison Control Centres and Clinical Toxicologists Position Statement is that “Based on volunteer and clinical studies, urine alkalization should be considered as first line treatment for patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis.”⁷⁹

The procedure for performing urine alkalization in salicylate poisoning is described in Box 48-2.

Effective alkalization of the urine may be very difficult to achieve. More recently, the effectiveness of urinary alkalization has been confirmed by Higgins and colleagues.⁸¹ They reported two separate episodes of salicylate poisoning in the same patient. In the first poisoning episode, hemodialysis was used without alkalization; in the second, alkalization was performed without hemodialysis. When urinary alkalization was performed, the salicylate level fell by 45% 5 hours after admission as compared with a fall of only 4% in the 4 hours prior to hemodialysis where alkalization had not been attempted.

The use of sodium bicarbonate in salicylate-poisoned patients is associated with certain side effects and has some contraindications. Adverse effects of alkalization include the creation of severe alkalemia (arterial pH > 7.55) and electrolyte disturbances (e.g., hypocalcemia, hypokalemia, hypernatremia) that may lead to arrhythmia or seizure, and to a lesser extent, fluid overload and congestive heart failure. Theoretical contraindications to the use of sodium bicarbonate include the presence of cerebral or pulmonary edema, oliguric renal failure, and an arterial pH of more than 7.55.

The use of acetazolamide to alkalize the urine is contraindicated, since it produces metabolic acidosis through renal elimination of bicarbonate, which may worsen salicylism and result in increased tissue penetration of salicylate. Tromethamine is not preferable to the use of bicarbonate when alkalization is required.

Extracorporeal Techniques

Salicylates are readily removed by extracorporeal means due to a small Vd (approximately 0.2 L/kg) and low molecular weight. At supratherapeutic levels, extracorporeal removal of salicylate is further facilitated by increased concentrations of free drug in the plasma. A number of extracorporeal removal techniques (e.g., exchange transfusion, peritoneal dialysis, hemoperfusion, hemodiafiltration, and hemodialysis) have been utilized in severe poisoning to decrease morbidity and mortality. As compared with hemodialysis, hemoperfusion provides a greater clearance of salicylate from plasma. Hemodialysis, however, is the preferred technique due to its superior safety, familiarity, and ability to correct fluid, electrolyte, and acid-base disturbances (see Chapter 2C).⁸² Hemodialysis can reduce the salicylate elimination half-life to 2 to 3 hours.⁸² Continuous veno-

BOX 48-2 PROCEDURE FOR PERFORMING URINE ALKALINIZATION IN SALICYLATE POISONING⁷⁹**Baseline Biochemical Assessment**

Measure plasma creatinine and electrolytes.
 Measure plasma glucose.
 Measure arterial acid-base status.

Clinical Preliminaries

Establish an intravenous line.
 Insert a central venous line, if appropriate.
 Insert a bladder catheter.
 Correct any fluid deficit.
 Correct hypokalemia, if indicated.
 Measure urine pH using narrow-range indicator paper (use fresh urine because pH will change as carbon dioxide blows off on standing) or pH meter.

Achieving Alkalinization

In an adult, give sodium bicarbonate 225 mmol or mEq (225 mL of an 8.4% [1mEq/mL] solution) intravenously over 1 hour.
 In a child, give sodium bicarbonate 25–50 mmol (25 mL of an 8.4% solution) intravenously over 1 hour.
 The period of administration of the loading dose of sodium bicarbonate may be shortened and/or the dose increased if there is preexisting acidemia.
 The goals of alkalinization are to achieve a blood pH of 7.50 and urine pH of 8.0.

Maintaining Urine Alkalinization

Give additional boluses of intravenous sodium bicarbonate to maintain urine pH in the range 7.5–8.5. This can be achieved by administering a continuous infusion of 100–150 mmol or mEq NaHCO₃ mixed in 1 L D5W at 150–200 mL/hr or two times maintenance IV requirements.

Monitor

Urine pH every 15–30 minutes.
 Plasma potassium hourly.
 Central venous pressure hourly.
 Acid-base status hourly (note: arterial pH should not exceed 7.55).
 Plasma salicylate concentrations hourly.
 Urine output—should not exceed 200 mL/hr.

Discontinue Urine Alkalinization

When plasma salicylate concentrations fall below 30 mg/dL in an adult or 25 mg/dL in a child.

venous hemodiafiltration (CVVHDF) is an alternative extracorporeal technique to hemodialysis. CVVHDF may be a more tangible option for patients who are too unstable to undergo hemodialysis or for whom hemodialysis is not available. Although its efficacy is not as well established as for hemodialysis, CVVHDF has provided significant reductions in salicylate levels for poisoned patients.⁸³ Exchange transfusion has been used successfully for salicylate-poisoned infants, where hemodialysis is not technically feasible in this patient population.⁸⁴ Manikian and colleagues described the successful double-volume exchange transfusion in a 4-month-old (5-kg) male infant with severe salicylate poisoning.⁸⁵

The decision to perform hemodialysis is usually made on clinical parameters rather than plasma salicylate concentrations. Clinical indications for hemodialysis include the presence of coma, seizures, cerebral or pulmonary edema, renal failure, refractory acid-base disturbances, or clinical worsening despite treatment. Little information exists on which to base this decision, and in each case an individual assessment is best. The

sole reliance on the plasma salicylate concentration is not advised. Serious consideration for hemodialysis, however, should be given to acutely poisoned patients with salicylate concentrations of at least 100 mg/dL or chronic patients with salicylate concentrations of at least 60 mg/dL. Early consultation with a renal medicine specialist is prudent to avoid any possible bureaucratic delays in establishing dialysis. Once initiated, hemodialysis should be continued until clinical improvement, correction of major acid-base disturbances, or a return to nontoxic salicylate levels occurs. Since greater morbidity and mortality are associated with chronic salicylism, hemodialysis is recommended at lower salicylate levels as compared with acutely poisoned patients.

DISPOSITION

Disposition decisions for salicylate-poisoned patients necessitate an assessment of the actual and predicted severity of illness, the initial salicylate concentration, the trend of that concentration, and the patient's clinical

state. Symptomatic patients should be admitted to the hospital, regardless of the amount ingested or of the plasma concentration. Mildly poisoned patients may be managed safely on a regular medical floor or short-stay observation unit, if available. Moderately or severely poisoned patients should be admitted to an intensive care unit. Patients with normal and falling concentrations, who are asymptomatic, and have normal acid-base status, electrolytes, and renal function may be medically discharged, provided there are no psychiatric issues that need to be addressed.

The Triptans

ANTHONY J. TOMASSONI, MD, MS ■ CARL A. GERMANN, MD

At a Glance...

- Triptans have improved safety and side effect profiles in the treatment of migraine relative to older ergot derivatives.
- Triptans activate the 5-HT_{1B} and 5-HT_{1D} receptors within the trigeminovascular system, including serotonin receptors on cerebral vessels and, to a lesser extent, on coronary arteries.
- Triptans are contraindicated in patients with ischemic heart disease because of concerns about vasospasm of coronary vessels that could lead to myocardial ischemia.
- If a patient taking triptans experiences chest pain that may be ischemic in origin, further triptan use should be avoided and appropriate evaluation initiated.
- Second-generation triptans have improved pharmacokinetics and may reduce the likelihood of chest pain in migraineurs; however, differences between these medications and first-generation triptans are subtle.
- Risk for precipitating serotonin syndrome may be increased by combining triptan therapy with other serotonergic medications.

The development of the triptans nicely illustrates the process of stepwise drug design. The medicinal properties of serotonin agonists have been recognized for hundreds of years.¹ Long ago, midwives used the vasoconstrictive effects of ergot to accelerate labor or reduce postpartum bleeding. Liquid extracts of ergot have also been used to treat “vascular headaches” in Europe and the United States for more than 100 years. However, the use of early ergot-derived medications frequently resulted in undesirable effects, including severe peripheral vasoconstriction, emesis, paresthesias, and psychosis.

Human experience with related compounds has been well documented since the outbreaks of ergotism in the Middle Ages, then known as St. Anthony’s fire. When contaminated rye enters the food supply, generally in the form of bread, epidemic ergotism may result. Vivid descriptions of individuals afflicted with gangrene of the extremities, burning neuropathic pain, and autoamputation survive to document this form of ergotism. An even more dramatic form of ergotism may result in psychosis, seizures, and death. It has been hypothesized that those accused of witchcraft in Salem, Massachusetts, in the late 1600s were stricken with this second form of ergotism. Ironically, it was in that same century that the cause of St. Anthony’s fire was traced to ergot (*Claviceps purpurea*), a fungus that grows on the kernels of rye during damp, cold weather.²

Before the availability of the triptans, ergotamines were used extensively for relieving migraine pain. Ergotamine was first isolated by Arthur Stoll of Sandoz (Novartis) in 1918. The drug was then found effective in the treatment of migraine headache in the 1930s. Further research at Sandoz resulted in the synthesis

of ergonovine, lysergic acid diethylamide, and other serotonin agonist and antagonist drugs.^{2,3} Armed with improved understanding of the potential role of serotonin in migraine headache developed during the 1970s, efforts to synthesize a safer, more selective, serotonin agonist were undertaken. This resulted in the introduction of sumatriptan in the early 1990s. Subsequent second-generation triptans seek to improve on the properties of sumatriptan by offering more rapid relief, longer duration of action, improved bioavailability and availability to the central nervous system (CNS), and reduced side effects. Since sumatriptan became available in 1992, six additional triptans have been introduced in the United States (Table 49-1).

Several theories and models have been advanced to explain the pathophysiology of migraine headache, but no unified model explains all the symptoms of a migraine headache. It seems possible that more than one mechanism may be responsible, and this may explain interindividual variations in response to migraine medications. Reductions in serotonin levels have been noted during migraine headaches. Of note, the triptans are structurally similar to serotonin (5-hydroxytryptamine [5-HT]) (Fig. 49-1)

The number of migraineurs in the United States has been estimated as approximately 23 million.⁴ GlaxoSmithKline reports that their sumatriptan products have been used to treat more than 646 million migraines over the past decade, approximately equal to treating one migraine headache every second.⁵ Of note, there are many similarities, but also significant differences between these selective serotonin agonists. Therefore, patients may be advised that if one of these drugs does not offer sufficient relief from their migraine pain, it is often worthwhile to try another drug from this class with different pharmacologic or pharmacokinetic characteristics. However, the overall efficacy rate for all orally administered triptans is approximately 65%.⁶ Little has been reported regarding substantial overdose of these medications; however, adverse effects associated with therapeutic use of the triptans are well described.

STRUCTURE

Sumatriptan is 3-[2-(dimethylamino) ethyl]-*N*-methyl-1H-indole-5-methanesulfonamide. Structures of serotonin and the triptans available in the United States may be compared in Figure 49-1. When compared with sumatriptan, the second-generation agents are characterized by enhanced lipophilicity and greater 5-HT₁ receptor selectivity. These chemical properties are associated with pharmacokinetic and pharmacodynamic improvements such as improved oral bioavailability,

TABLE 49-1 Some Available Triptans and Dates of Approval by the U.S. Food and Drug Administration (FDA)

GENERIC NAME	TRADE NAME	FORMULATION	DATE OF FDA APPROVAL
Sumatriptan	Imitrex	Injections	December 28, 1992
Sumatriptan	Imigran	Tablets	June 1, 1995
Sumatriptan	Imitrex	Nasal spray	August 26, 1997
Zolmitriptan	Zomig	Tablets	November 25, 1997
Naratriptan	Amerge	Tablets	February 10, 1998
Rizatriptan	Naramig	Tablets	June 29, 1998
	Maxalt	Tablets	
	Maxalt-MLT	Orally dissolvable tablets	
Zolmitriptan	Zomig-ZMT	Orally dissolvable tablets	February 13, 2001
Almotriptan	Axert	Tablets	May 17, 2001
Frovatriptan	Frova	Tablets	November 8, 2001
Eletriptan	Relpax	Tablets	December 26, 2002
Zolmitriptan	Zomig	Nasal spray	September 30, 2003

Some triptans were available in Europe before FDA approval in the United States.⁵⁷

FIGURE 49-1 Comparative structures of serotonin and selected antimigraine drugs. [Modified from Hart C: Forged in St. Anthony's fire: drugs for migraine. *Mod Drug Discovery* 1999;2(2):20-21, 23-24, 28, 31.]

rapid absorption to achieve maximum plasma levels faster (shorter time to maximum concentration [T_{max}]), longer elimination half-lives ($t_{1/2}$), better CNS penetration, and/or reduced cardiac effects. Improved central penetration and increased receptor affinity and selectivity for the 5-HT_{1D} (neuronal) receptor permit lower total oral dosing and reduced peripheral exposure to the coronary vasoconstrictor 5-HT_{1B} (vascular)

receptor, reducing the incidence and severity of chest pain that occurs with sumatriptan. Frovatriptan has a high affinity for the 5-HT_{1B} receptor when compared with other second-generation triptan agonists.^{7,8}

The chemical structure of frovatriptan conforms to structure-activity relationships established for 5-HT₁ receptor agonists. These include a nuclear indole heterocycle and a 3-alkylamine structure (incorporated into an

indole-fused cyclohexylamine moiety in frovatriptan). The 3-alkylamine function facilitates formulation of the triptans as water-soluble salts of acids. Of note, the 3-alkylamine feature serves as a substrate for MAO-A catabolism, except in the case of naratriptan.⁷ New agents that target the 5-HT_{1F} receptor are under investigation. Such agents may lack the vascular contractile effects of the current triptans that target 5-HT_{1B/1D} receptors.⁹

PHARMACOLOGY

At least seven classes of 5-HT receptors with different biologic effects have been identified. These classes are noted as 5-HT₁ through 5-HT₇. Except for the 5-HT₃ receptor, which is linked to an ion channel, all are G protein linked. The 5-HT₁ receptor class differs from the others in that it is inhibitory via adenylate cyclase, while the other receptor classes are excitatory. In general, 5-HT₁ receptors are the site of action of the migraine-abortive triptans and dihydroergotamine, which function as agonists at this receptor. In contrast, some migraine-preventative treatments such as amitriptyline and methysergide have 5-HT₂ antagonist activity. 5-HT₂ receptors are excitatory via phosphatidyl hydrolysis. 5-HT₃ antagonists have antiemetic activity.³

All triptans activate the 5-HT_{1B} and 5-HT_{1D} receptors and, to a lesser extent, the 5-HT_{1A} and 5-HT_{1F} receptors.¹⁰ Inhibition of vasodilation of meningeal vessels occurs via the 5-HT_{1B} receptor. Triptans are believed to relieve migraine, in part, by stimulating 5-HT_{1B} receptors on meningeal, dural, cerebral, or pial vessels to cause vasoconstriction, which counteracts the pain-inducing vasodilation involved in migraine. Inhibition of trigeminal nuclei cell excitability in the brainstem occurs via 5-HT_(1B/1D) receptor agonism; direct inhibition of these receptors is reported to have an antimigraine effect. Additionally, stimulation of presynaptic 5-HT_{1D} receptors inhibits both dural vasodi-

lation and inflammation.^{7,8} Triptans have low or no affinity for α - or β -adrenergic, cholinergic, or dopaminergic receptors.^{11,12} Anatomic studies using antibodies selective for human 5-HT_{1B} or 5-HT_{1D} receptors found that 5-HT_{1B} receptors are located primarily in the cranial circulation but are also found in the coronary circulation.^{13,14} While triptans constrict meningeal arteries more potently than they constrict coronary arteries, there have been concerns regarding potential myocardial ischemia secondary to induced coronary vasoconstriction. A summary of affinities of the triptans for receptor types is provided in Table 49-2.

Of interest, data have demonstrated potent anti-inflammatory effects in bacterial meningitis with administration of triptans to rats. Leukocyte influx into the cerebrospinal fluid was reduced, as was intracranial pressure and the formation of brain edema. Survival and clinical score were increased. That these findings may eventually be applicable to humans is suggested by clinically observed activation of the trigeminovascular system.¹⁵

PHARMACOKINETICS

Since this class of compounds was developed for affinity at specific receptors, there are only minor pharmacodynamic differences between the triptans. Despite significant pharmacokinetic improvements in the newer members of this class, only modest improvements have resulted in their ability to treat migraine. Pharmacokinetic relationships between the triptans are displayed in Table 49-3. Sumatriptan has low oral bioavailability (14%) due to first pass metabolism and incomplete absorption and, relative to newer triptans, a short elimination half-life of approximately 2 hours when administered subcutaneously or intranasally (approximately 2.5 hours when administered orally). Protein binding is approximately 14% to 21%; therefore, the effect of sumatriptan on the protein binding of other

TABLE 49-2 Affinities of Some Ergopeptides and Triptans for Serotonin Receptor Types

DRUG	RECEPTOR TYPE

drugs may be minor. The mean volume of distribution of sumatriptan after subcutaneous administration is 2.7 L/kg, and its total plasma clearance is approximately 1200 mL/min. Newer triptans have improved oral bioavailability. The absorption rate of rizatriptan is comparatively fastest when measured by the time to peak plasma concentration, and rizatriptan has been reported to result in more rapid relief of cephalalgia when compared with sumatriptan and zolmitriptan. Eletriptan and naratriptan have somewhat longer half-lives than sumatriptan, while frovatriptan has the longest half-life (up to 25 hours) of the triptans approved in the United States. Plasma levels of frovatriptan may be higher in elderly patients and in females.^{8,16}

SPECIAL POPULATIONS

All triptans are 5-HT_{1B} agonists and thus are contraindicated in patients with ischemic heart disease, uncontrolled hypertension, and cerebrovascular disease. Prudence dictates that patients should also be screened for conditions leading to accelerated atherosclerosis and coronary artery spasm. Related conditions may include family history of coronary artery disease or heart attacks, risk factors for coronary artery disease, longstanding or uncontrolled diabetes, hypercholesterolemia and hyperlipidemia, smoking, and physiologic or surgical menopause.

Clinical trials in the pediatric population have yielded positive results that triptans decrease symptoms of migraine, but often in the context of high placebo response rates. Although dosing for sumatriptan in younger patients has been reported, the manufacturer indicates that the use of sumatriptan injection, tablets, and nasal spray in those younger than 18 years is not recommended.¹⁶ In fact, a myocardial infarction has been reported in a 14-year-old boy following the use of oral sumatriptan with clinical signs occurring within 1 day of drug administration.¹⁶ While studies have demonstrated that adolescents may find triptans efficacious and tolerable, clinical data regarding the frequency of events in the pediatric population is still lacking.¹⁷⁻¹⁹

Since elderly patients may have decreased hepatic or renal function, since they may be more sensitive to drug-induced increases in blood pressure, and since they may be at higher risk for coronary artery disease, the use of triptans in the elderly is not advisable.

Triptans are category C drugs and should not be recommended for use by pregnant women. Review of data available from clinical trials, postmarketing monitoring, and the Sumatriptan Pregnancy Registry suggest no currently measurable increased risk for birth defects after prenatal exposure to sumatriptan. Sample sizes remain too small to draw definitive conclusions. Although use of triptans during pregnancy cannot be encouraged, data are reassuring where inadvertent exposure to sumatriptan has occurred during pregnancy.^{20,21}

DRUG INTERACTIONS

Triptans and ergotamines both stimulate serotonergic receptors; therefore, their combined use is not recommended. Monoamine oxidase (MAO) inhibitors, especially MAO-A inhibitors, can slow the metabolism of triptans and are thus contraindicated when using these medications. Also, the vasoconstrictive effects of the triptans may be additive to those of catecholamines. There have also been numerous case reports of suspected serotonin syndrome when MAO inhibitors and triptans are used concurrently.²²⁻²⁴ Given the fact that little reliable information exists regarding the combination of these two medicines, use of triptans should continue to be avoided in patients taking MAO inhibitors until further data demonstrating safety become available.

It is plausible that the combination of triptans and selective serotonin reuptake inhibitors may precipitate serotonin syndrome. Although serotonin syndrome has been reported with combinations of psychotropic medications, neurologists have considered the potential of triptans combined with selective serotonin reuptake inhibitors (SSRIs) to produce this syndrome as well. In general, clinical experiences and published reports indicate a low risk for serotonin syndrome with the combined use of an SSRI and a triptan.²³ However, considering the large volumes of SSRIs and other serotonergic drugs in use, the paucity of data regarding serotonin syndrome as a consequence of drug interactions with triptans suggests that further study is indicated to ascertain the relative risk of precipitating serotonin syndrome through drug interactions. Some documented and potential (but less likely) drug-drug interactions with triptans are listed in Table 49-4 and Box 49-1.

TOXICOLOGY

Triptans differ from each other in terms of tolerability but not in terms of safety.¹⁰ Animal overdose of sumatriptan has resulted in seizures, tremor, paralysis, behavioral changes, ptosis, erythema of the extremities, abnormal respiration, cyanosis, ataxia, mydriasis, salivation, lacrimation, and death.¹⁶ Clinical manifestations of triptans have been largely compiled from clinical experience, case reports, and systematic retrospective and prospective research. Therefore, the information that follows is derived primarily from observations of patients using an appropriate therapeutic dose.

The most frequent side effects, often called “triptan sensations,” are taste disturbances, tingling, paresthesias, and sensations of warmth in the head, neck, chest, and limbs.¹⁰ Other symptoms may include drowsiness, dizziness, flushing, and neck pain or tightness.

The most serious adverse consequences of triptan use involve the cardiovascular system. These insults are presumably due to coronary and cerebral vessels narrowing secondary to 5-HT_{1B} receptor activation. All triptans narrow coronary arteries by about 10% to 20% at

TABLE 49-4 Some Potential Drug Interactions with Triptans

INTERACTION TYPE	AGENT AND MECHANISM	EFFECT
Pharmacokinetic	Macrolide antibiotics: inhibition of CYP3A4 Monoamine oxidase A inhibitor	Increased almotriptan or eletriptan level Increased 5-HT ₁ agonism by sumatriptan, zolmitriptan, or rizatriptan
	Propranolol: inhibition of CYP1A2 Dihydroergotamine Acetaminophen	Increased zolmitriptan level 15% reduction in area under the curve for naratriptan Sumatriptan delays acetaminophen absorption
Pharmacodynamic	Ergopeptide Methysergide Serotonin reuptake inhibitors	Vasospasm; postpartum cerebral angiopathy Myocardial infarction reported with sumatriptan Increased serotonin concentration leading to serotonin syndrome (uncommon)
	Loxapine	Dystonia and movement disorder

The magnitude of these effects may be variable ranging from theoretical only or clinically insignificant to potentially life threatening. Compiled from Eadie MJ: Clinically significant drug interactions with agents specific for migraine attacks. *CNS Drugs* 2001;15(2):105–118.

conventional doses.²⁵⁻²⁷ Numerous studies have established the coronary vasoconstrictive effects of triptans.^{25,27-29} This constriction of coronary arteries may cause chest symptoms that closely mimic angina pectoris.¹⁰ However, the chest pain reported by 3% to 5% of patients taking oral triptans has generally not been associated with electrocardiographic changes and is unlikely to be due to cardiac ischemia.³⁰⁻³² In fact, in vitro data have shown that at therapeutic concentrations, triptans have little potential to cause clinically significant constriction of nondiseased coronary arteries.¹¹ Large retrospective studies show no increase in risk for myocardial infarction with triptan use in a general population of migraine sufferers.^{33,34} Noncardiac explanations for chest pain associated with the use of triptans include pulmonary vasoconstriction, esophageal spasm, muscle spasm, and anxiety.^{30,35,36}

In June 2002, the American Headache Society convened the Triptan Cardiovascular Safety Expert Panel to evaluate the evidence on triptan-associated cardio-

vascular risk and to formulate a consensus regarding the safety of triptans.³⁷ This consensus stated that chest symptoms occurring during the use of triptans are usually nonserious and usually not attributed to ischemia.³⁷ Also, while serious cardiovascular adverse events have occurred after the use of triptans, their incidence in both clinical trials and clinical practice appears to be extremely low.³⁷ Most of these data, however, are derived from clinical trials that typically excluded patients with cardiovascular risk factors or known ischemic heart disease. Therefore, the panel concluded that the cardiovascular risk-benefit profile of triptans favors their use in the absence of contraindications and that in patients at low risk for coronary artery disease, triptans can be safely prescribed without the need for prior cardiac status evaluation.³⁷

Triptan effects on diseased coronary arteries have not been well studied. It is plausible that even a small amount of induced vasoconstriction in patients with obstructive coronary artery disease may potentiate myocardial ischemia. Indeed, in rare instances triptan therapy has been associated with severe cardiovascular events.^{10,38-42} There have also been published reports of atrial fibrillation, ventricular tachycardia, and ventricular fibrillation following doses of sumatriptan.^{40,43-47} A majority of these episodes were reported to occur within 35 minutes of triptan administration. The evidence of increased risk for myocardial ischemia and infarction is largely based on the known pathophysiology of triptans and isolated case reports rather than epidemiologic data.³⁰

There is a paucity of data to support a correlative risk of ischemic stroke with triptan use.^{33,34,48} A study performed by Hall and colleagues showed no association between triptan prescription and stroke risk in 13,664 patients.⁴⁸ In another study of 12,339 patients who used injectable sumatriptan, there was an incidence of 1.08 strokes per 100,000 treated migraine episodes, which correlates with the natural occurrence of migraine and stroke.³⁴ It is also conceivable that some reports of stroke associated with triptans may have resulted from misiden-

tification of the primary cause of headache (i.e., some patients complaining of headache who received triptans may have had a primary stroke that was only definitively diagnosed after triptan administration).

Triptan-induced vasoconstriction has also been thought to induce ischemic colitis. There have been at least 11 reported cases associating triptan use with ischemic colitis.⁴⁹⁻⁵¹ However, no association was found in a large-scale prospective trial of the safety of subcutaneous sumatriptan.³⁴ Further studies are needed to explore this relationship because there is insufficient evidence thus far associating triptans and ischemic bowel disease.

Serotonin syndrome may result from the combined use of triptans with SSRIs. A handful of case reports describe such events.²²⁻²⁴ However, in one large prospective study combining SSRIs with triptans, there were no significant adverse neurologic events within 24 hours.⁵² Serotonin syndrome consists of a triad of altered mental status, dysautonomia, and neuromuscular changes.

There have been only a handful of case reports describing triptan overdose. Most of these articles report a paucity of adverse events with overuse.^{43,53,54} There are no published reports of death secondary to human overdose with triptans to date. However, there is one report of a woman with no underlying cardiovascular disease who presumably died secondary to complications of prolonged cardiac arrest following a single dose of oral sumatriptan.⁴⁰

Ocular toxicity consisting of corneal opacity and defects in the corneal epithelium has been reported in dogs at 30 days after daily administration of oral sumatriptan at three to five times the human daily exposure rate.¹⁶

Withdrawal of triptans following overuse (approximately 10 days per month for at least several months) may result in rebound (triptan-induced) headache. Triptan use should be limited to 3 days per week. Rebound headache may be characterized by refractoriness to preventive medication, and increasing attack frequency may be the first sign. Withdrawal headaches have also been described. Patients undergoing triptan withdrawal have been reported to request less symptomatic medication than patients undergoing withdrawal from ergot or analgesic medications, suggesting that their headaches were less severe than patients in the other study groups. Substituting medications that do not share cross-tolerance, or discontinuing the medication after the “washout” period is complete, may prove effective. Some patients may require inpatient therapy and/or psychiatric and social assessment and support.^{55,56}

DIAGNOSIS

Because adverse effects reported with triptan use are also associated with migraine headaches, effects of the drugs may be difficult to distinguish from those of the disease. Any adverse events, including myocardial ischemia, that occur more than a few hours after triptan use generally do not fit within the period of pharmacokinetic activity of these medications.³⁰ It may be prudent to exercise

longer periods of observation after potential adverse effects in the case of those triptans that have longer duration of action (i.e., frovatriptan and eletriptan), active metabolites, and elimination times.

MANAGEMENT

Treatment of symptoms following therapeutic doses or potentially toxic doses largely involves supportive measures along with management of any potential cardiovascular or neurologic effects. Benzodiazepines can be useful to control agitation and muscle spasticity associated with serotonin syndrome. Nitroprusside can be used to treat hypertension if end-organ damage is suspected. Labetalol, nitroglycerine, and phentolamine may be used as alternatives with a goal of 20% to 25% reduction in mean arterial pressure.

Decontamination

Activated charcoal is regarded as most effective in adsorbing unabsorbed drug from the gastrointestinal tract if given within 1 hour of ingestion after oral overdose. Some absorption of orally administered triptans might also be prevented by early gastric lavage, although the efficacy of this procedure may be no better than oral activated charcoal alone. In the event of massive triptan ingestion, a toxicologist should be consulted regarding decontamination procedures and management. No specific antidote exists.

Laboratory Studies

No specific laboratory work is generally indicated for inadvertent exposure to small amounts of triptans in asymptomatic patients. Specific drug levels are not clinically useful. For patients experiencing chest pain, a 12-lead electrocardiogram and continuous electrical monitoring should be performed if symptoms suggest myocardial ischemia or dysrhythmia. Serial cardiac enzymes may be considered. Since hepatic metabolism and renal excretion are important mechanisms of triptan and triptan metabolite formation and clearance, measures of hepatic and renal function might be useful, especially where presystemic “first pass” clearance of orally administered triptans is concerned. Patients with large exposures may be at risk for sequelae, including seizures and acidosis; laboratory studies should be obtained accordingly.

Disposition

There is a paucity of information regarding risk stratification of patients with triptan overdoses. Should a patient who is exposed to triptans experience chest pain that is believed to be ischemic in origin, further triptan use should be avoided until proper risk stratification can be completed.

A 3-year retrospective study of unintentional pediatric exposures to single-agent triptan acute ingestions has

been reported. Exposures to oral formulations of sumatriptan, zolmitriptan, naratriptan, and rizatriptan were documented in children younger than 7 years. Of 32 cases that met inclusion criteria, 26 patients ingested one or two adult doses, three patients ingested three or more doses, and three ingested an unknown amount. Five patients reported at least one effect (vomiting, nausea, abdominal pain, and/or drowsiness). Four of those five patients were treated in the emergency department, and three of the five received activated charcoal. None of the patients required admission or other treatment. Of those five symptomatic patients, one ingested a single tablet, one ingested two tablets, and the others ingested three or four tablets. All of those patients were asymptomatic at the time of follow-up phone call. This limited review suggests that while children who ingest only one to two adult doses of the triptans studied are likely to do well and might be observed at home, more experience and further investigation is needed to establish safe triage and observation guidelines.⁶³

Review of limited data available in the literature suggests that some patients who overuse triptans in the setting of acute accidental exposure or overuse do well. However, in the current absence of sufficient data to risk stratify patients with triptan overdose, it is safest to observe or admit patients with large triptan overdoses, comorbid conditions, and abnormal vital signs, as well as symptomatic patients or those with exposure to multiple serotonergic medications, since the consequences of serotonin syndrome or massive triptan overdose may be severe. Those with suprathreshold exposure to triptans with long half-lives should, at a minimum, be observed for an extended period until such time as further data become available to assist with risk stratification of patients taking excess doses of such triptans.

J. WARD DONOVAN, MD

At a Glance...

- Colchicine has a narrow therapeutic index and serious toxicity; fatalities can occur even with therapeutic doses.
- Colchicine is contraindicated in hepatic disease or renal failure, and should be avoided with macrolide antibiotics.
- The latent period of 4 to 12 hours after an overdose may mislead clinicians into discharging the patient prematurely.
- Toxicity develops in a first phase of severe gastroenteritis with hypovolemia; a second phase of bone marrow depression, cardiac and respiratory failure, hepatorenal syndrome, coagulopathy, and weakness; and a third phase of recovery with alopecia and rebound leukocytosis.
- Initial treatment includes gastric decontamination (even in late presentation), respiratory support, aggressive fluid replacement, and vasopressor use as needed.
- Elimination may be enhanced by multiple dosing of activated charcoal, but hemodialysis has no effect.
- Colchicine-specific Fab fragments show promise for future therapy, but are not currently available.
- Granulocyte colony-stimulating factor may aid in recovery from leukopenia.

INTRODUCTION AND RELEVANT HISTORY

Colchicine is an alkaloid that can be extracted from two plants of the lily family, *Colchicum autumnale* (autumn crocus, meadow saffron) and *Gloriosa superba* (glory lily), and is used as an anti-inflammatory agent in gouty arthritis. Colchicine was first recognized as a poison in the 3rd century BC by the Egyptian Dioscorides.¹ In the 6th century AD, Alexander of Trallis first recommended colchicine as a cathartic in the treatment of joint pain.² It was advocated as a diuretic in the New Edinburgh Dispensatory in 1788 and recommended as specific therapy for gout in medical texts of the early 1800s. It was probably introduced into the United States as therapy for gout by Benjamin Franklin.¹ In 1820, colchicine was isolated from the *C. autumnale* tuber and rapidly gained popularity. It is now used to treat acute gouty arthritis, primary biliary cirrhosis, amyloidosis, Behçet's disease, and condyloma acuminata, as prophylaxis for familial Mediterranean fever, and experimentally to study cell division in cytogenetics because of its antimitotic activity.³

The infrequency of colchicine toxicity is reflected in the annual report by the American Association of Poison Control Centers (AAPCC). In 2003, there were 213 colchicine exposures reported to the AAPCC, of which only 4 resulted in major toxicity and 4 resulted in death.⁴

Nevertheless, toxic effects may be encountered after accidental, suicidal, or therapeutic use of colchicine tablets. The tubers of the glory lily have also been mistakenly ingested due to their similarity to sweet potatoes. Large volumes of the plants are required to cause toxicity, but the effects are similar to those observed with tablet ingestion.

CLASSIFICATION AND STRUCTURE

The alkaloid colchicine has the chemical formula *N*-(5,6,7,9-tetrahydro-1,2,3,10-tetramethoxy-9-oxobenzo[a]heptalen-7-yl) acetamide. The structure is shown in Figure 50-1.⁵ Pharmaceutical colchicine is available as 0.5- and 0.6-mg tablets and as a parenteral solution of 0.5 mg/mL. *Colchicum* species are cultivated and are popular as houseplants. The species *C. autumnale* has long, tubular purple or white flowers with seeds, and plants emerge from an underground corm or bulb (see Chapter 24); colchicine is present at a concentration of approximately 1% in the flowers of this plant.⁶

PHARMACOKINETICS

Colchicine is rapidly absorbed from the gastrointestinal (GI) tract, reaching peak plasma levels within 0.5 to 2 hours.¹ Oral bioavailability has been estimated to be 25% to 44%.^{2,6} Because higher doses depress jejunal and ileal function, prolonged absorption may occur in toxic doses.² However, this was not observed in one study of human poisoning cases.⁷

Approximately 50% of circulating colchicine is bound to plasma proteins. Initial distribution half-lives range from 45 to 90 minutes, and distribution is complete after 3 to 6 hours.⁸ The reported volume of distribution has varied across a wide range; it has been estimated to be 2.2 to 8.5 L/kg with therapeutic doses and 21 L/kg in patients with toxic effects.^{6,8} A range of 12% to 44% of colchicine is excreted unchanged in the urine with therapeutic doses, similar to the 30% excretion found in overdose. In patients with liver disease, a larger fraction

**FIGURE 50-1** Chemical structure of colchicine.

of the drug is excreted unchanged. Metabolism is primarily via deacetylation in the liver mediated by cytochrome P-450 (CYP) 3A4, followed by biliary excretion. Significant enterohepatic recirculation occurs, as demonstrated by the presence of the parent drug and metabolites in large amounts in bile and intestinal secretions.

The terminal plasma elimination half-life in therapeutic doses has ranged from 9.3 to 41 hours.^{2,6-8} This is similar to half-lives of 10.6 to 31.7 hours in toxic ingestions. However, serum concentrations were essentially unchanged for 3 days in one case of colchicine co-ingested with drugs that prolonged drug absorption and caused renal and hepatic failure.⁸

DRUG INTERACTIONS

The CYP3A4 inhibitors cimetidine and ketoconazole can cause an increase in colchicine elimination half-life.² Likewise, the macrolide antibiotics erythromycin and clarithromycin have the potential for inhibiting the CYP3A4 isoenzyme and, thus, decreasing hepatic metabolism of colchicine. Any known inhibitor of CYP3A4 has the potential for impairing colchicine metabolism and potentiating toxicity from this agent (see Chapter 5). The macrolide antibiotics, including josamycin, also inhibit P-glycoprotein, a transporter involved in cellular efflux and biliary elimination of drugs.⁸ Thus, the coadministration of macrolides has been reported to cause serious colchicine toxicity.^{8,9} Cyclosporine toxicity has resulted with concomitant use of colchicine.

PATHOPHYSIOLOGY

Colchicine binds to intracellular tubulin, a structural protein necessary for normal cellular motility, shape, endocytosis and exocytosis, axonal transport, and cell division. As a result of tubulin binding, microtubule polymerization is inhibited, spindle formation cannot occur, and cell mitosis is inhibited in metaphase.¹⁰ Those cells with the highest turnover rate, such as intestinal epithelium, bone marrow, and hair follicles, are affected the earliest and to the greatest extent. By inhibiting tubulin polymerization, colchicine affects microtubule function and interferes with the transport of intracellular nutrients and organelles. Failed microtubule function may explain some aspects of the multiorgan failure seen in colchicine toxicity, particularly cardiac failure.¹¹ There may be a direct toxic effect on the myocardial cells with impairment of impulse generation and cardiac conduction. Alternatively, depressed cardiac conduction and inotropy associated with severe colchicine toxicity may be due to profound acidosis and electrolyte derangements.³ The action of colchicine in gout is largely due to impaired phagocytosis of urate crystals by leukocytes; these effects probably result from failed microtubule function in leukocytes and their inability to alter cellular shape and engulf crystals.

RANGE OF TOXIC EFFECTS

For acute gouty arthritis, the usual colchicine dose is 0.5 to 1.0 mg every 2 to 3 hours until relief or GI symptoms occur. Because GI warning symptoms do not occur with IV dosing, the recommended IV dose is half of the equivalent oral dose to a maximum of 2 to 4 mg per acute episode.² There is a significant risk for death when this cumulative IV dose is exceeded.¹² Maintenance colchicine therapy is usually provided as daily doses of 0.5 to 2 mg for adults and 0.5 mg per day for children. Colchicine is contraindicated in patients with combined hepatorenal disease, creatinine clearances below 10 mL/min, or extrahepatic biliary obstruction.⁵ Because of reduced elimination in those with renal impairment, doses should be no larger than 0.6 mg/day if the creatinine clearance is less than 50 mL/min or serum creatinine is greater than 1.6 mg/dL.¹³

Fatalities have occurred with total doses of 8 to 11 mg given therapeutically over several days.² Ingestions of 0.5 to 0.8 mg/kg result in severe toxic effects, and doses greater than 0.8 mg/kg or a total of 40 mg are considered to be uniformly fatal.^{2,14} However, outcome is dependent on the duration between exposure and treatment, and the use of appropriate aggressive therapy.¹⁵ Severe toxic effects followed by survival have occurred with doses of 50 to 60 mg (greater than 1 mg/kg).^{2,10} In children, the fatal dose may be as low as 0.37 mg/kg.¹⁵ Colchicine-containing plants rarely produce severe toxicity due to the low concentrations of toxin, but large ingestions can be fatal.¹⁶ Ten grams of tuber contain about 6 mg of colchicine, and 100 to 125 g of tubers (60 to 95 mg of colchicine) have produced severe toxic effects.¹⁷

Colchicine plasma levels do not correlate well with the severity of toxicity and are not clinically useful. For instance, in acute ingestions, plasma concentrations that are associated with GI effects alone have ranged from 11 to 63 ng/mL within 4 hours of exposure.⁷ In contrast, a level of 24 ng/mL was noted 27 hours after acute colchicine ingestion in a patient with severe hemodynamic instability.¹¹ In addition, reported colchicine plasma levels have ranged from 11 to 66 ng/mL in fatal cases.⁸ Because of enterohepatic recirculation, the drug accumulates in the bile in levels as high as over 5000 ng/mL. Thus, the bile may be the best source for analysis in forensic cases.¹⁸

CLINICAL MANIFESTATIONS

The clinical manifestations of colchicine overdose involve multiple organ systems, including GI, respiratory, hematologic, cardiovascular, renal, and neurologic. After a latent period of 4 to 12 hours, signs and symptoms of toxicity occur in three phases.¹⁹ The first phase is manifested largely by GI signs and symptoms with fluid losses, electrolyte imbalance, and hypovolemic shock. Life-threatening complications occur during the second stage, or from 24 to 72 hours after exposure. At this

time, cardiac insufficiency, arrhythmias, bone marrow depression, renal failure, hepatic injury, respiratory distress, coagulopathy, and neuromuscular abnormalities are present. This phase can last for 5 to 7 days and is followed by a recovery phase marked by a rebound leukocytosis and alopecia. The duration and features of each phase are outlined in Table 50-1, and details of each involved organ system are discussed separately.

Gastrointestinal

Nausea, vomiting, diarrhea, and burning abdominal pain are the initial symptoms of colchicine toxicity. The presence of GI symptoms can serve a protective effect by warning of the potential for further toxicity with continued use of the drug. In addition, the presence of early GI effects may be the earliest indicator of impending severe toxic effects that will occur after acute overdose. Severe dehydration, hypovolemia, and cardiovascular collapse can result if aggressive treatment is not instituted. GI effects are not prominent after IV use, suggesting a local action of colchicine on gut epithelial cells. Hepatocellular damage (with associated elevations of transaminases and alkaline phosphatase) and hepatomegaly can also occur with colchicine toxicity, but fulminant hepatic failure occurs very rarely.¹⁰ Pancreatitis and a paralytic ileus also frequently occur.

Cardiovascular

Hypotension occurs due to volume losses, extravasation of fluid into extracellular spaces, and myocardial depression. Development of cardiogenic shock due to a postulated direct myocardial injury is a poor prognostic sign.²⁰ Colchicine is also thought to impair cardiac conduction, leading to arrhythmias and even late asystole.¹⁹ Marked electrocardiographic changes indicative

of myocardial injury can occur, with ST and T wave changes.¹⁷ Elevation of serum troponin I may be indicative of acute myocardial injury and the risk for cardiovascular collapse.²¹

Respiratory

Respiratory distress occurs in about one third of cases and is a result of generalized muscle weakness and acute respiratory distress syndrome (ARDS).⁵ Colchicine is also thought to have a direct toxic effect on the lungs, causing capillary leakage. Prolonged hypotension, sepsis, and multiorgan failure probably also play a major role in this syndrome.

Neurologic

Mental status depression may progress to delirium, seizures, and coma. Peripheral neuropathy, loss of deep tendon reflexes, and ascending paralysis can also occur late in the course.^{2,19,20} Myelin degeneration is thought to be the cause of these neuropathic effects.⁵

Hematologic

The first phase of acute toxicity includes a peripheral leukocytosis, followed by bone marrow depression in the second phase. Severe leukopenia, thrombocytopenia, and a consumptive coagulopathy peak at 4 to 7 days postingestion.¹⁰ Disseminated intravascular coagulation and sepsis often complicate this phase. Hematologic studies show hypoprothrombinemia, decreased fibrinogen, and increased fibrin split products. At 8 to 10 days postingestion, bone marrow recovery is apparent, and a rebound leukocytosis occurs during the recovery phase. Neutropenia may occur without other toxic effects after several days of therapeutic use.²²

TABLE 50-1 Phases of Colchicine Toxicity

PHASE	COMPLICATION	TREATMENT
I (0–12 hr)	GI symptoms Volume depletion	Gastric lavage to ensure removal of all pills from stomach IV fluid replacement; treatment of shock with use of pressure if needed
II (2–7 days)	Peripheral leukocytosis Respiratory distress, ARDS, hypoxemia Cardiovascular shock Thrombocytopenia, DIC Myelosuppression, neutropenia Hyponatremia, hypocalcemia, hypophosphatemia Metabolic acidosis	Supplemental oxygen, ET intubation and mechanical ventilation, PEEP Monitor, CVP, Swan-Ganz, fluids, pressors Replacement therapy with blood products Blood cultures, treatment with antibiotics Electrolyte replacement Maintain volume status; treatment with HCO ₃ if necessary
III (1–2 wk)	Rhabdomyolysis, myoglobinuria, oliguric renal failure Rebound leukocytosis, alopecia	Fluids, diuretics to maintain urine output

ARDS, acute respiratory distress syndrome; CVP, central venous pressure; DIC, disseminated intravascular coagulopathy; ET, endotracheal; GI, gastrointestinal; IV, intravenous; PEEP, positive end-expiratory pressure.

Renal

Renal failure is common in severe colchicine toxicity, probably secondary to hypovolemia, hypoxia, and myoglobinuria.⁵ The typical clinical findings are an oliguria responsive to fluids, hematuria, and proteinuria.¹⁷ There is no evidence of direct renal toxicity, although colchicine does concentrate in the kidneys.⁷

Metabolic/Electrolytes

A lactic acid, anion-gap metabolic acidosis is common, again due to hypotension and hypovolemia. This is exacerbated by inhibition of intracellular metabolism and accumulation of organic acids.¹⁹ Hypophosphatemia, hyponatremia, hypocalcemia, and hypomagnesemia occur, primarily due to fluid losses. Hypocalcemia is also thought to be due to direct suppression of bone resorption by colchicine.²

Musculoskeletal

A direct myopathic effect of colchicine can lead to muscle weakness, necrosis, and rhabdomyolysis, especially with chronic colchicine use.¹⁰ Reported cases have been associated with preexisting renal failure, and either acute or long-term colchicine in low therapeutic doses.^{23,24} Typically, there is rhabdomyolysis with elevated creatine kinase and aminotransferases.²⁴ The diagnosis is aided by electromyography and muscle biopsy. If respiratory failure occurs, pulmonary function testing is recommended to determine if skeletal muscle weakness is a significant contributing factor. The myopathy is usually rapidly resolved with discontinuation of colchicine.

Dermatologic

Scalp hair loss is common and typically occurs during the recovery phase, but it can occur anytime between 6 and 30 days postingestion.^{2,10} Hair growth almost always recovers several weeks after exposure. A vesiculating, erythematous rash resembling toxic epidermal necrolysis has been reported in rare cases, with histopathology showing subepidermal bullae and apoptosis of keratinocytes.²⁵

Miscellaneous

Colchicine has been associated with delayed corneal ulcer healing, azoospermia, and oligospermia.²⁶

DIAGNOSIS

The diagnosis should be suspected in anyone with access to colchicine and displaying the typical colchicine toxidrome of gastroenteritis, hypotension, lactic acidosis, and prerenal azotemia. In the early phases of colchicine toxicity, the diagnosis could be mistaken for sepsis, nonsteroidal anti-inflammatory drug or iron toxicity, or pancreatitis.²⁷ Findings associated with the later phase of colchicine toxicity (e.g., peripheral neuropathy and

alopecia) could be mistaken for heavy metal poisoning. Differentiation from both is possible by the presence of severe bone marrow suppression in the second phase of colchicine toxicity.

Laboratory monitoring should include frequent measurements of electrolytes (including calcium, magnesium, and phosphate), platelets, and creatine kinase; complete blood count; prothrombin time; serum troponin I; renal and liver function tests; and urinalysis for myoglobinuria. If coagulopathy is suspected, fibrinogen and fibrin split products should be monitored. In severe or persistent hypotension, echocardiography and pulmonary catheter monitoring is warranted.²¹ Colchicine measurements are not clinically useful except to establish or confirm the diagnosis.

TREATMENT

Initial Supportive Measures

Treatment for colchicine poisoning is mainly supportive. Patients with significant central nervous system or respiratory depression should have their airway protected, breathing assisted, and cardiovascular support provided as necessary. Initial therapy for hypotension includes aggressive replacement of fluid losses with IV crystalloid (20 to 60 mL/kg of normal saline or lactated Ringer's solution); vasopressors are indicated for hemodynamic instability that is not fluid responsive or severe. If the vasopressor therapy is necessary, it should be guided by Swan-Ganz catheter placement and measurement of hemodynamic parameters. This is important, given the propensity for myocardial depression, hypovolemia, alterations in systemic vascular resistance, and ARDS. Respiratory failure may require mechanical ventilation with positive end-expiratory pressure.

Transfusions of whole blood, fresh frozen plasma, vitamin K, and platelets may be necessary to treat coagulopathies. Because of frequent sepsis complicating neutropenia, the use of broad-spectrum antibiotics should be considered for febrile patients.

Decontamination

Gastric decontamination is warranted if the patient presents during the latent period prior to the onset of gastroenteritis and a potentially toxic amount (greater than 5 to 10 mg in adults) has been ingested. Adsorption of colchicine by activated charcoal has not been studied but is thought to be effective. Even late decontamination should be performed, because large residual amounts of colchicine have been found in the stomach many hours after ingestion. The known enterohepatic recirculation of colchicine also supports late and repeated doses of activated charcoal, but paralytic ileus may complicate this approach.¹⁵ In such cases, duodenal tube suction could be utilized. Cathartics should not be routinely employed due to the expected onset of spontaneous diarrhea, and whole bowel irrigation would also be of limited value for this reason.

Antidotes

Colchicine-specific Fab fragments have been developed and used with success in studies in laboratory animals.¹¹ The Fab fragments are prepared from the antiserum of goats immunized with colchicine, and their infusion results in reversal of colchicine binding to tubulin. This investigational agent has been successfully employed in a case of severe toxicity in a human without any adverse effects.¹¹ Administration of the Fab fragments resulted in a rapid reversal of life-threatening hemodynamic instability, although bone marrow suppression did not significantly improve. The dose given was 480 mg of colchicine-specific Fab fragments, with half given over 1 hour and the remainder over the ensuing 6 hours.¹¹ However, this agent remains an investigational antidote and is available only in France, in very limited quantities.

Granulocyte colony-stimulating factor (G-CSF) has been used in colchicine toxicity in an attempt to accelerate production of neutrophils within the bone marrow.^{10,28} In such cases, an accelerated leukocytosis was observed within 1 to 2 days, but at a time when rebound leukocytosis may naturally occur. Because colchicine-induced bone marrow suppression is short-lived, use of G-CSF should be considered only in life-threatening sepsis during the second phase of toxicity.

Enhanced Elimination

As discussed with decontamination, repeated doses of activated charcoal should theoretically enhance colchicine elimination because of its enterohepatic recirculation, but this has not been tested. This treatment would be problematic in some cases due to the presence of emesis and, possibly, paralytic ileus. With its large volume of distribution, high protein binding, and relatively small fraction of renal excretion, it is unlikely that forced diuresis, hemodialysis, exchange transfusion, or hemoperfusion would be effective for drug removal.¹³ Hemodialysis may be necessary to treat the associated renal failure.

Disposition

Because of its narrow therapeutic index and latent phase, any patient should be observed for 8 to 12 hours after acute ingestion of colchicine. The onset of GI symptoms or leukocytosis warrants hospital admission until at least the second phase of toxicity has ended.

J. WARD DONOVAN, MD

At a Glance...

- Acute nonsteroidal anti-inflammatory drug toxicity may produce gastrointestinal (nausea, vomiting), neurologic (lethargy, coma, hallucinations, seizures), and metabolic (acidosis, renal failure) effects.
- Nonsteroidal anti-inflammatory drug toxicity should be included in the differential diagnosis of an anion gap metabolic acidosis, which can be severe ($\text{pH} < 7.1$) in large overdoses.
- Absorption and onset of effects are rapid (1 to 4 hours) following acute overdose.
- Cyclooxygenase-2 nonsteroidal anti-inflammatory drugs have fewer adverse gastrointestinal effects with chronic use, but have similar toxic effects in overdose and have a risk for inducing adverse cardiovascular events in chronic use due to their prothrombotic effects.
- Management is supportive and must include rehydration to prevent and reverse the renal and metabolic effects.

INTRODUCTION AND RELEVANT HISTORY

Nonsteroidal anti-inflammatory drugs (NSAIDs) were first developed in the late 19th century; they achieved widespread use even before the marketing of acetylsalicylic acid. The first NSAIDs were the pyrazolones, phenazone and amidopyrine; phenylbutazone, of the same class, was not introduced until after World War II. Other NSAIDs were identified in the late 1950s and the 1960s, and they have undergone an explosive increase in use over the past 30 years. Ibuprofen was first introduced in the United States in 1974 and was approved for over-the-counter use in 1984.

The widespread availability of NSAIDs has naturally resulted in a marked increase in the number of overdoses and reported adverse effects. In the 4-year period 1985 through 1988, 55,800 cases of ibuprofen exposure were reported to the American Association of Poison Control Centers (AAPCC), but 71,043 ibuprofen exposures and a total of 97,123 NSAID exposures were reported in 2003 alone.^{1,2} Ibuprofen exposures account for more than 5% of the total cases reported to the London Poisons Information Centre.³ NSAIDs are now the most commonly utilized class of medications in the world, accounting for more than 4% of all prescriptions, with 73 million prescriptions written per year.^{4,5} Piroxicam, with its extended plasma half-life, potency, and safety, has become one of the most widely prescribed NSAIDs in the world.⁶

Despite their extensive use, NSAIDs are among the safest pharmaceuticals in use. Adverse drug reaction frequency is reported as only 24.4 per million prescrip-

tions, with fatal adverse reactions of 1.1 per million prescriptions.⁷ Symptoms were absent or minor in 33.6% of cases with known outcomes reported to the AAPCC.² However, the potential does exist for serious illness and even death in a few cases, as reflected in the 578 reported serious outcomes and 47 deaths involving NSAIDs in the United States in 2003. NSAIDs are now a common cause of renal failure, and at some regional poison treatment centers, mefenamic acid has accounted for the majority of reported drug-induced seizures.^{8,9} Chinese herbal medications have been found to contain NSAIDs, and their use has caused renal failure and aplastic anemia.¹⁰

STRUCTURE AND STRUCTURAL RELATIONSHIPS

The NSAIDs are a heterogeneous group of chemicals that share similar therapeutic properties. These acids are classified as subgroups of one of two families: the carboxylic or enolic acids. The carboxylic acids are further subdivided into arylacetic (phenylacetic) acids, propionic acids, fenamic acids, isoxazoles, and carbocyclic and heterocyclic acetic acids. The enolic acetic acids are subdivided into pyrazolones and oxicams (Box 51-1). Aspirin, a salicylic acid of the carboxylic family, is discussed in Chapter 48. The structures of various NSAIDs are shown in Figure 51-1.¹¹

NSAIDs are also classified by their activity as a specific or nonspecific inhibitor of the cyclooxygenase isoenzymes COX-1 and COX-2. Selective inhibition of COX-2, which affects inflammatory responses, is desirable, while inhibition of COX-1, affecting gastric mucosal protection, is not. Selective COX-2 inhibitors celecoxib and rofecoxib have up to a 200 to 300 times greater selectivity for COX-2 than COX-1.¹² The novel coxibs etoricoxib, valdecoxib, parecoxib, and lumiracoxib have even greater COX-2 selectivity, with the possibility of using increased doses to improve efficacy.¹³ However, they have renal side effects similar to those of the nonselective NSAIDs, thereby limiting the use of higher doses. Some other NSAIDs also have a modest degree of COX-2 selectivity, particularly etodolac, nabumetone, and meloxicam.¹² A potential disadvantage of the COX-2 inhibitors are that they are prothrombotic, whereas COX-1 inhibition has antithrombotic activity.¹⁴

PHARMACOLOGY: MECHANISM OF ACTION

The primary mechanism of action of NSAIDs is via inhibition of prostaglandin synthesis. Prostaglandins are derived from phospholipids in cell membranes synthesized

BOX 51-1 CLASSIFICATION OF NSAIDS**Salicylic Acids**

Acetylsalicylic acid (aspirin)
 Choline salicylate (arthropan)
 Diflunisal (Dolobid)
 Magnesium salicylate (Doan's, Magan)
 Salicylamide
 Salsalate (Disalcid)
 Sodium salicylate
 Sodium thiosalicylate
 Trolamine salicylate (Aspercreme, Myoflex Crème)

Phenylacetic Acids

Diclofenac (Voltaren)

Carbocyclic and Heterocyclic Acetic Acids

Aceclofenac
 Acemetacin
 Bromfenac (Duract)
 Diclofenac
 Etodolac (Lodine)
 Indomethacin (Indocin)
 Ketorolac (Toradol)
 Nabumetone
 Sulindac (Clinoril)
 Tolmetin (Tolectin)
 Zomepirac

Fenamic Acids

Benzydamine (Tantum, Difflam, Andolex, Opalgyn)
 Floctafenine
 Flufenamic acid
 Mefenamic acid (Ponstel)
 Meclofenamate (Meclomen)

Propionic Acids

Carprofen
 Ibuprofen (Advil, Nuprin, Motrin)
 Naproxen (Naprosyn, Anaprox)
 Fenbufen
 Flurbiprofen (Ansaid)
 Fenoprofen (Nalfon)
 Indoprofen
 Ketoprofen (Orudis)
 Loxoprofen
 Oxaprozin (Daypro)
 Piroprofen
 Suprofen (Suprol)
 Tiaprofenic acid

Furanones

Rofecoxib (Vioxx)

Isoxazoles

Valdecoxib (Bextra)

Pyrazoles

Celecoxib (Celebrex)

Pyrazolones

Azapropazone
 Fenprazone
 Phenylbutazone (Butazolidin)
 Oxyphenbutazone (Oxalid)

Oxicams

Isoxacam
 Lornoxicam
 Piroxicam (Feldene)
 Meloxicam (Mobic)
 Sudoxicam

from arachidonic acid. This synthesis is mediated by the enzyme cyclooxygenase, which is reversibly inhibited by NSAIDs. Thus, NSAIDs block the conversion of arachidonic acid to the various prostaglandins, which are involved in renin release, local vascular tone, regional circulation, water homeostasis, and potassium balance. The prostaglandin pathway and functions are outlined in Figure 51-2.

Prostaglandin E_2 (PGE_2), PGD_2 , PGF_2 , and prostacyclin (PGI_2) promote salt and water excretion, and the renal vasodilatory action of PGE_2 , PGD_2 , and prostacyclin enhances this effect. It is thought that PGE_2 and prostacyclin also stimulate renin release.¹⁵ In addition, prostaglandins antagonize the effects of antidiuretic hormone.¹⁶ The net effect of NSAIDs is decreased inhibition of prostaglandins, decreased renal blood flow, and decreased glomerular filtration rate, leading to sodium, potassium, and water retention (Fig. 51-3).

PGE_2 also inhibits lymphocytes and other cells involved in inflammation and allergic response, and this

may play a role in the development of interstitial nephritis and hepatotoxic effects in some patients using NSAIDs.^{16,17} This has occurred most with fenoprofen and the carbocyclic and heterocyclic acetic acids.

Other actions of NSAIDs are inhibition of platelet activation and mast cell mediation. The former contributes to prolonged bleeding, and the latter may be involved in NSAID-induced anaphylactic reactions and idiosyncratic hypersensitivity reactions. Also, prostaglandins, particularly prostacyclin, are formed in gastric tissue and exert gastric mucosal protective actions. Inhibition of this action by NSAIDs as well as their direct disruption of the gastric mucosal barrier can cause gastritis and gastrointestinal (GI) bleeding. The selective COX-2 inhibitors have less likelihood of adverse GI events, and large clinical trials have validated this theory.¹⁸ However, by decreasing vasodilatory and anti-aggregatory prostacyclin production, COX-2 inhibitors may be prothrombotic. This is discussed further under cardiopulmonary effects.

PHARMACOKINETICS

The carboxylic acid and enolic acid NSAIDs share similar pharmacokinetics, pharmacodynamic properties, and metabolic pathways. However, there are some clinically significant differences in rates of absorption and elimination and in drug interactions (Table 51-1).^{19,20}

Absorption

Therapeutic oral doses for most NSAIDs are absorbed almost completely, producing peak levels within 1 to 2 hours. Exceptions to this are oxaprozin, mefenamic acid, and diflunisal, which have delays of peak levels of up to 3 to 4 hours. The presence of food can delay the absorption of all NSAIDs.²⁰ In overdose, some delay may take place in achievement of peak serum levels. Five patients in a series of 29 patients with mefenamic acid overdoses had increasing serum levels after admission, which peaked at 8 to 12 hours postingestion.⁸

Distribution

The NSAIDs are extensively protein bound (98% to 99%), primarily to albumin. Sulindac and indomethacin have slightly lower degrees of binding, in the range of 90% to 93%.^{6,20} Principally because of their high protein binding, apparent volumes of distribution are low, ranging from 0.10 to 0.36 L/kg.^{6,20} Acute renal insufficiency, liver disease, and hypoalbuminemic states can decrease plasma protein binding and increase volumes of distribution.²⁰ Plasma protein binding can also decrease when NSAIDs are taken in high doses.

Metabolism

The elimination of NSAIDs is primarily by hepatic biotransformation to metabolites, which are excreted in

TABLE 51-1 Pharmacokinetics of NSAIDs

NSAID	T _{MAX} (hr)	V _d (L/kg)	RENAL EXCRETION OF UNCHANGED DRUG (%)	CLEARANCE (mL/min)	T _{1/2} (hr) (THERAPEUTIC DOSE)	T _{1/2} (hr) (OVERDOSE)

t_{1/2} elimination half-life; T_{max} time of maximum concentration; V_d, volume of distribution.

Adapted from Beebeek RK, Blackburn JL, Loewen GR: Clinical pharmacokinetics of non-steroidal anti-inflammatory drugs. Clin Pharmacokinet 1983;8:302–303.

the urine. The major mechanism is conjugation with glucuronic acid, and in some cases this is preceded by oxidation and hydroxylation.²⁰ Some NSAIDs undergo significant enterohepatic recirculation, including sulindac, indomethacin, diclofenac, flufenamic acid, ibuprofen, phenylbutazone, and piroxicam.²⁰ Urinary excretion of unchanged drug is less than 5% for most NSAIDs, but larger amounts of indomethacin, flurbiprofen, tolmetin, and piroxicam are eliminated by this route.²⁰ Sulindac and nabumetone are metabolized to active metabolites.¹⁹

The elimination half-lives of NSAIDs vary widely and range from as brief as 1 to 1.5 hours for tolmetin, ketoprofen, and diclofenac, 2.5 hours for ibuprofen, and up to 25 to 50 hours for oxaprozin and piroxicam.^{20,21} The half-lives of many NSAIDs are also prolonged in neonates and patients in renal failure. In overdose, some NSAIDs follow nonlinear kinetics at high serum levels and have prolonged half-lives, although this did not occur with a massive ingestion of ibuprofen.²¹⁻²³ Reported half-lives of NSAIDs in overdose are listed in Table 51-1.^{8,20,22-29}

Pregnancy

Most NSAIDs are classified by the U.S. Food and Drug Administration as pregnancy category C or D, indicating that their use in pregnancy is not recommended. Certain propionic derivatives (e.g., ibuprofen, naproxen), however, are classified as pregnancy category B in the first and second trimesters. In the third trimester, all NSAIDs are pregnancy category D due to their ability to produce premature closure of the ductus arteriosus.

DRUG INTERACTIONS

Drug interactions with NSAIDs may be both pharmacokinetic and pharmacodynamic, but the latter is of greatest clinical significance. Significant interactions lead primarily to toxicity from the other agents rather than from the NSAID.

The most serious NSAID interactions are with oral anticoagulants, sulfonylurea agents, and methotrexate.³⁰ The risk for GI bleeding from NSAIDs is enhanced by coumarin-type anticoagulants. NSAID-induced GI bleeding can also be increased by inhibition of NSAID metabolism by the pyrazolones. Risk for GI bleeding is also increased if NSAIDs are used with alcohol or tobacco, or with other NSAIDs, including COX-2 inhibitors. Methotrexate renal clearance is inhibited by several NSAIDs, and this can result in bone marrow toxic effects and renal or hepatic dysfunction. Lithium clearance may be reduced and lead to increased lithium levels during concurrent use, both by nonselective NSAIDs and COX-2 inhibitors.³¹ This is thought to be due to the inhibition of prostaglandins, which are involved in the renal clearance of lithium. NSAIDs may decrease the effect of antihypertensives, including β blockers, angiotensin-converting enzyme inhibitors, central α_2 -receptor agonists, and angiotensin II blockers.³² Renal failure may result from concurrent

TABLE 51-2 Drug Interactions with NSAIDs

DRUG	EFFECT
Alcohol	Increased risk for GI bleeding
Antacids	Reduced absorption of NSAIDs
Antihypertensives	Increased risk for NSAID-induced renal failure, reduced antihypertensive effect
Anticoagulants	Increased risk for NSAID-induced GI bleeding; pyrazolones inhibit warfarin metabolism
Aminoglycosides	Decreased renal clearance
Antineoplastic agents	Increased risk for bleeding due to thrombocytopenia
Cholestyramine	Binds to and interrupts enterohepatic recirculation of NSAIDs, lowers NSAID levels
Cholinesterase inhibitors	Increased risk for GI adverse effects
Corticosteroids	Prolonged concurrent use increases risk for adverse GI effects
Cyclosporine	Increased risk for renal failure; reduced cyclosporine clearance
Sulfinpyrazone	Increased NSAID concentrations; decreased platelet aggregation
Sulfonylureas	Metabolism is inhibited and hypoglycemia enhanced
Methotrexate	Decreased renal clearance
Pemetrexed	Decreased renal clearance
Digoxin	Decreased renal clearance
Lithium	Decreased renal clearance
Ofloxacin/levofloxacin	Concurrent use may lower seizure threshold
Phenytoin	Displacement of phenytoin from albumin
Diuretics	Effect antagonized by salt and water retention of NSAIDs
SSRIs	Increased risk for GI bleeding due to enhanced antiplatelet activity
Triamterine	Hyperkalemia; indomethacin combination may precipitate renal failure
Valproic acid	Clearance decreased; decreased plasma protein binding

GI, gastrointestinal

diuretic and NSAID use due to inadequate renal blood flow, especially in those who rely upon renal prostaglandins to maintain perfusion. NSAID-drug interactions are summarized in Table 51-2.³⁰

TOXICOLOGY

Range of Toxic Effects

Despite their widespread use, reports of serious acute NSAID overdose have been relatively few. They enjoy a wide therapeutic index, and most overdose cases do not result in serious morbidity and mortality. Nevertheless, severe toxic effects and death can occur with large ingestions. Lethal doses have not been firmly established for the various agents.

Chronic NSAID use, particularly in the elderly, causes a greater incidence of toxic and adverse effects. The risk for upper GI tract bleeding is 1.5 to 2.7 times higher in those using NSAIDs than in the general population, with an incidence of 1.0 to 3.3 bleeding events per 1000 users.³³

The enolic acid NSAIDs are thought to be more toxic in overdose than the carboxylic acids.^{6,22} However, there are multiple exceptions to this, such as the high incidence of serious neurologic effects with mefenamic acid.⁸ In chronic use for rheumatoid arthritis, toxicity was consistently greater for indomethacin, tolmetin, meclofenamate, and ketoprofen, whereas the least toxic were the propionic acids ibuprofen and naproxen.³⁴ Based on case reports, some ranges of toxic doses and serum levels can be established. However, serum quantification for all NSAIDs is neither generally available nor clinically useful.

Ibuprofen

Because of the frequency of its use, considerable data are available on ibuprofen toxicity. In children, doses of less than 100 mg/kg are very unlikely to induce symptoms. In one study, asymptomatic children had a mean ibuprofen dose of 114 mg/kg, but symptoms occurred in those with a mean ingestion of 440 mg/kg.^{25,35} In adults, central nervous system (CNS) symptoms occur only in those who ingest more than 3 g, and renal effects require more than 6 g.¹ Severe symptoms in adults are associated with ingestions of greater than 20 g, although estimated ingestions of up to 60 g have resulted in few or no toxic effects.^{1,21,35,36} Complications leading to death have occurred in overdoses of 6.8 g in a child and 24 g in an adult.^{25,35}

As with most overdoses, symptoms correlate better with ibuprofen blood levels than with the history of the ingested amount. In one study, all patients with significant symptoms had plasma ibuprofen levels of greater than 50 µg/mL within 10 hours after ingestion.¹ At 1 to 5 hours postingestion, those with symptoms had a significantly greater mean level (294 µg/mL) than those who were asymptomatic (144 µg/mL). Renal impairment is associated with levels greater than 280 µg/mL any time within 10 hours postingestion.²⁶ Multiple organ failure, including coma, renal failure, GI bleeding, and severe metabolic acidosis, has been reported with levels of greater than 200 to 300 µg/mL at 10 hours postingestion.^{21,36} However, levels up to 725 µg/mL have occurred in asymptomatic patients.³⁶

A nomogram of ibuprofen plasma levels versus time postingestion has been constructed to predict the likelihood of toxicity (Fig. 51-4).¹ The nomogram plots a semilogarithmic line connecting 100 µg/mL at 1 hour and 25 µg/mL at 12 hours postingestion, below which no significant symptoms are expected to occur. However, most ingestions with levels above the line are characterized by only minor symptoms. Considering that symptoms develop within 4 hours of ingestion in most cases, and that ibuprofen levels are usually not readily available, the utility of the nomogram is minimal.^{26,37}

FIGURE 51-4 Nomogram of ibuprofen plasma levels versus time postingestion, used to predict likelihood of toxicity.

Diflunisal

In children, mild GI symptoms and drowsiness can occur with ingestions of 3.5 g. In adults, only mild symptoms are expected with ingestions of less than 7.5 to 10 g.²² Serious symptoms can occur with as little as 10 g, although usually more than 15 g is required.²² Death has been reported with an ingestion of 33 g, but a patient who ingested 29 g survived after a deep coma of 10 hours.³⁸ The plasma diflunisal level was 500 µg/mL at 16 hours postingestion in a patient with severe symptoms.²² Levels in fatal cases typically exceed 600 µg/mL.²² Diflunisal is a difluorophenyl derivative of salicylic acid but is not converted to salicylic acid in vivo. Due to its structural similarity to salicylate, diflunisal often produces positive qualitative screens for salicylate and false elevations in serum salicylate concentrations.

Diclofenac

An acute diclofenac overdose of 1500 mg in a 19-year-old man caused confusion and hypotonia.²⁴ The serum level at 7 hours postingestion during the peak toxic effects was 60.1 µg/mL. A 2-g ingestion resulted in renal injury.³⁹

Indomethacin

Doses of 75 to 175 mg in children and 175 to 1500 mg in adults have caused only mild CNS or GI symptoms. In a series of 31 indomethacin overdoses in adults, 61% of patients remained asymptomatic and the rest developed only minor GI toxic effects, drowsiness, headache, and tinnitus.²² Ingestions of 0.5 and 0.9 g caused mild symptoms and plasma levels of 21 and 84 $\mu\text{g}/\text{mL}$, respectively.²⁷

Sulindac

Ingestions of 5 to 8 g of sulindac have resulted in mild GI symptoms and brief courses of hematemesis and renal insufficiency.³⁹ Ingestions of 10 g or more have caused prolonged courses of renal dysfunction.

Naproxen

Ingestions of 3 to 5 g of naproxen have caused mild GI distress and temporary renal insufficiency.^{22,39} Larger overdoses have caused seizures and acidosis.^{22,28}

Flurbiprofen

An ingestion of 3 to 6 g in an adult caused coma and respiratory depression, but it was unknown whether other ingestants were involved.²²

Fenoprofen

Ingestions of 300 to 3000 mg in children and 2 to 15 g in adults have been reported to cause only mild drowsiness, ataxia, tinnitus, and nausea. However, ingestions of as little as 3.75 g in adults have caused hypotension, tachycardia, and tachypnea.²² Ingestions of greater than 30 g have resulted in hypotension, coma, and renal failure. A postmortem blood level following death from ingestion of an unknown amount was 711 $\mu\text{g}/\text{mL}$.²²

Ketoprofen

Overdoses of 2 to 5 g in adults have produced only drowsiness, abdominal pain, and vomiting.²² Ingestion of an unknown amount in an adolescent resulted in seizures, with a serum level of 1128 $\mu\text{g}/\text{mL}$.²³

Mefenamic Acid

Seizures can occur with acute overdoses only modestly greater than the recommended maximum daily dose of 1.5 g. A 12-year-old had seizures after a 2.5 g ingestion, and adults can suffer convulsions after doses of less than 5 g.²² Ingestions of 12 to 15 g have produced status epilepticus, coma, and renal failure.^{8,22}

Seizures have occurred in patients with mefenamic acid plasma levels at or just above the maximum therapeutic level of 10 $\mu\text{g}/\text{mL}$. In one study, plasma concentrations in patients who had convulsions were significantly higher than in those without (73 versus 38 $\mu\text{g}/\text{mL}$).⁸ Most patients with seizures have concen-

trations above a semilogarithmic line plot connecting 100 $\mu\text{g}/\text{mL}$ at 2 hours and 5 $\mu\text{g}/\text{mL}$ at 15 hours postingestion.⁸ However, seizures can occur with levels well below this line.

Benzydamine

Oral administration of 500 mg of a topical preparation resulted in immediate vomiting, followed 2 hours later by hallucinations lasting 17 hours.⁴⁰ No other symptoms or metabolic abnormalities occurred.

Phenylbutazone

Acute phenylbutazone overdoses in children of 1.7 to 3 g result in toxic effects, and death can occur after doses of 2 to 5 g.²² Severe toxic effects occur in adults after ingestions of 4 to 8 g or more, and death occurs with doses of 14 to 28 g.^{9,22}

Piroxicam

Ingestion of 200 to 400 mg appears to cause only mild symptoms, although 100 mg in a child caused severe multisystem toxicity.²² Doses of 600 mg in adults have the potential for severe toxicity.

CLINICAL EFFECTS

NSAID overdose usually produces minimal or no toxicity. When present, signs and symptoms of toxicity typically include mild GI or neurologic effects such as abdominal pain, nausea, vomiting, lethargy, confusion, headache, or blurred vision.

In studies of acute overdoses of ibuprofen in adults, about 60% remain asymptomatic, 30% to 40% develop mild to moderate symptoms, and fewer than 3% suffer severe symptoms.^{1,41} Of the symptomatic group, onset is within 4 hours of ingestion and effects are usually of short duration. Severe and life-threatening toxic effects include metabolic acidosis, GI bleeding, dizziness, seizures, coma, respiratory depression, hypotension, and hepatic and renal injury.

The elderly and those with preexisting renal, cardiovascular, or hepatic disease are at particular risk for development of adverse effects with chronic NSAID use. Most organ systems can be involved, but GI effects are the most common and account for the majority or deaths from chronic use.

Gastrointestinal

GI effects, primarily nausea, vomiting, diarrhea, and abdominal pain, are common in both overdose and chronic use.^{22,25,41} The incidence of GI complaints in acute ibuprofen overdose has ranged from 6% to 42%.^{35,36,41} The associated fluid losses and resultant dehydration cause hypotension, acidosis, and acute renal failure. Peptic ulceration and GI hemorrhage are rare in acute overdose; the incidence in chronic use is 1.5%.^{8,41} Perforation of a duodenal ulcer has been reported

following acute overdose.⁴² In another acute overdose, gangrenous ischemic colitis occurred, probably due to inhibition of the cyclooxygenase enzyme, increased vasoconstrictor leukotrienes, and direct injury to GI epithelial cells.⁴³ Acute mild pancreatitis has also been reported after short courses of NSAIDs.⁴⁴

Neurologic

CNS depression is one of the most common effects of NSAID overdose and chronic use.^{4,22,25} In one series of ibuprofen overdose cases, CNS effects occurred in 30% of patients.³⁶ CNS effects may range from drowsiness to coma. Coma can occur independent of hypotension, respiratory depression, seizures, or acidosis.⁴⁵ Decreased memory and ability to concentrate have been reported with chronic NSAID use, particularly in the elderly taking indomethacin, sulindac, and naproxen.⁴

Seizures occur most commonly after mefenamic overdose, but they have also been reported in overdoses of naproxen, phenylbutazone, piroxicam, ibuprofen, and ketoprofen.^{8,22,25,28} Acute delirium, psychosis, hallucinations, and myoclonus have been described, particularly with indomethacin, sulindac, diclofenac, benzydamine, and mefenamic acid, but also with ibuprofen.^{4,8,40,46,47} The mechanism for these CNS effects is unexplained, but the structural similarities that indomethacin and sulindac have with serotonin suggest a possible causal role from this neurotransmitter.

Aseptic meningitis has occurred rarely with therapeutic NSAID use, usually in patients with systemic lupus erythematosus, but it can occur in otherwise healthy patients.⁴ Other neurologic effects include tinnitus, deafness, ataxia, nystagmus, headache, and disorientation.^{6,27}

Metabolic

Metabolic acidosis has been described in adults and children, usually in association with coma, seizures, hypotension, or renal failure.^{22,28,35,48} However, metabolic acidosis with increased anion gap has also been reported in the absence of these other effects.¹ Acidosis may be remarkably severe, with a serum pH of less than 7.1, and serum bicarbonate of less than 10 mEq/L despite only mild hypotension.^{48,49} The weakly acidic nature of NSAIDs and their metabolites may account for some of this acidosis, along with possible uncoupling of oxidative phosphorylation.^{41,50}

Hyperkalemia is a reported but unusual complication of NSAIDs after therapeutic use and overdose.¹⁶ Hyperkalemia could be the result of direct NSAID effect on cellular potassium uptake and delivery to distal renal tubules or of transient renal impairment. Hyponatremia and fluid losses result from both NSAID-induced gastroenteritis and inhibition of prostaglandin-mediated diuresis and natriuresis.

Hematologic

Thrombocytopenia, prolonged prothrombin times, agranulocytosis, and pancytopenia have been reported

with acute ibuprofen, piroxicam, naproxen, and etodolac overdoses.^{27,51} Decrease of platelet aggregation and adhesiveness contribute to bleeding disorders and GI hemorrhage. With therapeutic use, hematologic effects are uncommon, but they cause a disproportionate number of deaths. Aplastic anemia, agranulocytosis, hemolytic anemia, and thrombocytopenia have been associated with therapeutic use of various NSAIDs.^{41,44,52}

Hepatic

Hepatotoxicity of both hepatocellular and cholestatic types has occurred with use of all classes of NSAIDs, but it is most common with phenylbutazone and sulindac. The incidence of chronic NSAID-induced hepatic injury is low at 1.1 events per 100,000 prescriptions, and it is seen only rarely in acute overdose.⁵³ The usual finding is mild elevation of transaminase levels, which resolves after discontinuation of the drug. More severe involvement can occur as part of multiorgan involvement. The at-risk populations appear to be the elderly and patients with autoimmune connective tissue diseases. The mechanism of hepatotoxicity is likely a hypersensitivity reaction. One case report described subfulminant liver failure requiring transplantation, but there was also a history of alcohol abuse and arterial hypertension.⁵⁴

Renal

Problems associated with chronic use of NSAIDs are now among the most common reasons for hospitalization of patients with renal function abnormalities. It has been estimated that about 1% of those taking NSAIDs on a chronic basis will develop some deterioration of renal function.¹⁶ In acute overdose, renal failure has also been well described in case series and in isolated case reports.^{25,54-56}

Acute renal insufficiency, as a result of alterations in renal blood flow and glomerular filtration rates, is the most common renal complication. Those dependent on prostaglandin-mediated renal regulation are most at risk, including those with volume depletion, congestive heart failure, cirrhosis, hypoalbuminemia, advanced age, and preexisting renal disease.⁵⁴ However, renal failure has also been described after acute overdose in healthy individuals and in brief therapeutic use after binge alcohol drinking.^{25,54-56} This may be mediated by increased formation of the leukotrienes, causing renal vasoconstriction and mesangial cell contraction.⁵⁵ The renal insufficiency is typically mild; it resolves within 24 to 72 hours and may be oliguric or nonoliguric. The presentation consists of flank pain, elevated blood urea nitrogen (BUN) and creatinine levels, and, in chronic cases, weight gain and hyperkalemia. Urinalysis may show microscopic hematuria and cell casts. In cases associated with other severe manifestations such as coma, acidosis, and hypotension, recovery may be prolonged and require hemodialysis.⁴⁸

Acute interstitial nephritis and the nephrotic syndrome have been reported after short courses of NSAIDs or with chronic use.¹⁰ This syndrome has most often been

associated with the acetic and propionic acid derivatives and is a hypersensitivity reaction.¹⁵ Proteinuria is usually, but not always, present. Hemodialysis is required in as many as a third of these cases.¹⁰

Cardiopulmonary

Hypotension and tachycardia, most likely secondary to volume depletion, occur in fewer than 5% of cases.^{25,41} Congestive heart failure may result from chronic NSAID-induced fluid and salt retention.⁴¹ Most recently, the COX-2 inhibitors have been found to be associated with an increased risk for cardiovascular adverse effects.^{14,57,58} In one study, rofecoxib was associated with a greater than twofold increased risk of a thrombotic cardiovascular event as compared with naproxen; no increased risk for adverse cardiovascular events was associated with the use of celecoxib in two other studies.^{18,58} In another trial, however, celecoxib at doses of greater than or equal to 400 mg/day was associated with a 2.5 to 3.4 times greater risk for a cardiovascular event as compared with placebo.¹⁸ As a result of these reports, rofecoxib has been withdrawn from the U.S. market and warnings issued to avoid COX-2 inhibitors as first-line therapy, particularly for those with cardiovascular risk factors.¹⁸

Respiratory depression and arrest are unusual-but-reported manifestations of NSAID overdose.^{25,45} Adult respiratory distress syndrome has occurred in the setting of severe multiorgan toxic effects.⁴⁸ This may be due to prostaglandin inhibition causing increased alveolar capillary permeability.⁴⁸ Bronchospasm may be precipitated by NSAIDs, especially in persons with drug allergies or asthma.⁴¹

DIAGNOSIS

NSAID toxicity should be suspected in the case of any overdose that is accompanied by a symptom constellation of gastroenteritis, CNS depression, metabolic acidosis, and renal insufficiency. Ibuprofen (and other NSAIDs) should be included in the differential diagnosis of an increased anion gap acidosis, particularly in large overdoses with very low serum bicarbonate levels and serum pH. The clinical appearance with NSAID toxicity can mimic that with salicylate toxicity (acidosis, tachypnea, altered mental status, gastritis) without tinnitus, and salicylate levels should be measured to exclude this diagnosis. Note that diflunisal cross-reacts with some salicylate assays to produce false-positive results.⁵⁹ NSAID toxicity should also be suspected with a history of over-the-counter analgesic ingestion when acetaminophen and salicylates are undetected in the blood.

Laboratory studies for serious overdoses should include assay of electrolytes with anion gap calculation, complete blood count, coagulation studies, and arterial blood gas, BUN, creatinine, and transaminase levels. Renal insufficiency is unlikely to occur if an adult ingests less than 6 g, so renal function tests are not routinely necessary in these cases.¹ In patients at high risk for renal or hepatic complications, baseline renal and liver

function tests should be performed prior to initiating NSAID therapy and again in 5 to 7 days.

Routine ibuprofen assays are not particularly useful or predictive of outcomes, and are not routinely available.⁴¹ However, quantification of ibuprofen levels might be useful to determine if an initially asymptomatic patient will remain so. If the ibuprofen level is in the “significant toxicity unlikely” region (see Fig. 51-4), the patient can safely be discharged from medical care without further observation.¹

MANAGEMENT

Supportive Measures

The therapy of NSAID toxicity is primarily supportive and symptomatic, and there is no antidote. Early correction of any volume depletion is essential to maintain adequate renal blood flow, and 1 to 2 L (15 to 20 mL/kg) normal saline should be given rapidly. Hypotension usually responds to fluid replacement, but a short course of vasopressors may be required. Dopamine may be the best option to maintain renal blood flow in patients at high risk for renal insufficiency.⁴⁵ Acidosis should resolve with aggressive hydration, but intravenous (IV) administration of 1 to 2 mEq/kg sodium bicarbonate may be required if the serum pH is less than 7.1.

The coagulopathies of NSAID overdose rarely warrant specific therapy unless active bleeding is occurring. In such cases, fresh frozen plasma and 10 mg phytonadione (vitamin K₁) subcutaneously would be appropriate.

Seizures may require immediate therapy with benzodiazepines, such as 5 to 10 mg IV (0.2 mg/kg in children) diazepam. As with most drug-induced seizures, phenytoin is unlikely to be effective, and long-term treatment is usually unnecessary.

Antacids, H₂-receptor antagonists, and/or sucralfate may be considered for reducing any prolonged GI effects.⁶

Decontamination

Activated charcoal has been shown to reduce absorption of ibuprofen, piroxicam, mefenamic acid, and phenylbutazone, and it is likely to adsorb other NSAIDs as well.^{6,60} Single-dose activated charcoal is the GI decontamination procedure of choice. Syrup of ipecac and gastric lavage have also been recommended, but effectiveness of these methods has not been studied in NSAID overdose.

Decontamination has been recommended if the amount ingested is more than 10 times the therapeutic dose for adults or 5 times the dose for children.⁶ For ibuprofen, decontamination is thought to be unnecessary in children if less than 100 mg/kg is ingested (10 times the therapeutic dose).²⁵ Although syrup of ipecac has been suggested for child ingestions of ibuprofen of 100 to 400 mg/kg, the symptoms created by ipecac are indistinguishable from ibuprofen toxicity in this dosage range.^{6,25,41} Because of the rapid absorption of NSAIDs, it is unlikely that decontamination will be of benefit more

than 2 to 4 hours postingestion.^{6,20} Patients who have taken overdoses of NSAIDs that carry a high risk for seizures (e.g., mefenamic acid), CNS depression (e.g., phenylbutazone), or large amounts of other NSAIDs (e.g., more than 400 mg/kg of ibuprofen) should not be given syrup of ipecac.^{6,25}

Elimination Enhancement

Because NSAIDs are greater than 90% protein bound, extensively metabolized, and excreted in essentially unchanged form, it is unlikely that elimination would be enhanced by any method.^{6,20} This has been supported by a lack of efficacy of hemodialysis and hemoperfusion in limited studies.^{6,9} Nevertheless, hemoperfusion has been employed in phenylbutazone overdoses with some limited success.⁶ Hemodialysis may be necessary in cases of prolonged or severe renal failure following NSAID overdose.^{10,48}

Multiple doses of activated charcoal have been reported to enhance the elimination of phenylbutazone, indomethacin, and piroxicam by interrupting enterohepatic and/or enteroenteric recirculation.^{6,60} This benefit might also be expected in sulindac, diclofenac, flufenamic acid, and ibuprofen, all of which also undergo some enterohepatic recirculation.²⁵ However, this therapy would be warranted only in the small number of severely symptomatic patients.

DISPOSITION

Ingestions of greater than 10 times the therapeutic dose of NSAIDs other than ibuprofen in adults, or greater than 5 times in children, probably warrant observation in a medical facility for 4 to 6 hours postingestion.^{6,25} For ibuprofen, ingestions of more than 300 mg/kg in children and more than 6 to 20 g in adults warrant observation.²⁵ Mild symptoms usually resolve quickly and may not necessitate hospitalization. The development of CNS depression, acidosis, seizures, or renal insufficiency should mandate admission and careful monitoring.

ANTIMICROBIAL, CHEMOTHERAPEUTIC, AND IMMUNOSUPPRESSIVE AGENTS

52

Antibacterial and Antifungal Agents

MELISSA L. GIVENS, MD, MPH ■ JAVIER R. CALDERA, MD ■ ROUHOLLAH PRUEITT, MD

At a Glance...

- Antibacterial and antifungal agents include a broad range of chemically and toxicologically diverse substances.
- The major toxicities from antibacterial and antifungal agents result from adverse effects of therapeutic dosing and consist primarily of hypersensitivity reactions.
- In overdose, selected antibacterial and antifungal agents have significant toxicity. These include seizures from penicillins, renal injury from aminoglycosides and amphotericin, cardiovascular collapse from chloramphenicol, and "gasping baby syndrome" from benzyl alcohol.
- The imidazole antifungal agents (e.g., ketoconazole) are potent inhibitors of CYP3A4, producing significant drug-drug interactions.
- Treatment of antibacterial and antifungal overdose is supportive.

Antibiotics are a diverse class of medications used to kill microorganisms. They can cause adverse effects from hypersensitivity reactions, drug-drug interactions, and direct drug toxicity. Many of the complications associated with antibiotic toxicity occur with routine use or as a result of iatrogenic complications; they are less often related to intentional abuse. Antibiotics are well known to be involved in drug-drug interactions, primarily through cytochrome P-450 interactions (Box 52-1), but also through various other mechanisms.

Because antibiotics are commonly prescribed both for use in the hospital and in the home, they are a common source of toxic exposures. There were 65,623 cases of human exposure to antibiotics reported to the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) in 2003, which accounted for 2.7% of all exposures.¹ Fortunately, antibiotic toxicity rarely results in death. In the 2003 TESS data, only three deaths were attributed solely to antimicrobial toxicity. Two deaths were a result of exposure to parenteral tilmicosin, a veterinary-grade macrolide, and one death occurred in a suicidal ingestion of hydroxychloroquine and methotrexate.¹

HISTORY

The discovery of antibiotics constitutes one of medicine's major breakthroughs. Antimicrobial efficacy predates Alexander Fleming because the use of sulfonamide subcutaneously lowered the mortality from meningococcal meningitis from 70% to 90% to about 10%.² Fleming's discovery of the inhibition of staphylococcal growth by the mold *Penicillium notatum* while cleaning his laboratory at Saint Mary's Medical School in London in 1928 was a landmark moment in medicine. Fleming later received the Nobel Prize along with Florey and Chain for the discovery and use of penicillin in infectious disease. Other fortuitous discoveries, such as cephalosporin C-producing organisms found in sewer water, further advanced the science of antimicrobials.³

HYPERSENSITIVITY REACTIONS

A history of antibiotic hypersensitivity, or drug allergy, is reported in as many as 25% of hospitalized patients.⁴ Hypersensitivity reactions occur as a result of immunologic phenomena, are unpredictable, and are independent

of the expected pharmacology of the drug. Risk factors for hypersensitivity are most closely tied to the chemical properties of the medication, but may also be related to dose, route of administration, duration of treatment, and host factors such as age, gender, atopy, and genetic polymorphisms.^{5,6} An allergic response requires previous exposure to the drug or to an immunochemically related substance and usually occurs within the first 2 weeks of administration.⁷ There are also pseudo-allergic (anaphylactoid) responses, which are immunoglobulin E (IgE)-independent reactions clinically indistinguishable from an IgE-mediated reaction. The most classic example of an anaphylactoid reaction occurs in response to radiocontrast material, but anaphylactoid reactions have been reported with antibiotics such as ciprofloxacin.^{8,9} Vancomycin and polymyxin are also known to cause direct release of mediators from mast cells, which results in urticaria or even anaphylaxis-like symptoms.¹⁰ Other investigators have used the term *pseudo-anaphylactic* for well-described reactions following the administration of procaine penicillin. This response is believed to be related to the procaine and not the β -lactam structure.¹¹

True drug allergy requires an antigen-antibody reaction. Most drugs are low-molecular-weight compounds that cannot alone prompt an antibody response. However, when these drugs, or more commonly their metabolites, bind to carrier molecules, antigenic processing can occur. β -Lactam antibiotics are well-known haptens that can bind to carrier molecules both as parent drug and as highly reactive metabolites.¹² Cross-reactivity is often a concern, especially among β -lactam antibiotics such as penicillins and cephalosporins, which share the β -lactam ring structure.^{13,14} The true extent of cephalosporin cross-reactivity in penicillin-allergic patients is hard to determine because much variability exists in the literature. The risk for allergic reactions to cephalosporins in penicillin-allergic patients can be from two times to four times the normal population.^{15,16} To further confound the issue, many patients who are sensitive to penicillin also have a higher incidence of hypersensitivity reaction to immunologically unrelated compounds.^{12,17,18} In addition, immunohematologic reactions must be considered separately because they are usually IgG and IgM mediated in comparison with IgE-mediated

anaphylaxis and urticaria.¹⁵ Skin testing in penicillin-allergic patients reveals a 30% to 50% cephalosporin cross-reactivity of IgE antibodies.¹⁹ However, only about 50% to 70% of those with IgE reactivity to penicillin will develop clinical symptoms, and this reaction rate is expected to be much lower with cephalosporins, especially second- and third-generation drugs.^{16,20-22} Many authors recommend avoiding administration of β -lactam antibiotics to penicillin-allergic patients until formal skin testing and desensitization (if indicated) has been performed.^{5,7,12,23-26} Unfortunately, the majority of patients who suffer anaphylaxis have no prior history of systemic reaction.²⁷ Cephalosporins are not the only β lactams with cross-reactivity. Carbapenems show similar cross-reactivity and should be used with discretion in penicillin-allergic patients.²⁸ The monobactam aztreonam lacks an adjoining ring structure to the β -lactam ring and thus has negligible cross-reactivity and is weakly immunogenic in general.²⁹⁻³¹

Immunologic reactions can precipitate an array of responses. Table 52-1 is a synopsis of the four types of immunologic response as described by Gell and Coombs. Penicillin alone has been known to cause all four types of immunologic response. Immune responses to drugs can also be classified by clinical presentation and organ system involvement, as described below.

Multisystem Involvement

Because anaphylaxis and anaphylactoid reactions produce similar clinical reactions, they can both be considered multisystem, generalized reactions and will be discussed together.

ANAPHYLAXIS

Portier and Richet were the first to describe anaphylaxis (from Greek *ana*, meaning “backward,” and *phylaxis*, meaning “protection”) after dogs paradoxically reacted to repeat exposure of a sea anemone-derived toxin intended to produce a protective immunization effect.³² Richet earned a Nobel Prize in 1913 for his work related to anaphylaxis and is recognized as the founder of the science of allergy.

Antibiotics, especially penicillins, are the leading cause of anaphylaxis in the United States.^{33,34} Penicillins

TABLE 52-1 Gell and Coombs' Classification of Immune Reactions

CLASSIFICATION	IMMUNOREACTANTS	CLINICAL PRESENTATION	EXAMPLE
Type I	Mast cell mediated IgE dependent IgE independent	Anaphylaxis, urticaria, angioedema, asthma, rhinitis	Penicillin anaphylaxis
Type II	Antibody mediated IgG and IgM	Immune cytopenias Organ inflammation	Amoxicillin: hemolytic anemia Sulfonamide: thrombocytopenia
Type III	Immune complex Complement IgG/IgM immune complexes	Serum sickness, vasculitis	Drug fever Cefaclor serum sickness-like reaction
Type IV	T-lymphocyte mediated Type 1 cytokines	Contact dermatitis	Topical penicillin

TABLE 52-2 Antibiotics Known to Cause Anaphylaxis/Anaphylactoid Reaction

SUBSTANCE	IgE MEDIATED
β lactams	Yes
Tetracyclines	Yes
Sulfonamides	Yes
Nitrofurantoin	Possible
Streptomycin	Possible
Vancomycin	No
Chloramphenicol	No
Ciprofloxacin	No
Amphotericin B	No

are reported to cause fatal anaphylaxis at a rate of 0.002% and nonfatal anaphylaxis at a rate of 0.7% to 10%.^{14,35} Penicillins and radiocontrast material may be responsible for 1300 of the predicted 1500 annual deaths from anaphylaxis/anaphylactoid reactions. Although parenteral administration is frequently associated with anaphylaxis, oral administration may also cause anaphylaxis and death.³⁶ Table 52-2 lists some drugs known to cause anaphylactic and anaphylactoid reactions.^{8,9,37}

Pathophysiology

Anaphylaxis is a result of IgE-mediated release of chemical mediators from mast cells and basophils. The reaction is initiated when an allergen combines with an IgE antibody bound to the surface membranes of mast cells and basophils, leading to a signal transduction cascade that results in degranulation and the release of anaphylaxis mediators. Histamine, a preformed mediator stored in mast cell and basophil cytoplasmic granules, can cause bronchoconstriction, vasodilatation, enhanced mucus secretion, and enhanced vascular permeability by acting on histamine (H₁ and H₂ receptors). Other preformed mast cell mediators include neutral proteases such as tryptase, acid hydrolase, oxidative enzymes, chemotactic factors, and proteoglycans. Tryptase is often used as a clinical marker for anaphylaxis because it peaks 60 to 90 minutes after anaphylaxis onset, but its role in the pathophysiology of anaphylaxis is not yet fully understood.^{36,38,39}

Leukotrienes B₄, C₄, and E₄; prostaglandin D₂; and platelet-activating factor are membrane-derived mediators formed from arachidonic acid metabolism. Release of these mediators can cause bronchoconstriction, mucus secretion, and alterations in vascular permeability.^{35,40} Platelet-activating factor can additionally lower blood pressure and activate clotting.⁴¹ These mediators, in addition to the activation of other proinflammatory pathways and enhanced nitric oxide synthesis, can lead to a severe systemic reaction with the potential for disastrous outcomes.⁴⁰

Clinical Presentation

Clinical features of anaphylaxis include a variety of organ systems. The majority of patients with anaphylaxis manifest symptoms within 1 hour of exposure, but delayed onset has been reported.³⁵ Cutaneous involvement may

present as urticaria, flushing, pruritis, erythema, or even angioedema. Mucous membrane congestion is commonly reported along with edema of the tongue or lips, and even edema of the larynx or epiglottis, which may lead to airway obstruction. Bronchoconstriction, manifested as chest tightness, shortness of breath, or wheezing, can lead to severe hypoxia and hypercapnia. Cardiovascular compromise from distributive shock can be profound. There are also reports of cardiac arrhythmias and evidence of tissue ischemia.⁴² Central nervous system hypoperfusion can lead to dizziness, confusion, seizures, and loss of consciousness. Gastrointestinal (GI) disturbances such as nausea, vomiting, abdominal pain, and diarrhea also may occur.³⁵

Treatment

Anaphylaxis is a life-threatening reaction that requires immediate medical attention and aggressive supportive care (Fig. 52-1). The first step is to remove the antigenic source as soon as features of anaphylaxis develop. Other treatment modalities are aimed at counteracting mediator release, supporting vital functions, and preventing further mediator release. Special attention should be directed to airway, breathing, and circulation. The patient should have large-bore intravenous access and continuous cardiovascular and pulse oximetry monitoring. Early airway support may be crucial in the setting of laryngeal edema.

Epinephrine is the mainstay of treatment in anaphylaxis.⁵ The β₁ effects support cardiac output, the β₂ stimulation promotes smooth muscle relaxation aiding in bronchial dilation, while the α effects counteract mediator-induced vasodilatation. Epinephrine may also prevent further release of anaphylactic mediators. Epinephrine is administered as a 1:1000 solution, and the standard dose is 0.3 mL intramuscularly in adult patients with urticaria and reactive airways with stable blood pressure. The pediatric dose is 0.01 mL/kg of the 1:1000 solution. In the setting of hypotension or cardiac arrest, 1 mg of epinephrine may be given intravenously as a 1:10,000 solution (0.1 mL/kg in children). Persistent hypotension may require a continuous infusion, and there is much variability in the literature regarding concentrations and dosage.⁴³ Advanced cardiac life support guidelines recommend diluting 30 mg of 1:1000 epinephrine (30 mL) in 250 mL of normal saline or 5% dextrose, starting the infusion at 100 mL/hr, and then titrating to effect.⁴⁴ Patients who receive epinephrine should be closely monitored for side effects, which include cardiac arrhythmias, myocardial ischemia, or severe hypertension. Patients on β-adrenergic blocking agents may have hypotension refractory to epinephrine.⁴⁵ These patients may require 1 to 5 mg glucagon given as a bolus followed by a glucagon infusion run at 5 to 15 μg/min.^{36,46} Patients should also receive intravenous fluids for vascular support.

Supplemental oxygen may be necessary for patients with cardiac or respiratory symptoms. Clinical signs of airway reactivity, such as wheezing and chest tightness, may require inhaled β agonists in addition to epinephrine. Corticosteroids (hydrocortisone 5 mg/kg or

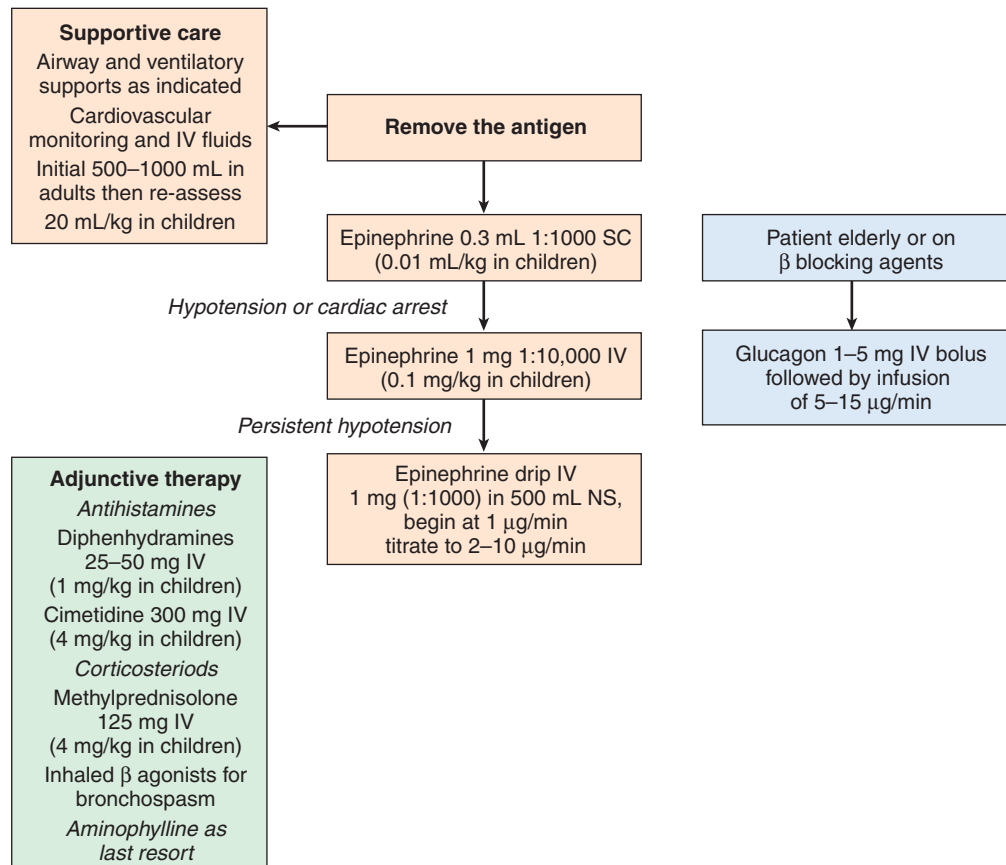

FIGURE 52-1 Treatment of anaphylaxis.

methyprednisolone 125 mg in an adult or 1 mg/kg in children) and antihistamines are unlikely to affect the acute response but may serve a role in reducing prolonged or recurrent symptoms.⁴⁷ However, one study by Stark showed little effect of corticosteroids on the occurrence of biphasic or prolonged anaphylaxis.⁴⁸ Antihistamines, to include both H₁ (diphenhydramine or hydroxyzine 25 to 50 mg) and H₂ blockers (cimetidine 300 mg) have been widely used both intravenously and orally to reduce pruritis and urticaria associated with the type I immune response. Patients who manifest clinical symptoms of anaphylaxis should be admitted to the hospital as a precaution to avoid premature dismissal of patients at risk for recurrence. Risk factors for recurrent or prolonged symptoms included a delayed onset (greater than 30 minutes) from exposure to manifestation of symptoms and patients who suffered a reaction to oral medications.⁴⁸

SERUM SICKNESS AND SERUM SICKNESS-LIKE REACTIONS

β-Lactam antibiotics are one of the most common causes of nonserum, serum sickness-like reactions. Although this phenomenon is well described in the literature, the reaction is uncommon (estimated at 1.8 per 100,000 prescriptions of cefaclor and 1 per 10 million for cephalexin and amoxicillin).⁴⁹⁻⁵² Serum sickness-like

reactions have also been ascribed to other antibiotics, including sulfonamides, ciprofloxacin, metronidazole, and streptomycin.⁵³ Serum sickness usually occurs 6 to 21 days after drug exposure. This time course allows for antibody production and the development of IgG and IgM immune complexes. Symptoms include fever, malaise, skin eruptions, joint symptoms, and lymphadenopathy. Treatment is supportive, and antihistamines and/or corticosteroids may provide some benefit.¹⁰

DRUG-INDUCED AUTOIMMUNITY

Hypersensitivity vasculitis (HSV) is an inflammatory condition of blood vessels and has been associated with antibiotic use, specifically penicillin and sulfonamides. HSV mortality may approach 25%, but if the causative agent is identified and exposure eliminated, the prognosis is very good.¹⁰

Organ-Specific Reactions

DERMATOLOGIC MANIFESTATIONS

Cutaneous reactions are one of the most common adverse drug events, occurring in 2% to 3% of hospitalized patients, and antibiotics are often the culprit.⁵⁴ The most commonly implicated antibiotics include amoxicillin, trimethoprim-sulfamethoxazole, and ampicillin. Exanthematous (or morbilliform) eruptions are the most

common drug-induced skin eruptions, and the clinical course is usually benign. Urticaria follows morbilliform rashes in frequency and may occur with or without anaphylaxis.⁵⁵ The rash may be a result of IgE or pseudo-allergic mechanisms. Onset may be immediate or delayed and will increase with ongoing exposure. Symptoms usually respond to antihistamines, but corticosteroids may be necessary.⁷

Allergic contact dermatitis is a type IV immune response following topical sensitization. Neomycin is a well-known sensitizer, but other implicated antibiotics include other aminoglycosides, penicillin, sulfonamides, chloramphenicol, and antifungal agents.⁵⁶ Cross-reactions may occur when these agents are administered systemically.⁵⁷

Erythema multiforme is another cutaneous reaction that has been reported most commonly with the use of sulfonamides but also with aminopenicillins, cephalosporins, fluoroquinolones, tetracyclines, vancomycin, and imidazole antifungals.⁵⁸ The reaction can manifest as a spectrum of illness from erythema multiforme minor to major and some even consider toxic epidermal necrolysis (TEN) the extreme of this spectrum (others consider it a separate entity). Symptoms usually begin 1 to 3 weeks after institution of the offending drug. High-dose corticosteroids are indicated early in the course of erythema multiforme. Patients with TEN should be transferred to a burn center, where the risk for mortality may be reduced from 50% to 30%.⁵⁹ The safety and efficacy of corticosteroid therapy in TEN patients is controversial.^{7,59}

Photosensitivity is another common skin reaction to antibiotic exposure. The reaction may be a nonimmunologic phototoxic reaction seen with tetracycline therapy or the less common photoallergic reaction, which requires sensitization. Photoallergic reactions have been described with the use of sulfonamides and fluoroquinolones.⁵

PULMONARY MANIFESTATIONS

Pulmonary infiltrates with eosinophilia have been associated with penicillins, sulfonamides, and nitrofurantoin. The patient may have nonproductive cough, fever, malaise, and chest discomfort. Treatment is withdrawal of the offending drug and corticosteroids.⁶⁰

HEMATOLOGIC MANIFESTATIONS

Antibiotics may influence hematologic parameters in various ways to include eosinophilia, thrombocytopenia, hemolytic anemia, and agranulocytosis. These reactions are believed to be mediated by immunologic mechanisms; however, agranulocytosis may also occur from direct bone marrow suppression. Eosinophilia in the absence of other clinical manifestations of an immune response may occur with ampicillin, sulfonamides, vancomycin, and streptomycin. Discontinuation of the drug is indicated in the presence of rising eosinophilia.¹⁰ Thrombocytopenia has been described with many pharmaceuticals, but the most commonly implicated antibiotics are the sulfonamides. Recovery usually occurs within 2 weeks of withdrawal of the drug.

Hemolytic anemia may occur through several immune mechanisms, including (1) immune complex, (2) hapten

formation, or (3) autoimmune induction. Nitrofurantoin, rifampin, and streptomycin are all known to cause hemolytic anemia through immune complex formation. The antidrug antibody binds to drug and a specific blood group antigen on the red blood cell membrane, leading to hemolysis, and the direct Coombs' test results are usually positive.⁶¹ Hapten-induced hemolysis results with high-dose penicillin therapy (more than 10 million units daily intravenously) and may also occur with tetracycline and cephalosporins.⁶¹⁻⁶³ Hemolysis usually occurs after 1 week of therapy and the Coombs' test result is positive.

RENAL MANIFESTATIONS

Drug-induced immunologic nephropathy is known to occur with the use of large doses of benzyl penicillin, methicillin, or sulfonamides. These patients often have fever, rash, and eosinophilia in addition to evidence of renal tubular dysfunction, which reverts to normal after drug discontinuation.⁵

OTHER MANIFESTATIONS OF HYPERSENSITIVITY

Drug-induced vasculitis, as a result of immune complex deposition, has been described with most antibiotic classes. A leukocytoclastic vasculitis is most common, but Henoch-Schönlein purpura and polyarteritis nodosum are known to occur with β lactams and sulfonamides. Affected patients may present with petechiae, purpura, arthralgias, myalgias, or nephritis. Symptoms usually resolve with discontinuation of the drug, but corticosteroids may be necessary.⁶⁴

Drug hypersensitivity due to altered hepatic metabolism that results in reactive metabolites has been commonly associated with the use of sulfamethoxazole in HIV-infected patients who present with fever and rash.⁶⁵ This reaction is usually self-limited, and most patients tolerate reexposure.⁶⁶ Altered hepatic metabolism has also been implicated in the pathogenesis of the serum sickness-like reaction seen with cefaclor.⁵²

In addition to hypersensitivity reactions, antibiotics can cause direct toxicity both at therapeutic doses and in overdose. The following is a discussion of the more significant toxicities associated with antibiotics and antifungals.

ANTIBIOTICS

Penicillins and β Lactams

Penicillins and other β lactams in acute overdose can usually be safely handled by the poison center at home due to their wide margin of safety. However, penicillins can produce toxic effects, especially at high doses. One that is widely known is the central nervous system (CNS) toxicity of penicillins either in large intravenous doses (more than 50 million units) or intraventricular injection.⁶⁷⁻⁶⁹ Seizures are thought to be related to binding of penicillin near the γ -aminobutyric acid (GABA) binding site, which prevents GABA from binding on its receptor, resulting in lack of inhibition.⁷⁰ Other β lactams, such as monobactams and carbapenems, may be

epileptogenic at therapeutic doses; and cephalosporins are known to have epileptogenic effects in acute overdose in patients with acute and chronic renal failure.^{71,72} Benzodiazepines or barbiturates can be used for penicillin-induced seizures, and cerebrospinal fluid exchange may be performed in case of intraventricular penicillin injection.^{67,68}

Penicillin G may also rarely cause hyperkalemia when given in large doses to patients with renal failure.^{73,74} Injection of procaine penicillin has been associated with Hoigne syndrome. This syndrome is characterized by anxiety, psychomotor instability, altered mental status, hallucinations, and paranoid thoughts. Procaine is thought to be the causative agent.⁷⁵⁻⁷⁷ Other β lactam agents are known to cause adverse events at therapeutic doses. Amoxicillin/clavulanic acid has been associated with intrahepatic cholestatic hepatitis that usually resolves after discontinuing therapy.^{78,79} Ampicillin is well known for producing a rash in children with infectious mononucleosis, but the mechanism of this phenomenon is poorly understood.⁸⁰ Cephalosporins with the *N*-methylthiotetrazole (nMTT) side chain, such as cefazolin, cefotetan, and cefoperazone, have the unique toxicity of causing a disulfiram-like reaction due to nMTT inhibition of aldehyde dehydrogenase. nMTT also has been associated with hypothermia by depleting vitamin K-dependent factors.^{74,81,82}

Sulfonamides

Sulfonamides in an acute single overdose are usually not life threatening and typically cause only nausea and GI upset. Hemolysis has been described in patients with glucose-6-phosphate deficiency (G6PD) treated with sulfonamides. Newborns given sulfonamides may develop kernicterus due to displacement of bilirubin.^{83,84} Sulfonamides have rarely been associated with methemoglobinemia.⁸⁵⁻⁸⁸

Fluoroquinolones

Disturbances of the GI tract, CNS symptoms, and photosensitivity are well-known adverse effects of therapy with fluoroquinolones.⁸⁹ Fluoroquinolones may also possess epileptogenic effects due to GABA inhibition. Norfloxacin is the most potent GABA inhibitor in the class.⁹⁰ Use of fluoroquinolones in young children and pregnant women is generally discouraged due to their known adverse effect on the development of collagen and glucosaminoglycans that results in faulty cartilage formation. However, newer literature suggests that these agents can be safely used in children.^{89,91,92} Achilles tendon rupture in adults is another well-known complication of fluoroquinolone treatment.^{89,93} Fluoroquinolones, most notably sparfloxacin and grepafloxacin, are known to cause QT interval prolongation by blocking myocardial potassium currents much like class III antiarrhythmics, so caution should be used when prescribing these agents to patients that may be taking other drugs known to prolong the QT interval.^{89,94,95}

Aminoglycosides

The aminoglycosides are one of the most commonly used antibiotics due to their efficacy against gram-negative bacteria. They are elaborated from the actinomycetes *Streptomyces* and *Micromonospora*. They have poor GI tract absorption, low protein binding, and small volumes of distribution, making them removable via hemodialysis. Aminoglycosides are only available in parenteral forms; therefore, most of the toxicity is due to dosing errors, which occurs most commonly in neonates. Nephrotoxicity usually presents in patients who receive long courses of the drug and resolves after the drug is retired. Acute single overdoses in persons with normal renal function are unlikely to cause nephrotoxicity.^{96,97} Aminoglycoside nephrotoxicity may be diminished by the concomitant use of ticarcillin.⁹⁸ Ototoxicity is more common with prolonged use, and the effect is usually permanent. As few as two doses in a dialysis patient have led to ototoxicity.⁹⁹ Treatment of aminoglycoside overdose includes removal of the offending agent, hemodialysis, and supportive treatment.

Tetracyclines

Tetracyclines are also broad-spectrum antibiotics. Significant toxicity after acute overdose is unlikely. Side effects are well recognized and include GI irritation and discoloration of the teeth. Tetracycline has been associated with esophagitis, ulcers, pancreatitis, and hepatitis.¹⁰⁰⁻¹⁰² Declomycin has been reported to cause nephrogenic diabetes insipidus.¹⁰³

Macrolides

Macrolides, derived from *Streptomyces*, have poor GI absorption, are known to cross the placenta, and are transmitted into breast milk. Pancreatitis and GI upset are known adverse effects.¹⁰⁴ Erythromycin has been associated with hypoacusis that resolved after stopping the drug.¹⁰⁵

QT prolongation has been reported on several occasions after therapeutic doses of erythromycin, particularly when it is given intravenously.¹⁰⁶ Daleau, in an animal study in 1994, postulated that erythromycin blocks the rapid component of the delayed rectifier potassium current and lengthens the repolarization phase of cardiac muscle.¹⁰⁷ Stanat and Carlton reported in an in vitro study that clarithromycin and erythromycin inhibit the HERG (the human ether-a-go-go-related gene) potassium current at therapeutic doses, thus increasing repolarization time.¹⁰⁸

Vancomycin

Vancomycin is produced by the actinomycete *Streptococcus orientalis* and is effective against a number of gram-positive organisms, most notably methicillin-resistant *Staphylococcus aureus*. Acute oral overdose rarely causes significant problems and can be managed with

supportive care alone. Multiple-dose activated charcoal decreased the half-life of vancomycin in neonates who received an iatrogenic overdose.^{91,109} Vancomycin is known to cause reversible nephrotoxicity and ototoxicity, both of which resolve after stopping the drug.⁹¹ Probably the most well-known toxicity of vancomycin, red man syndrome, is an infusion rate–related reaction that consists of chest pain, dyspnea, pruritus, urticaria, flushing, and angioedema. This is best treated by stopping the drug and supportive measures, such as intravenous fluids and diphenhydramine. Because red man syndrome is not a true allergic reaction, subsequent use of the drug is not prohibited.¹¹⁰⁻¹¹²

Nitrofurantoin

Nitrofurantoin is an antibiotic with great specificity for the pathogens of the urinary tract and is commonly used in pregnant patients. Side effects include GI upset and acute pulmonary toxicity that ranges from mild dyspnea to noncardiogenic pulmonary edema. Full recovery can be expected with discontinuation of the drug and use of steroids, bronchodilators, and supportive care.¹¹³

Chloramphenicol

Chloramphenicol is a nitrobenzene-based antibiotic capable of inhibiting protein synthesis in rapidly proliferating eukaryotic and bacterial cells. In acute overdose it is known to cause nausea and vomiting. It has been shown to cause cardiovascular collapse at levels of 30 to 277 $\mu\text{g}/\text{mL}$ and after doubling the dose for 60 hours.^{114,115} In early, massive overdoses, orogastric lavage may have a role in decontamination. Extracorporeal removal of the drug by hemodialysis or charcoal hemoperfusion may also be effective in patients with hepatic or renal insufficiency.¹¹⁶ Chloramphenicol is well known for causing “gray baby syndrome,” which was first described in 1959. Infants on chloramphenicol (doses of 100 to 165 mg/kg) for more than 72 hours developed vomiting, refusal to suck, irregular respirations, abdominal distention, diarrhea, acidosis, cyanosis, ashen color, flaccidity, and cardiovascular collapse.¹¹⁵ Chloramphenicol also can cause dose-dependent bone marrow depression, which most commonly affects erythropoiesis. Resolution occurs with discontinuation of the drug.

Oxazolidinones

Oxazolidinones (linezolid and eperezolid), currently used for multidrug-resistant gram-positive organisms, are the newest antibiotic class; thus, information on human overdose is limited. Common side effects of therapy include GI symptoms, headache, and thrombocytopenia in up to 10% of patients.¹¹⁷ Linezolid causes a reversible brownish tongue discoloration in up to 33% of patients on therapeutic doses.^{118,119} Linezolid is a weak monoamine oxidase inhibitor and concomitant use of selective serotonin reuptake inhibitors has resulted in serotonin syndrome.¹²⁰

Benzyl Alcohol

Historically, benzyl alcohol was used as a bacteriostatic flush for intravenous lines. In 1981 and 1982, several deaths in the neonatal intensive care unit were attributed to the use of benzyl alcohol. These patients presented with neonatal gasping syndrome, characterized gradual neurologic deterioration, severe metabolic acidosis, sudden onset of gasping respirations, skin breakdown, hepatic and renal failure, hypotension, and cardiovascular collapse.^{121,122}

Extensive workup in these patients revealed that the illness was the result of repetitive administration of the bacteriostatic solutions containing the benzyl alcohol. Benzoic acid is a by-product of benzyl alcohol, and it is likely that neonates are unable to detoxify the benzoic acid when benzyl alcohol is given repetitively.¹²² The syndrome disappeared after use of benzyl alcohol was discontinued in nurseries.

Dapsone

Dapsone (4-4'-diaminodiphenylsulfone [DDS]) is a synthetic sulfone that has been used as a bacteriostatic antimicrobial and as an anti-inflammatory agent in many dermatologic conditions. The first use of oral dapsone was in the treatment of *Mycobacterium leprae* in 1949.¹²³ Shortly thereafter, several dermatologic uses for sulfones were discovered, including the treatment of acne vulgaris, dermatitis herpetiformis, and subcorneal pustular dermatosis.¹²⁴⁻¹²⁶ Dapsone, with or without trimethoprim or pyrimethamine, also has strong anti-*Pneumocystis carinii* activity. Oral dapsone is readily absorbed by the GI tract and reaches peak serum concentrations between 0.5 and 4 hours. The volume of distribution is 1.0 to 1.5 L/kg, approximately 70% is protein bound, and the elimination half-life ranges from 12 to 30 hours. Dapsone undergoes enterohepatic circulation, and about 85% is excreted in the urine and 10% in the bile.^{127,128} The drug blocks dihydropterolate synthase. This enzyme catalyzes the conversion of para-aminobenzoic acid and pteridine into dihydroptericoic acid in the first step of folic acid synthesis. Therefore, dapsone affects bacteria that are dependent on intrinsic folic acid synthesis.¹²⁹ The mechanism involved in the anti-inflammatory influence of dapsone has been related to the suppression of leukocyte chemotactic and cytotoxic functions.¹³⁰ The most widely known toxicities of dapsone are hemolytic anemia and methemoglobinemia. Other less common effects of dapsone include sulfhemoglobinemia, agranulocytosis, hepatitis, maculopathy, and acute renal failure.¹³¹⁻¹³⁴ Dapsone causes an oxidative stress on the hematologic system by dapsone-derived free radicals. These radicals bind erythrocyte membranes and hemoglobin molecules and form precipitates and denatured proteins (Heinz-bodies). These proteins are subsequently sequestered by the reticuloendothelial system and destroyed, causing drug-induced hemolytic anemia.¹³⁵ This hemotoxicity is dose dependent, with a few cases reported at 100 mg/day , and

almost all patients involved in one study who were taking 250 mg/day.¹³⁶⁻¹³⁸ Significant methemoglobinemia has been reported in patients chronically receiving 100 mg/day.¹³⁹ Most cases of mild dapsone-induced methemoglobinemia and hemolytic anemia respond to discontinuation of dapsone and observation. Intravenous methylene blue continues to be the mainstay of treatment for severe methemoglobinemia but does not treat sulfhemoglobinemia. Exchange transfusion can be considered for methemoglobinemia or sulfhemoglobinemia unresponsive to supportive care and methylene blue.¹⁴⁰ Studies demonstrate that the use of multidosed activated charcoal increases dapsone elimination by interfering with its enterohepatic circulation. In one report, the elimination half-life of dapsone was reduced from 20.5 (± 2) to 10.8 (± 0.4) hours after multiple doses of charcoal.¹⁴¹ However, multiple-dose activated charcoal has not been clinically proven to decrease the incidence of methemoglobinemia and hemolytic anemia.¹⁴² Dapsone is poorly dialyzable due to its high protein binding and large volume of distribution.

ANTIFUNGALS

Amphotericin B

Amphotericin B is an intravenous polyene antifungal agent produced by the microorganism *Streptomyces nodosus*. It has been available in the United States since 1956. Amphotericin B lipid complex, amphotericin B cholesteryl sulfate complex, and amphotericin B liposome are alternative formulations that have been developed to reduce nephrotoxicity. Amphotericin B is usually reserved for life-threatening fungal infections due to its high incidence of nephrotoxicity. Amphotericin B causes reduced renal blood flow, decreased glomerular filtration rate, and direct tubular injury, resulting in acute tubular necrosis.^{143,144} Approximately 80% to 87% of patients receiving therapeutic doses of amphotericin B experience a decrease in renal function that appears to be dose related and cumulative, and is generally reversible over several months.¹⁴⁴⁻¹⁴⁹ Permanent renal damage may occur in patients receiving 4 g or more. Nausea, anorexia, vomiting, fever, and chills are also seen with therapeutic amphotericin B therapy. The fever and chills have been observed to be independent of the infusion rate and are likely mediated through prostaglandin E₂ synthesis.^{145,146,150} Amphotericin-induced electrolyte disturbances include hypokalemia, hypomagnesemia, and, rarely, hyperkalemia.¹⁵¹⁻¹⁵³ Anemia, leukopenia, and thrombocytopenia have also been reported with therapeutic administration.¹⁵⁴⁻¹⁵⁶

There is no antidote for amphotericin B toxicity. In addition to general supportive care, limiting dosage, and correcting volume deficits, other therapies have also been found to be useful in preventing or treating amphotericin toxicity. Both ibuprofen and meperidine have been advocated to prevent or ameliorate the fever and chills caused by amphotericin B.¹⁵⁷⁻¹⁵⁹ Supplementing dietary sodium chloride intake daily with

150 mEq of sodium chloride intravenously or orally when amphotericin B therapy is initiated may prevent nephrotoxicity.¹⁶⁰

Triazoles and Imidazoles

Fluconazole, itraconazole, terconazole, and voriconazole are triazole antifungal agents that inhibit ergosterol synthesis in fungal cell membranes. This causes cell leakage and death in the fungal cell. With therapeutic use, the most common adverse effects include nausea, vomiting, and bloating.^{161,162} Elevation of transaminase levels has been observed during fluconazole, itraconazole, and voriconazole therapy.^{161,163,164}

The imidazoles include clotrimazole, econazole, ketoconazole, and miconazole. Imidazoles also inhibit the biosynthesis of ergosterol or sterols, triglycerides, and phospholipids in fungal cells.¹⁶⁵ Severe toxic effects following oral overdose are expected to be negligible due to minimal oral absorption. Ingestion of even large quantities should produce only minor GI symptoms. At therapeutic doses, adverse effects of ketoconazole include hypertension, nausea, vomiting, gynecomastia, adrenal suppression, suppression of androgen synthesis, and menstrual irregularities. Ketoconazole-induced inhibition of steroid synthesis is a consequence of cytochrome P-450 enzyme inhibition. The competitive inhibition of CYP3A4 makes the triazoles (fluconazole and itraconazole) and the imidazoles (ketoconazole and miconazole) potentiators of other drugs that are more likely to cause serious toxicities such as phenytoin, cyclosporine, and warfarin. Prolonged QT syndrome, torsades de pointes, seizures, and death have been reported in coadministration of ketoconazole with astemizole, cisapride, or terfenadine (all of which are no longer available in the United States). This interaction is less frequently observed with itraconazole and fluconazole.¹⁶⁶⁻¹⁶⁹ Other side effects of ketoconazole include alopecia, drug-induced hepatitis, pruritus, and allergic rash.¹⁶⁸

At a Glance...

- The nucleoside reverse-transcriptase inhibitors, including didanosine, lamivudine, and stavudine, used to treat human immunodeficiency virus infection, is among the largest class of antiviral agents. They also have a broad range of significant adverse effects.
- Protease inhibitors, another large class of antiviral agents, have important effects on the cytochrome P-450 enzymes, producing important drug interactions.
- The guanosine analogs, another important class of antiviral agents, include acyclovir and ganciclovir. As prodrugs that require biotransformation to become active, these agents are important in the treatment of herpes simplex and varicella-zoster viruses.
- M2 protein blockers, which include amantadine, are the third most important class of antiviral agents; they are used commonly in the treatment of influenza.

Ten to 15 years ago only a few drugs were licensed for the treatment of viral infections. Recently, the drive to combat the human immunodeficiency virus (HIV) along with a better understanding of the viral life cycle resulted in the discovery of new antiviral medicines. New antiviral drugs have been developed against HIV, cytomegalovirus, herpes simplex virus, varicella-zoster virus, respiratory syncytial virus, hepatitis C, and the influenza viruses.

Antiviral medicines can be targeted against viral or human cellular proteins. The first approach is more specific against viruses and yields more specific and less toxic drugs; however, the development of drug resistance is more likely. The latter approach yields antiviral drugs with a broader activity and a higher likelihood of toxicity.

It is relevant to understand the viral life cycle in order to develop suitable antiviral medicines that have minimal toxicity to the patient. The viral life cycle encompasses several crucial steps, starting with the attachment of the virus to the cell followed by the replicative cycle and the release of the progeny virions from the cell. In retroviruses, this replicative cycle begins with reverse transcription (RNA→DNA); the proviral DNA then becomes integrated into the cellular genome and follows the classical transcription and translation processes of the human host cell. Cytolytic viruses (e.g., the herpesviruses) replicate their genome and express their genes autonomously, independent of the human host cell.

The following steps can be targeted by antiviral medicines: virus adsorption, virus–host cell fusion, viral RNA or DNA synthesis, and viral enzyme activity, for example, proteases and neurominidases. Two host enzymes,

inosine 5'-monophosphate (IMP) dehydrogenase and S-adenosylhomocysteine hydrolase can also be targets for certain classes of antiviral agents.^{1,2} Medicines have been developed to interfere with one of the steps in the viral life cycle. However, the emergence of viral resistance to antiviral drugs and the appearance of drug-related side effects are the main reasons that further research and refinement of antiviral medicines are needed.

The most important goals for treating viral infections in immunocompetent patients are to reduce the severity of illness and to decrease the rate of transmission of the virus. Thus, efficacy, safety, and convenience are key factors in antiviral drug development. Treatment efficacy is of primary importance in order to prevent viral damage to vital organs such as the liver, kidneys, lungs, gastrointestinal tract, and nervous system. Antiviral drugs are used for prophylaxis, suppression of viral replication in order to prevent tissue damage, or treatment of overt disease.

In this chapter the potency and ranked value of antiviral agents against particular viruses will not be discussed. The reader is referred to the website <http://AIDSinfo.nih.gov> and references.^{2,6} The main adverse effects that are important from a clinical toxicology point of view are summarized below and in Table 53-1. For an extensive overview of adverse effects of antiviral drugs, the reader is referred to handbooks, review articles, and websites concerning antiviral treatment. The endogenous antiviral agent interferon is also not discussed here. While drug interactions are discussed, in-depth discussion can be found in several of the cited articles.^{7,8}

NUCLEOSIDE REVERSE-TRANSCRIPTASE INHIBITORS

Nucleoside reverse-transcriptase inhibitors (NRTIs) are a class of anti-HIV drugs. They include abacavir, didanosine, lamivudine, zalcitabine, stavudine, zidovudine, adefovir, tenovir, and emtricitabine. Structurally, they are analogs of the natural nucleotides that form the building blocks of RNA and DNA in both human cells and viruses. Nucleoside and nucleotide analogs typically require intracellular phosphorylation by human cellular kinases to achieve their triphosphate form. This triphosphate form competes with the natural nucleotide for inclusion in the growing DNA chain. Absence of the hydroxyl group at the 3' position of the ribose ring in the analogs means a new 3',5'-phosphodiester bond cannot be formed with the next nucleotide, and hence the further extension of this DNA strand is prevented. Thus, NRTIs are competitive inhibitors of mitochondrial DNA

TABLE 53-1 Currently Available Antiretroviral Drugs (See Text for References)

SUBSTANCE NAME	TRADE NAME	RECOMMENDED DAILY DOSE (mg)*	ORAL AVAILABILITY (%)	T _{max} (hr)	Vd (L/kg)	THERAPEUTIC PLASMA CONCENTRATION (mg/L)	PROTEIN BINDING	AVERAGE PLASMA HALF-LIFE (hr)
Nucleoside-Reverse-Transcriptase-Inhibitors (NRTIs)								
NUCLEOSIDE ANALOGS								
Abacavir (guanosine analog)	Ziagen	300 mg po bid, Child: 8mg/kg po bid	83	1.5	0.8–1.9		50	0.8–1.5
Didanosine (adenosine analog)	Videx, ddl	Adult < 60 kg: po 250 mg; Adult > 60 kg: po 400 mg; Child > 6 yr: po 240 mg/m ² body surface		30–50	0.7–1	0.8–1.2	<5	1–1.8 (in children 0.8)
Lamivudine (cytidine analog)	Epivir, 3TC	150 mg po bid	86 for adults, 55–65 for children < 12 yr	1	1.3–2			1.2–9
Stavudine (thymidine analog)	Zerit, d4T	> 60 kg: 40 mg po bid Child: 1 mg/kg po bid	86	0.6–1.5	0.5			1–2
Zalcitabine (cytidine analog)	Hivid, ddC	0.75 mg po tid Child: 0.01 mg/kg po tid	85, child: 55	1	0.5–0.6		<5	1.2–2
Zidovudine (thymidine analog)	AZT, Retrovir	300 mg po bid Child: 160 mg/m ² po tid	60	0.5–1	1.5–2.5		20–38	1.1
ACYCLIC NUCLEOTIDE ANALOGS								
Adefovir	Hepsera	10 mg po daily	59	1.75 (0.6–4)	0.3–0.4		4	7.5
Tenofovir	Viriad	300 mg po for adults with CrCl > 60 mL/min; in children unknown	25 in fasting state, 39 with fatty meal	1–2.3	1.3		7	14,417
THICYTIDINE NUCLEOTIDE ANALOG								
Emtricitabine	Emtriva	200 mg po daily; in children unknown	93	1–2			<4	10

INTRACELLULAR HALF-LIFE TIME (hr)	ADVERSE EFFECTS	TOXIC EFFECT	RELEVANT ISSUES FOR DRUG METABOLISM	REMARKS
3.3	Nausea, vomiting, diarrhea, abdominal pain, headache, fever, lethargia, hypersensitivity reaction, bone marrow depression	Lactate acidosis, generally in combination with hepatomegalia	Metabolized by alcohol dehydrogenase and glucuronyl transferase	Contraindications: severe liver and renal failure, metabolites are for 82% excreted with the urine.
25–40	Numbness in extremities caused by peripheral neuropathy, nausea, vomiting, diarrhea, headache, fever, lethargia, seizures, bone marrow depression, diabetes mellitus, pancreatitis more common, hyperuricemia	Lactate acidosis, generally in combination with hepatomegalia, 1600 mg has been survived by 28 yr-old man without relevant toxicity		Be careful in cases with history of pancreatitis and liver disease. About 50% of the dose is excreted with the urine. Be careful with comedication rifampicine, rifabutin, ribavirin, tenofovir.
16–19	Nausea, vomiting, diarrhea, abdominal pain, fever, pancreatitis	Lactate acidosis, generally in combination with hepatomegalia		Unchanged excreted in the urine. Plasma concentration increases with renal failure.
3.5	Peripheral neuropathy, rare pancreatitis, gastrointestinal complaints, headache	Lactate acidosis, generally in combination with hepatomegalia		About 50% of the dose is excreted with the urine.
3	Peripheral neuropathy, stomatitis, rare pancreatitis	Lactate acidosis, generally in combination with hepatomegalia		About 70% of the dose is excreted with the urine.
3	Gastrointestinal complaints, headache, insomnia, asthenia, bone marrow depression, myopathy	Lactate acidosis, generally in combination with hepatomegalia	Metabolized to AZT, glucuronidated GAZT, renal excretion of GAZT	15%–20% is excreted unchanged with the urine, the rest mainly as zidovudine glucuronide.
10–50	Fever, headache, nausea, vomiting, diarrhea, flatulence, liver failure, weakness, renal failure Asthenia, headache, nausea, vomiting, diarrhea, flatulence		Induces a slight inhibition of CYP1A2	Elimination is impaired in renal failure, hemodialysis is useful. Primarily excreted by glomerular filtration and active tubular excretion; not recommended for patients with creatinine clearance < 60 mL/min.
	Headache, nausea, diarrhea rash	Lactate acidosis, generally in combination with hepatomegalia, 1200 mg was tolerated in 11 patients, without severe adverse reactions		85% is excreted with the urine and 15% in the feces, hemodialysis is useful, adjust dose in renal impairment.

TABLE 53-1 Currently Available Antiretroviral Drugs (See Text for References)—*cont'd*

SUBSTANCE NAME	TRADE NAME	RECOMMENDED DAILY DOSE (mg)*	ORAL AVAILABILITY (%)	T _{max} (hr)	Vd (L/kg)	THERAPEUTIC PLASMA CONCENTRATION (mg/L)	PROTEIN BINDING	AVERAGE PLASMA HALF-LIFE (hr)
Non-NRTIs								
Delavirdine (delavirdine)	Rescriptor	400 mg po tid; in children unknown	85	1.0-4	0.7		97	2-11
Efavirenz	Sustiva, Stocrin	600 mg po daily; children: 12-15 mg/kg once per day	65	3-5		1.8-4.1	99.5	40-55
Nevirapine	Viramune	200 mg po for 14 days, then if no rash 200 mg po bid	> 90 ≈	0.8-2.2	1.2-1.5	3.7-5.9	60	25-30
Protease Inhibitors (PI)								
Amprenavir	Agenerase	1200 po bid; child < 50 kg: 22.5 mg /kg po bid	90 in fasting state (see also tenofovir in this table)	0.5-2	5-6.1 l/kg		90	6-11
Indinavir	Crixivan	800 po tid; child: 500 mg/m ² po tid	60-65 in fasting state	0.7-1	0.4-2.25	0.15-8	60-70	1.8-2
Lopinavir	Kaletra (+ combination with ritonavir)	400 (+ 100) mg po bid; child < 40 kg 10-12 mg (+2.5-3 mg) po bid		2-5			98-99	5-6
Nelfinavir	Viracept	750 mg po tid	20-80	2-4	2.0-7.0	1.6-4	>98	3.0-5
Ritonavir	Norvir	600 mg po bid; child: 350-400 mg/m ² po bid	66-75	1-1.5	0.4-0.5	3.5-9.6	98-99	3.0-5

INTRACELLULAR HALF-LIFE TIME (hr)	ADVERSE EFFECTS	TOXIC EFFECT	RELEVANT ISSUES FOR DRUG METABOLISM	REMARKS
	Rash in \approx 4.3%, increased transaminase levels, headache		Metabolized by cytochrome P450 (CYP3A4 and CYP2D6)	Be careful with co-mediations that interact with P450 metabolism, 50% is excreted with the urine as glucuronidated metabolites, 44% in feces.
	Rash in \approx 1.7%, increased transaminase levels, dizziness, somnolence, insomnia, abnormal dreams, confusion, impaired concentration, amnesia, agitation, depersonalization, hallucinations, euphoria, retinal toxicity		Metabolized by cytochrome P450 (CYP3A4 and CYP2B6)	Be careful with co-mediations that interact with P450 metabolism, 14%–34% excreted with the urine as glucuronidated metabolites, 16%–61% in feces, false positive cannabinoid test.
	Skin rash in \approx 7%, even in 0.3% a Stevens Johnson's toxic necrotic epidermolysis, nausea, fever, insomnia, increased transaminase levels, hepatitis		Metabolized by cytochrome P450 (CYP3A4 and CYP2B6)	Be careful with co-mediations that interact with P450 metabolism, 80% excreted with the urine as glucuronidated metabolites, 10% in feces.
	GI symptoms, transient rash 7–14 d after start, hypertriglyceridemia, perioral paresthesias, buffalo hump, hyperglycemia, hemolytic anemia		Metabolized by CYP3A4, inhibition of CYP3A4; avoid terfenadine, astemizole, bepridil, ergotamine, potent benzodiazepines such as midazolam and triazolam	Be careful with comediations that interact with P450 metabolism, \approx 75% is in the feces excreted and 15% with the urine.
	Nausea; diarrhea; nephrolithiasis in days till weeks after start (3%–15%); hyperbilirubinemia; elevated AST, ALT, and amylase levels; acute hemolytic anemia	6 g in 47 yr-old man transient neurologic and gastrointestinal symptoms; ARF, renal atrophy, interstitial nephritis	Metabolized by CYP3A4, inhibition of CYP3A4; avoid terfenadine, astemizole, ergotamine, potent benzodiazepines like midazolam	Be careful with comediations that interact with P450 metabolism; take care for adequate hydration.
	Dose-dependent diarrhea		Standard combination with ritonavir 100 mg bid	Be careful with comediations that interact with P450 metabolism.
			Metabolized by CYP3A4; avoid terfenadine, propafenone, flecainide, astemizole, ergotamine, potent benzodiazepines like midazolam and triazolam	Be careful with comediations that interact with P450 metabolism.
	GI complaints, fatigue, perioral paresthesias, hypertriglyceridemia 5%, elevated AST, ALT, and GGT	3 g results in transient paresthesias	Metabolized by CYP3A4; avoid terfenadine, propafenone, flecainide, astemizole, ergotamine, potent benzodiazepines like midazolam and triazolam	Be careful with comediations that interact with P450 metabolism.

INTRACELLULAR HALF-LIFE TIME (hr)	ADVERSE EFFECTS	TOXIC EFFECT	RELEVANT ISSUES FOR DRUG METABOLISM	REMARKS
	Nausea diarrhea, peripheral neuropathy, headache, hyperbilirubinemia, elevated AST, rash, athralgia, pancreatitis	In adults: safe till single dose 8 g or 7.2 g/day for 25 wk	Metabolized by CYP3A4, all inhibitors P450 (ketoconazole) increase AUC plasmaconc by 300%; avoid terfenadine, astemizole, ergotamine, potent benzodiazepines like midazolam and triazolam	Be careful with comedications that interact with P450 metabolism.
	5% hypertriglyceridemia, elevated AST, ALT, hyperglycemia, first degree AV block (heart)		Metabolized by CYP3A4; avoid terfenadine, propafenone, flecainide, astemizole, ergotamine, potent benzodiazepines like midazolam and triazolam	Be careful with comedications that interact with P450 metabolism; 80% excreted via feces, 7% unchanged with the urine, 6% of the metabolites is excreted with the urine; in liver dysfunction adjust dosages.
	Injection site reactions		No effect on CYP450 enzymes	Unknown in liver dysfunction or severe renal failure. Clearance was not affected in patients with CrCl > 35 mL/min.
	Nausea, vomiting, diarrhea, phlebitis	Nephrotoxic (tubular crystal formation), neurotoxic: tremor, myoclonus, confusion, lethargy, agitation, hallucination, dysarthria, seizures or hemiparesis	Be careful in dehydration, previous neurological symptoms.	80% excreted unchanged with the urine, during hemodialysis plasma half-life is reduced to 5.7 L.
	Nausea, diarrhea, vomiting, hepatitis			70% is excreted unchanged with the urine.
	Nausea, diarrhea, vomiting, hepatitis, neurotoxicity, psychosis, nephrotoxic	Granulocytopenia (40%), thrombocytopenia (15%), ventricular ectopia, TTP		70% is excreted unchanged with the urine.
	Nausea, vomiting, diarrhea, headache, phlebitis	Nephrotoxic, neurotoxic	Be careful in dehydration, previous neurological symptoms.	
	Neurotoxicity, nephrotoxic, thrombocytopenia, hepatitis	Neutropenia, anemia, diarrhea		80% excreted unchanged with the urine, 50% is removed by hemodialysis.
	Nausea, anorexia, nervousness, difficulty concentrating, fatigue, arrhythmias	Hyperthermia, long QT interval, ARDS, psychosis, coma, ventricular ectopia, torsades de pointes, rhabdomyolysis, anticholinergic syndrome		Elimination by glomerular filtration and tubular secretion of the intact drug; in elderly (>65 yr), in renal or liver dysfunction 50% dose reduction
	Nausea, anorexia	NA	75% metabolized in the liver by hydroxylation	50% dose reduction in elderly (>65 yr), renal or liver dysfunction
	Gastrointestinal symptoms (10%)	None	No effect on CYP450 enzymes	Elimination exclusively by renal excretion

TABLE 53-1 Currently Available Antiretroviral Drugs (See Text for References)—*cont'd*

SUBSTANCE NAME	TRADE NAME	RECOMMENDED DAILY DOSE (mg)*	ORAL AVAILABILITY (%)	T _{max} (hr)	Vd (L/kg)	THERAPEUTIC PLASMA CONCENTRATION (mg/L)	PROTEIN BINDING	AVERAGE PLASMA HALF-LIFE (hr)
Zanamivir	Relenza	Inhaled 10–20 mg daily for adults and children > 12 yr	10–20	Poorly absorbed following oral administration; bioavailability about 2%				NA
Pyrofosfate Analogs								
Foscarnet	Foscavir	60 mg/kg intravenously tid, or 90 mg/kg intravenously bid	10–20		0.4–0.7	0.33–0.50 mmol/L	17	first phase, 0.5–1.4 second phase, 3.3–6.8 third phase, up to 18
Others								
Ribavirin	Rebetol, Copegus	>75 kg: 600 mg po bid (generally + interferon); <75 kg: 400 mg in the morning and 600 mg po in the evening	50	1–2	5–29 L/kg		nihil	20–50
Ribavirin	Virazole	20 mg/mL as aerosol 18–20 hr per day and 3–7 days long					nihil	9.5
Cidofovir	Vistide	5 mg/kg IV once weekly for 14 days, thereafter once per 14 days	<5		0.26–0.51		<10	2.2
Palivizumab	Synagis	15 mg/kg in once monthly		0.7	0.07–0.11			18–20 days

(mtDNA) polymerase- γ , which is responsible for mtDNA synthesis, leading to decreased mtDNA. Furthermore, these agents are chain terminators.⁹ mtDNA is the only extrachromosomal, extranuclear DNA in humans. The mitochondria perform an essential respiratory role known as oxidative phosphorylation. The mechanism of mitochondrial toxicity by antiviral agents such as NRTIs has been discussed by several investigators.^{9–11} Mitochondrial toxicity leads to impairment of normal oxidation of long-chain fatty acids in mitochondria. This causes esterification of triglycerides and an increase in nonesterified fatty acids. These accumulate as intracellular vesicles or are released on cell death. Impaired energy production and probably direct toxic effects of nonesterified fatty acids are likely etiologic in cell death.¹² Different human cells carry varying levels of mitochondria; therefore, impairment of mitochondrial

function is likely to become apparent in tissues that are metabolically most active. Common NRTI-associated mitochondrial dysfunction includes lactic acidosis, hepatic steatosis, peripheral neuropathy, pancreatitis, myopathy, and lipodystrophy.^{13–19} Free radicals may also contribute to nucleoside toxicity, potentially playing a role in didanosine-associated pancreatitis.^{9,16} The most relevant and regularly occurring adverse effects are summarized below. These effects have been reported in all NRTIs.

Adverse Effects of Nucleoside Reverse-Transcriptase Inhibitors

LACTATE ACIDOSIS

Lactic acidosis most commonly occurs in patients undergoing prolonged therapy with NRTIs. The onset of lactic acidosis can be either abrupt or insidious. Clinical

INTRACELLULAR HALF-LIFE TIME (hr)	ADVERSE EFFECTS	TOXIC EFFECT	RELEVANT ISSUES FOR DRUG METABOLISM	REMARKS
	None	None		All absorbed drug is excreted unchanged in urine.
	Renal failure, hypo- and hyperphosphatemia, hypocalcemia, bone marrow depression, headache, paresthesia, dizziness, anorexia, nausea, vomiting, fever skin rash, anemia. Less frequently: several other adverse effects (phlebitis after peripheral intravenous administration), penile ulceration, nephrogenic diabetes insipidus, thrombocytopenia	Acute hypocalcemia, convulsions, renal toxicity. One patient died after 12.5 g for 3 instead of 10.9 mg/day. He suffered a grand mal seizure and became comatose. Of nine patients with 1.14 to 8 times their recommended dose, three suffered seizures, three renal failure, four had paresthesia, and five calcium and phosphate disturbances.	Preverably do not administer in combination with other nephrotoxic drugs	Elimination increased by hemodialysis; Foscarnet is hardly metabolized and the majority of the dose is unchanged excreted with the urine. Be aware for hypo- and hypercalcemia, hypomagnesemia and hyper- and hypophosphatemia. Hemodialysis and hydration may be of benefit in reducing drug plasma concentrations.
	Nausea, joint and muscle pain, bone marrow depression, tachycardia, pancreatitis, hyperuricemia	Water intoxication has been reported.		Mainly excreted with the urine, for 30% unchanged
	Nausea, vomiting, fever, neutropenia, renal toxicity with proteinuria, rare pancreatitis, very rarely ototoxicity	Nephrotoxicity (proximal tubula cell injury)		Co-administration of probenecid may reduce nephrotoxicity, 80%–100% is excreted unchanged with the urine. The compound is hemodialysable.
	Injection site reactions			

symptoms can include abdominal distention and pain, nausea, vomiting, diarrhea, anorexia, tachypnea, weakness, weight loss, and hepatomegaly. Liver and/or renal failure, clotting abnormalities, seizures, and cardiac arrhythmias may be present. In addition to hyperlactatemia, laboratory evaluation may reveal an increased anion gap, elevated aminotransferases, creatine phosphokinase, lactic dehydrogenase, lipase, and amylase.^{16,19-23} Echography and computed tomography scans may indicate an enlarged fatty liver; histologic examination of the liver might reveal microvesicular steatosis.¹⁹

Antiretroviral treatment should be ceased if clinical and laboratory manifestations of the lactic acidosis syndrome occur. For certain patients, this adverse event resolves after discontinuation of NRTIs^{19,24} and a revised NRTI-containing regimen can be resumed.^{19,25} However, insufficient data exist to recommend this strategy versus

treatment with an NRTI-sparing regimen. Intensive therapeutic strategies and intensive care treatment may be necessary. Thiamine²⁶ and riboflavin^{27,28} have been administered on the basis of the pathophysiologic hypothesis that sustained cellular dysfunction of the mitochondrial respiratory chain is responsible for this fulminant clinical syndrome. However, efficacy of these latter interventions requires clinical validation. Although cases of severe lactic acidosis with hepatomegaly and steatosis are rare, when it occurs, this syndrome is associated with a poor prognosis.^{14,16,23,29}

PERIPHERAL NEUROPATHY

NRTIs cause a dose-dependent distal, bilateral, symmetrical peripheral neuropathy. This neuropathy typically manifests as pain and have abrupt onset and progression. The main features are pain, numbness, and

paresthesia. Lower extremities are more involved than upper extremities. Zalcitabine and stavudine are associated with comparable rates of peripheral neuropathy, and didanosine a lower rate. Zidovudine, lamivudine or abacavir are not generally associated with peripheral neuropathy. Acetyl-L-carnitine has analgesic effects in painful neuropathy and may have some benefit in these patients.³⁰ However, efficacy of this latter intervention requires clinical validation.

MYOPATHY

In the myopathy of NRTI use, skeletal muscles are most commonly affected, leading to proximal weakness, fatigue, muscle pain, and muscular wasting, together with a raised creatine kinase level.^{16,31-33} Skeletal myopathy has been reported predominantly with zidovudine and is dose dependent.³³ It is unusual with the other NRTIs.³⁴ Tissue-specificity studies with zidovudine have demonstrated that the greater impact of muscle cells may involve inhibition of succinate transport systems rather than direct mitochondrial toxicity.³⁵ In vitro studies have established that L-carnitine may both prevent zidovudine-induced myotoxicity and hasten recovery.^{36,37}

FAT MALDISTRIBUTION

Fat maldistribution is often referred to as the lipodystrophy syndrome. Clinical findings include central obesity, lipomas, visceral and dorsocervical (“buffalo”) fat accumulation, as well as breast enlargement, peripheral fat wasting, and facial thinning.³⁸⁻⁴⁰ Lipodystrophy may occur in association with insulin resistance and hyperlipidemia.⁴¹ The prevalence of this adverse effect has been reported to increase with long-term NRTI exposure.^{39,42,43} Theories on the role of NRTIs in fat redistribution have focused on mitochondrial toxicity and the potential impact on peripheral versus visceral and brown fat cells.^{15,17}

No clearly effective therapy for fat accumulation or lipodystrophy has been found. In the majority of victims, discontinuation of antiretroviral medications or class switching has not resulted in substantial benefit; however, among a limited number of persons, improvement in physical appearance has been reported.

Specific Agents

ABACAVIR

Pharmacokinetic information and adverse effects of abacavir (Fig. 53-1) are summarized in Table 53-1.⁴⁴⁻⁴⁶ Among the NRTIs, skin rash occurs most frequently with abacavir. Skin rash may be a symptom of abacavir-associated systemic hypersensitivity reaction; in that case,

FIGURE 53-1 Abacavir.

therapy should be discontinued without future attempts to resume abacavir therapy. Single doses of up to 1200 mg and daily doses of up to 1800 mg have been administered to patients in clinical studies without adverse effects. Acute overdose with abacavir has not been reported but is presumed to produce minimal toxicity.

DIDANOSINE

Pharmacokinetic information and adverse effects of didanosine (Fig. 53-2) are summarized in Table 53-1.⁴⁶⁻⁵⁰ Diarrhea is the most common adverse effect associated with didanosine. Further treatment-limiting toxicities of

FIGURE 53-2 Didanosine.

didanosine are peripheral neuropathy and pancreatitis.⁵¹ Acute overdose with didanosine has not been widely reported. In one case, hemodialysis for 4 hours removed approximately 20% of the amount present in the body at the start of dialysis.⁵⁰

LAMIVUDINE

Pharmacokinetic information and adverse effects of lamivudine (Fig. 53-3) are summarized in Table 53-1.^{46,52,53} Adverse effects associated with lamivudine use are primarily gastrointestinal and include nausea, vomiting, abdominal pain or cramps, and diarrhea.

FIGURE 53-3 Lamivudine.

Acute, single overdoses produce minimal toxicity. In one reported case, an adult ingested 6 g of lamivudine. No clinical symptoms were reported. Hematologic indices remained normal.⁵

ZALCITABINE

Pharmacokinetic information and adverse effects of zalcitabine (Fig. 53-4) are summarized in Table 53-1.^{46,47,54,55}

FIGURE 53-4 Zalcitabine.

Peripheral neuropathy and oral stomatitis are frequently reported adverse effect with zalcitabine therapy. Acute overdoses with zalcitabine have not been reported.

STAVUDINE

See also Table 53-1.^{46,56} The major clinical toxicity with stavudine (Fig. 53-5) is dose-related reversible peripheral

FIGURE 53-5 Stavudine.

neuropathy. Experience with adults exposed to 12 to 24 times the recommended dose has indicated that no significant acute toxicity develops.

ZIDOVUDINE

See also Table 53-1.^{46,47,57,58} Zidovudine (Fig. 53-6) is the most extensively used of the NRTIs. Overdoses have been reported both in pediatric and adult patients. After acute overdose, the only consistent findings have been nausea and vomiting. Headache, dizziness, drowsiness, lethargy, and confusion have also been reported. In one case report, ocular nystagmus and ataxia occurred, resolving

FIGURE 53-6 Zidovudine.

48 hours after ingestion of 10 to 20 g.^{59,60} When a 34-year-old man ingested 100 tablets of 200-mg zidovudine, the zidovudine level 12 hours after ingestion was 185 $\mu\text{mol/L}$ (normal range 0.6 to 4.4 $\mu\text{mol/L}$). He was drowsy but otherwise asymptomatic.⁶¹ In an unusual case, a patient who ingested 36 g zidovudine had a grand mal seizure 3 hours after ingestion.⁶²

Hematologic variables remain generally normal after acute overdose; in long-term use myelodepression may occur.^{59,63,64} Treatment of this overdose is supportive.

ADEFOVIR

For a summary of pharmacokinetic information and adverse effects of adefovir (Fig. 53-7), see Table 53-1.⁶⁵ (See also adefovir dipivoxil, FDA Advisory Committee Briefing Document, NDA 21-449, July 5, 2002.) Acute overdoses with adefovir have not been reported; its toxicity profile is therefore largely unknown.

FIGURE 53-7 Adefovir.

TENOFOVIR

See Table 53-1.⁶⁶⁻⁶⁹ Acute overdoses with tenofovir (Fig. 53-8) have not been reported.

FIGURE 53-8 Tenofovir.

EMTRICITABINE

See Table 53-1.^{49,70} Acute overdoses with emtricitabine (Fig. 53-9) have not been reported.

FIGURE 53-9 Emtricitabine.

NON-NUCLEOSIDE REVERSE-TRANSCRIPTASE INHIBITORS

The non-nucleoside reverse-transcriptase inhibitors (NNRTIs) include delavirdine, efavirenz, and nevirapine. These agents interrupt the reverse transcription of viral RNA to DNA, a crucial step for HIV replication, by a mechanism of action different from nucleoside analogs. The NNRTIs bind to reverse transcriptase and block the RNA-dependent and DNA-dependent DNA polymerase activities by causing a disruption of the enzyme catalytic site.

Adverse Effects

SKIN RASH

Skin rash appears to be a class-wide adverse reaction of the NNRTIs. The majority of skin eruptions are mild to moderate, occurring within the first weeks of therapy. A syndrome of drug rash with severe or even life-

threatening manifestations (e.g., Stevens-Johnson syndrome, toxic epidermal necrosis [TEN], and eosinophilia with systemic symptoms) is frequently described and should prompt permanent discontinuation of NNRTIs.^{71,72} Systemic symptoms can include fever, hematologic abnormalities, and multiple organ involvement. Among the NNRTIs, skin rash occurs more frequently and with greater severity with nevirapine. Females appear to have a higher risk for developing severe skin rashes than male patients.^{73,74} The prophylactic use of systemic corticosteroid or antihistamine therapy at the time of nevirapine initiation has not proven to be effective.⁷³

The incidence of cross-reactivity in the adverse effects among these agents is unknown. In a limited number of reports, patients with nevirapine-associated skin rashes have been able to tolerate efavirenz without increased rates of cutaneous reactions.^{75,76} Initiating NNRTI for a patient with a history of mild to moderate skin rash with another NNRTI should be performed with caution.

HEPATOTOXICITY

Hepatotoxicity, which is defined as a three- to fivefold increase in serum transaminases, with or without clinical hepatitis, has been reported among patients receiving NNRTIs. Among the NNRTIs, nevirapine possesses the greatest potential for producing clinical hepatitis.⁷⁷ Nevirapine-associated hepatitis can also be present as part of a hypersensitivity syndrome (e.g., skin rash, fever, and eosinophilia). Approximately two thirds of the cases of nevirapine-associated clinical hepatitis occur within the first 12 weeks of therapy. Fulminant and even fatal cases of hepatic necrosis have been reported. Victims may also experience nonspecific gastrointestinal and flu-like symptoms with or without increased liver enzyme levels. The syndrome can progress rapidly to hepatomegaly, jaundice, and hepatic failure within days. Because of the potential severity of clinical hepatitis, close monitoring of liver enzymes and clinical symptoms after nevirapine initiation is necessary (e.g., every 2 weeks for the first month; then monthly for the first 12 weeks, and every 1 to 3 months thereafter). Patients who experience severe hepatotoxicity while receiving nevirapine should not receive nevirapine therapy again in the future.

Specific Agents

DELAVIRDINE

Pharmacokinetic information and adverse effects of delavirdine (Fig. 53-10) are summarized in Table 53-1.^{46,48,78-82} Consequences of acute overdose with delavirdine have not been characterized.

FIGURE 53-10 Delavirdine.

EFAVIRENZ

For pharmacokinetic information and adverse effects of efavirenz (Fig. 53-11) see Table 53-1.^{46,49,80,81,83,84} The most significant adverse events observed in patients who take efavirenz chronically are neurotoxicity and rash.

FIGURE 53-11 Efavirenz.

Occasional cases of pancreatitis have also been described; increases in serum amylase levels have been observed in a significantly higher number of patients treated with 600 mg of efavirenz than in control patients. Increases in total cholesterol of 10% to 20% have been observed in clinical trials. Acute overdoses with efavirenz have not been reported.

NEVIRAPINE

For pharmacokinetic information on nevirapine (Fig. 53-12) see Table 53-1.^{46,53,80,81,85,86} Rash is the most frequently observed adverse effect with nevirapine, manifesting as a maculopapular eruption with or without fever, edema, myalgia, and arthralgia. This rash is in general mild and transient. However, severe fatal reactions such as Stevens-Johnson syndrome may occur. Nevirapine-associated rashes have been reported to

FIGURE 53-12 Nevirapine.

occur in as many as 48% after a starting dose of 400 mg/day. Starting with a lower dose and slowly increasing the dose reduced the occurrence of rashes to 9% to 32%. Hepatotoxicity is frequently observed in patients receiving nevirapine, occurring predominantly in the first 8 weeks of administration. Granulocytopenia has also been observed, particularly in children. Consequences of acute overdose with nevirapine have not been characterized.

GUANOSINE ANALOGS

The guanosine analogs include acyclovir, valaciclovir, ganciclovir, penciclovir, famciclovir, and valganciclovir. These agents exert their effect after being metabolized to their triphosphate form. The initial step in this process, the formation of the monophosphate form, is catalyzed by a thymidine kinase induced by herpes simplex virus types 1 and 2 and varicella-zoster virus in the infected cells or by a protein kinase produced by cytomegalovirus.^{1,2,87-89} In the triphosphate form, guanosine analogs inhibit the synthesis of viral DNA, either as a competitive inhibitor or as an alternative substrate with respect to the natural substrate (2'-deoxyguanosine triphosphate) for viral DNA poly-

merase. Once the guanine analog is inserted into the replicating viral DNA, synthesis stops. In this process, the triphosphate form of the guanosine analog is a potent inhibitor of herpes simplex type 1 DNA polymerase and of human cellular α -DNA polymerase.^{1,90} The limited production of the guanosine analog triphosphate form in uninfected cells and its specificity for viral DNA polymerase result in minimal cellular toxic effects.

Specific Agents

ACYCLOVIR

Pharmacokinetic information and adverse effects of acyclovir (Fig. 53-13) are summarized in Table 53-1.⁹¹⁻⁹⁴ The kidneys account for 75% of the total clearance of acyclovir. Renal clearance of this drug is approximately three times that of creatinine, suggesting that elimination occurs both by glomerular filtration and tubular secretion.⁹⁵ Neurotoxicity and nephrotoxicity by tubular crystal formation or by acute interstitial nephritis are potentially serious complications of acyclovir.^{93,96-99} The potential for neurotoxicity is increased when renal elimination is impaired.¹⁰⁰ Peak plasma acyclovir levels do not correlate well with symptoms of neurotoxicity.¹⁰¹⁻¹⁰⁵

FIGURE 53-13 Acyclovir.

There have been several reports of acyclovir overdose. In one, a neonate received an inadvertent overdose of 750 mg (220 mg/kg) intravenous acyclovir. Treated with saline hydration alone, he had only a transient increase in serum creatinine.¹⁰⁶ Neurotoxicity from acyclovir is more common in the elderly, in patients with renal dysfunction, or in patients taking other neurotoxic drugs.^{92,107-110} Acyclovir nephrotoxicity typically resolves after discontinuation of the drug. Extracorporeal clearance of acyclovir with hemodialysis can be of modest benefit.^{91,96,111} In serious neurotoxicity, hemodialysis should be considered.¹¹² Further treatment is supportive.

VALACYCLOVIR

For pharmacokinetic information and adverse effects of valacyclovir (Fig. 53-14) see Table 53-1.¹¹³⁻¹¹⁵ Valacyclovir, a prodrug, is the L-valyl ester of acyclovir.¹¹⁶ After ingestion, the drug is rapidly converted to acyclovir by the enzyme valacyclovir hydrolase in the gastrointestinal tract and liver.¹¹⁷ Its oral bioavailability is three to five times that of acyclovir.¹¹⁸ In terms of toxicity, a few cases of neurotoxicity in patients with end-stage renal disease are described.^{114,115,119} High-dose valacyclovir (8 g/day) has been associated with the development of thrombotic thrombocytopenic purpura, although HIV itself could not be excluded as the etiology in these reported cases.^{113,120} Treatment principles follow that of acyclovir.

FIGURE 53-14 Valacyclovir.

GANCICLOVIR

For pharmacokinetic information and adverse effects of ganciclovir (Fig. 53-15) see Table 53-1.^{121,122} Ganciclovir differs from acyclovir by the addition of a hydroxymethyl group at the 3' position of the acyclic side chain.⁵ The value of the oral formulation is limited due to its low bioavailability. The metabolism and action of ganciclovir are similar to those of acyclovir, although it is not an absolute DNA chain terminator.¹²³ Ganciclovir is converted to ganciclovir monophosphate by a viral-encoded phosphotransferase produced in cytomegalovirus-infected

FIGURE 53-15 Ganciclovir.

cells. Ganciclovir's affinity for this phosphotransferase is better than that of acyclovir. The intracellular half-life of ganciclovir triphosphate (12 hours) is significantly longer than that of acyclovir (1 to 2 hours). Hematologic toxicity from ganciclovir is increased by its combination with other myelotoxic drugs.¹²⁴ In one reported case, a cardiac transplant recipient received 50 mg/kg ganciclovir for 36 hours without immediate or delayed adverse effects or toxicity. In another series, two patients developed ventricular tachycardia and died after the intravenous administration of 5 mg/kg ganciclovir.¹²⁵ Retinal toxicity has been observed after a high intravitreal dose (400 μ g/0.1 mL).¹²⁶

PENCICLOVIR

For pharmacokinetic information and adverse effects of penciclovir (Fig. 53-16) see Table 53-1.⁵ Penciclovir is similar to the ganciclovir molecule, differing only by the substitution of a methylene bridge for the ether oxygen in the acyclic ribose part of the molecule.⁵ The oral bioavailability of penciclovir is poor. The drug is only approved for topical treatment of herpes labialis. Following intravenous administration, the volume of distribution is approximately 1.5 L/kg, with a mean terminal-phase half-life of 2.0 hours. Approximately 70% of drug is excreted unchanged in the urine.¹²⁷

FIGURE 53-16 Penciclovir.

FAMCICLOVIR

For pharmacokinetic information and a summary of adverse of famciclovir (Fig. 53-17) effects see Table 53-1.^{117,128,129} Famciclovir is an oral prodrug of penciclovir. It is well absorbed after oral administration and is

FIGURE 53-17 Famciclovir.

rapidly metabolized to penciclovir by deacetylation in the gastrointestinal tract, blood, and liver, after which it is oxidized by the liver at position 6 of the purine ring. The intracellular half-life of the active drug, penciclovir triphosphate, is long.¹¹⁷ Experience with acute toxicity is limited. A report of acute overdosage of 10.5 g was notable in the absence of significant symptoms.

VALGANCICLOVIR

For pharmacokinetic information and adverse effects of valganciclovir (Fig. 53-18), see Table 53-1.¹³⁰⁻¹³⁵

FIGURE 53-18 Valganciclovir.

Valganciclovir, the L-valyl ester of ganciclovir, is an orally administered prodrug of ganciclovir. Its oral bioavailability is good (10 times higher than ganciclovir). Valganciclovir is rapidly converted to ganciclovir. After its absorption the drug has pharmacokinetic properties approaching those of intravenously administered ganciclovir. Adverse effects are similar to those of intravenous ganciclovir and require periodic monitoring of complete blood count and renal function.

PROTEASE INHIBITORS

Most protease inhibitors contain a synthetic analog of the phenylalanine-proline sequence of the GAG-POL polyprotein.^{136,137} HIV protease inhibitors prevent cleavage of GAG and GAG-POL protein precursors in all infected cells, arresting maturation and blocking the infectivity of nascent viral particles. In order to achieve maximal drug levels, protease inhibitors often must be administered at high doses, potentially compromising tolerability and adherence.

Protease inhibitor-associated liver enzyme abnormalities can occur any time during the treatment course. In a retrospective review, severe hepatotoxicity (defined as an increase of greater than five times over baseline aspartate aminotransferase or alanine aminotransferase) was observed more often among patients receiving ritonavir or ritonavir/saquinavir-containing regimens than those receiving indinavir, nelfinavir, or saquinavir.¹³⁸ Other potential risk factors for hepatotoxicity include hepatitis B or C infection,¹³⁹⁻¹⁴² alcohol abuse,¹⁴¹ baseline elevated liver enzymes,¹⁴³ stavudine use,¹⁴² and concomitant use of other hepatotoxic agents.

Adverse Effects

HYPERLIPIDEMIA

Dyslipidemias are known to occur with the use of protease inhibitors; however, its frequency varies from an increased association with ritonavir to limited association with newer agents, indicating that hyperlipidemia might be a drug-specific toxicity rather than a class-specific toxicity.⁴¹ Moreover, the magnitude of changes varies substantially and occurs inconsistently. Frequently, anti-retroviral-associated dyslipidemias are sufficiently severe to require therapeutic intervention.

Indications for monitoring and intervention in HIV therapy-associated dyslipidemias are the same as among uninfected populations. Hypercholesterolemia might respond to 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors (statins). There is an increased risk for fat accumulation with the protease inhibitors, and whether specific drugs are more strongly associated with this toxicity is unclear.^{38,41}

HYPERGLYCEMIA

Protease inhibitors are associated with the development of hyperglycemia; the incidence does not vary substantially between the agents within this class.¹⁴⁴ The pathogenesis of these abnormalities has not been fully elucidated; it may result from peripheral and hepatic insulin resistance, relative insulin deficiency, or an impaired ability of the liver to extract insulin.^{145,146}

Specific Agents

AMPRENAVIR

Pharmacokinetic information and adverse effects of amprenavir (Fig. 53-19) are summarized in Table 53-1.^{81,82,147-150} Amprenavir is well tolerated. Acute overdoses with amprenavir have not been reported, but can be predicted to produce little significant toxicity.

FIGURE 53-19 Amprenavir.

INDINAVIR

See Table 53-1.^{81,136,150-152} The most significant adverse effect from indinavir (Fig. 53-20) is nephrolithiasis, which typically resolves after hydration. In one described

FIGURE 53-20 Indinavir.

case a patient ingested 6 g of indinavir, developing nausea and limb paresthesias. The patient was treated with activated charcoal and hydration. The symptoms resolved within 4 hours, and no nephrolithiasis occurred.¹⁵¹

LOPINAVIR

For pharmacokinetic information and adverse effects of lopinavir (Fig. 53-21) see Table 53-1.^{81,150} Acute overdoses with lopinavir have not been reported to date.

FIGURE 53-21 Lopinavir.

NELFINAVIR

For pharmacokinetic information and adverse effects of nelfinavir (Fig. 53-22) see Table 53-1.^{81,136,150,152,153} Nelfinavir is well tolerated. Other adverse events are rare. Rash (30%) and diarrhea (18%) are common with nelfinavir.¹⁵⁴

FIGURE 53-22 Nelfinavir.

RITONAVIR

For pharmacokinetic information and adverse effects of ritonavir (Fig. 53-23) see Table 53-1.^{81,136,150,152} Diarrhea is the most common adverse effect reported with ritonavir. One death due to pancreatitis was possibly caused by lopinavir/ritonavir, but it could have been related to the thymidine nucleoside analogs as well.¹⁵³ In a clinical trial, one patient ingested 1500 mg/day for 2 days. Paresthesias developed, which resolved after the dose was decreased.

FIGURE 53-23 Ritonavir.

OTHER AGENTS

Pharmacokinetic information and adverse effects for saquinavir (Fig. 53-24) and atazanavir (Fig. 53-25) are summarized in Table 53-1.^{81,136,150,152}

FIGURE 53-24 Saquinavir.

FIGURE 53-25 Atazanavir.

VIRUS CELL FUSION INHIBITORS (ENFUVIRTIDE)

Enveloped viruses undergo a fusion between their envelope and the host cell membrane that is followed by uncoating, after which the virus RNA enters the host cell. Thereafter, the RNA is read by reverse transcription to form DNA. The DNA integrates with the host DNA after which, via transcription replication of the virus genome,

FIGURE 53-26 Enfuvirtide.

the viral RNA is formed. After proteolytic processing by viral protease, the new virus genome and viral proteins are assembled at the cell membrane, from which new virions are released.

For HIV, the cell fusion is preceded by the interaction of gp120 with its coreceptor on the host cell: the C-X-C chemokine motif receptor-4 (CXCR4) for T-tropic or X4 HIV strains, or the C-C chemokine motif receptor 5 (CCR5) for M-tropic or R5 HIV strains. CXCR4 and CCR5 normally act as the receptors for the C-X-C chemokine stromal cell derived factor 1 (SDF1) and the C-C chemokines RANTES (regulated upon activation, normal T-cell expressed and secreted) and macrophage inflammatory protein 1 (MIP1), respectively. The interaction of gp120 with its coreceptor (CCR5 or CXCR4) triggers a series of changes in the gp120-gp41 complex. These changes ultimately lead to fusion of the viral and host cell membranes. Consequently, agents that interfere with the gp120-gp41 complex and its interaction with the cellular membrane might be expected to inhibit this fusion process.^{1,155}

Pharmacokinetic information and adverse effects are summarized in Table 53-1.^{156,157} Enfuvirtide (Fig. 53-26), or T-20, derived from the HR2 sequence of HIV-1, is a virus cell fusion inhibitor.¹⁵⁸ Enfuvirtide, a 36-amino-acid peptide, is not absorbed orally and must be administered subcutaneously.^{159,160} Mild injection site reactions are common with enfuvirtide. Approximately 3% of patients discontinue treatment because of local reactions.

M2 PROTEIN BLOCKERS

During the initial stage of viral entry, after it has been surrounded by a lipid layer, the cell. In the formed vesicles, after influx of hydrogen ions, the pH falls. This acidity is needed to allow the viral uncoating process (decapsidation), so that the ribonucleoprotein can enter the cell nucleus and initiate replication. Hydrogen ions pass through the M2 channel.^{2,161} Amantadine and rimantadine exert their function by blocking the viral M2 protein ion channel and its ability to modulate intracellular pH. Consequently, viral replication is hampered.

Specific Agents

AMANTADINE

For pharmacokinetic information and adverse effects of amantadine (Fig. 53-27) see Table 53-1.¹⁶²⁻¹⁶⁶ Amantadine hydrochloride is an amine with a unique 10-carbon ring.

FIGURE 53-27 Amantadine.

Besides anti-influenza A virus activity, amantadine is used as an antiparkinson drug. The drug blocks presynaptic reuptake of dopamine, resulting in higher levels of postsynaptic dopamine.

Amantadine is excreted unchanged in the urine; dose adjustments are required for relatively modest decrements in renal function (creatinine clearance less than 60 to 80 mL/min). However, even reduced dosage has been associated with excess rates of adverse effects and has required discontinuation of the drug.

Amantadine has many adverse effects, particularly in those with renal dysfunction and in the elderly, in whom peak concentrations are approximately three times as high as in younger adults given the same dose. The plasma half-life in the elderly is about 12 hours longer. Many cases of amantadine overdose and toxicity are reported in the literature. In general, iatrogenic poisoning occurred in the elderly or was related to renal or liver dysfunction. Hyperthermia, long QT interval, adult respiratory distress syndrome (ARDS), and death, resulting from one overdose of 12 g in a 37-year-old suicidal woman, have been reported.¹⁶⁷ Acute psychosis and hallucinations in adults (1.2 g in 24 hours) and children, coma (after ingestion of 600 mg), and death (after ingestion of 2 g) have all been reported.^{163,164,168-171} Furthermore, cardiac ventricular ectopic beats after ingesting 1.4 g (in 17-year-old girl) and torsades de pointes after ingesting 2.5 g (in a 37-year-old woman) have been reported.^{165,172} Rhabdomyolysis and an anticholinergic syndrome were seen in a patient with a combined poisoning of phenobarbital and amantadine (0.8 g).¹⁶² Treatment is mainly supportive.¹⁶⁷ Physostigmine may reverse anticholinergic neurologic symptoms in adults and children.^{166,171}

RIMANTADINE

For pharmacokinetic information and adverse effects of rimantadine (Fig. 53-28) see Table 53-1.¹⁷³⁻¹⁷⁵ Rimantadine hydrochloride is an analog of amantadine, with an amine inserted with a methylated carbon bridge between the amino group and the 10-carbon ring. Experience with overdose by this agent is limited. However, its profile of toxicity is likely to parallel that of amantadine.

FIGURE 53-28 Rimantadine.

NEURAMINIDASE INHIBITORS

Neuraminidase (sialidase) is a surface glycoprotein with enzymatic activity. Neuraminidase cleaves off the terminal sialic acid of the host cell receptor, allowing virus particles to leave the cell after the viral replicative cycle has been completed. The viral neuraminidase is therefore needed for the elution of newly formed particles from the cell. In addition, the viral neuraminidase might promote viral movement through the respiratory tract mucus, thereby enhancing viral infectivity.^{1,176}

Zanamivir and oseltamivir are both neuraminidase inhibitors with a similar rate of effectiveness against influenza A and B viruses.^{177,178}

Specific Agents

ZANAMIVIR

For pharmacokinetic information and adverse effects of zanamivir (Fig. 53-29) see Table 53-1.^{176,179,180} Zanamivir is administered by inhalation.¹⁸¹ Scintigraphic studies showed 13% of the inhaled 10-mg dose to be deposited

FIGURE 53-29 Zanamivir.

in bronchi and lungs, with 78% being deposited in the oropharynx. High concentrations are retained in tracheal and bronchial epithelium for 24 hours after a single 10-mg dose.¹⁷⁹ Impairment of renal function has no effect on maximal concentration (C_{max}) values.¹⁸⁰ Minor adverse effects have been reported in a minority of persons (fewer than 5%), although these effects were similar to those in placebo-control groups.¹⁷⁹ In patients with chronic respiratory disease (e.g., asthma), bronchospasm and ARDS have been reported.

OSELTAMIVIR

For pharmacokinetic information and adverse effects of oseltamivir (Fig. 53-30) see Table 53-1.^{179,182} Oseltamivir produces GI symptoms such as nausea and vomiting in about 10% of persons. When the drug is taken with food, the incidence of side effects is reduced, while pharmacokinetics were not altered.

FIGURE 53-30 Oseltamivir.

FOSCARNET

Foscarnet (Fig. 53-31) is a competitive inhibitor of the pyrophosphate binding site on the polymerases. Therefore, it acts by blocking viral DNA polymerase and reverse transcriptase, which are necessary for copying genetic material (from RNA to DNA). This copying process is required for the reproduction of the virus.

FIGURE 53-31 Foscarnet.

For pharmacokinetic information and adverse effects see Table 53-1.¹⁸³⁻¹⁸⁵ The most common adverse effect from foscarnet, nephrotoxicity, seems to be dose dependent.¹⁸⁶ To reduce the risk for nephrotoxicity, creatinine clearance should be calculated even if the serum creatinine is within the normal range. Drug dose should be adjusted accordingly. Adequate hydration reduces the risk for nephrotoxicity. Due to foscarnet's propensity to chelate divalent metal ions, such as calcium, magnesium, iron, and zinc, serum concentrations of these ions should be monitored. Hypocalcemia has been reported after foscarnet is administered in combination with pentamidine or after rapid infusion. Severe hypocalcemia might lead to Trousseau's and Chvostek's signs, seizures, and heart rhythm disturbances.^{183,187-190} Other electrolyte changes (e.g., hypokalemia, hypophosphatemia, and hyperphosphatemia) have been reported. Since foscarnet is excreted in high concentrations in the urine, local irritation and ulceration may ensue.^{191,192} In patients with severe intoxication, hemodialysis and hydration may be of benefit in reducing drug plasma concentrations, but the effectiveness of these interventions has not been evaluated.

CIDOFOVIR

For pharmacokinetic information and adverse effects of cidofovir (Fig. 53-32) see Table 53-1.^{65,193-195} After

FIGURE 53-32 Cidofovir.

intracellular phosphorylation to the diphosphate form, and incorporation at the 3' end of the viral chain, cidofovir acts as a chain terminator.² Nephrotoxicity is common after overdose with this agent. Concomitant oral probenecid decreases both the renal clearance of cidofovir and the incidence of nephrotoxicity.

RIBAVIRIN

For pharmacokinetic information and adverse effects of ribavirin (Fig. 53-33) see Table 53-1.¹⁹⁶⁻²⁰¹ Ribavirin interacts (in its 5'-monophosphate form) with inosine monophosphate (IMP) dehydrogenase, which converts (IMP) to xanthosine monophosphate, a key step in the biosynthesis of guanosine triphosphate and deoxyguanosine triphosphate. In its 5'-triphosphate form, ribavirin can also interfere with the viral RNA polymerase and the 5'-capped oligonucleotide primer formation required for transcription of the influenza genome. It is administered in an aerosol and orally.

FIGURE 53-33 Ribavirin.

Adverse effects from ribavirin have been reported. Water intoxication in a 6-week-old girl was observed after a nebulized dose of 6 g in 100 mL distilled water four times daily. On day 2, convulsions occurred and plasma sodium was 108 mmol/L.²⁰² An 8-week-old girl was treated with 6 g in 300 mL distilled water nebulized for 18 hours when seizures occurred, and plasma sodium was 116 mmol/L.²⁰³ Treatment is supportive.

Ribavirin is administered as an aerosol, with delivery of the drug into a mist tent, hood, or ventilator. In certain small animals dosed systematically with ribavirin, teratogenicity and embryopathy have been found. Furthermore, ribavirin can significantly affect sperm morphology in rats; it is a germ cell mutagen in rats. These effects in experimental models have led to concerns about exposure to health care personnel administering aerosolized ribavirin and have significantly reduced its use in the health care setting. Though the effect on fetal development in humans is not known, it is recommended that occupational exposure to ribavirin aerosol be minimized as much as possible.

PALIVIZUMAB

For pharmacokinetic information and adverse effects of palivizumab see Table 53-1.^{204,205} Palivizumab is a humanized monoclonal immunoglobulin G1 antibody to the fusion protein of the respiratory syncytial virus (RSV) that is highly active against RSV A and B strains. Adverse effects are mild and transient.

54 Anthelmintics

MAHESH SHRESTHA, MD ■ DANIEL C. KEYES, MD, MPH

At a Glance...

- The anthelmintics include:
 - Imidazoles (mebendazole, albendazole, thiabendazole, flubendazole, niridazole)
 - Piperazines (diethylcarbamazine)
 - Antischistosomal agents (praziquantel, metrifonate, oxamniquine, hycanthone)
 - Unclassified (ivermectin, niclosamide, suramin, pyrantel pamoate, pyrvinium pamoate, antimony)
- The anthelmintics are a broad range of substances with variable toxicity. Most are designed to be neurotoxic to helminths and other parasites.
- While many of the older anthelmintics contain known toxins (e.g., antimony), newer agents have a significantly better safety profile.
- The major clinical toxicity of these agents is neurologic; many produce seizures.
- Treatment of anthelmintics overdose is supportive; no antidotes are available.

Infections caused by worms, or helminths, may be the most prevalent of all human infections. It has been estimated that there may be as many worms infecting people as there are people.¹ A thorough review of all the helminths, the clinical syndromes caused, and their diagnoses and treatments are beyond the scope of this chapter. The major organisms are briefly examined, followed by a discussion of the individual chemotherapeutic agents used to treat the infections they cause. Although the mechanisms of action of the anthelmintic medications are poorly understood,² they are presented whenever available. A discussion of toxicities of individual agents concludes this chapter.

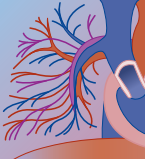

Helminths are divided into three broad categories: nematodes (roundworms), trematodes (flatworms, or flukes), and cestodes (tapeworms).

Nematodes include two general categories, intestinal nematodes and tissue nematodes. Intestinal nematodes include the abundant *Ascaris lumbricoides* (giant roundworm), *Trichuris trichiura* (whipworm), and *Enterobius vermicularis* (pinworm), as well as the hookworms *Ancylostoma duodenale* (European hookworm), *Necator americanus* (North American hookworm), and *Strongyloides stercoralis*. In the United States, *E. vermicularis*, which causes pruritus ani, is the most common of all helminthic parasites, infecting 42 million people.³ The prevalence of strongyloidiasis in the southern United States is estimated at 0.4% to 4%. The other helminths are found mainly in tropical areas of the globe, but they are also present in the southeastern United States. It is estimated

that 1 billion of the world's population (4.4 million in the United States) are infected with *A. lumbricoides*, 800 million (2.2 million in the United States) with *T. trichiura*, and one fourth of the world's population with hookworm. Hookworm disease was controlled almost in its entirety in the United States during the early part of this century and is uncommon here. The treatment of choice for all of these intestinal nematode infections, except strongyloidiasis, is mebendazole, an imidazole. Thiabendazole, a related compound, is currently the treatment of choice for strongyloidiasis. Albendazole is the newest of this group of medications. It achieves greater tissue levels and has a broader spectrum of activity. Pyrantel pamoate can also be used.

Tissue nematodes include *Trichinella spiralis* (the causative agent of trichinosis), *Dracunculus medinensis* (causing skin ulcers through which the worm appears), the three causative agents of filariasis (*Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*), *Loa loa*, and *Onchocerca volvulus*. No completely effective treatment has been found for trichinosis, but use of thiabendazole is recommended within 24 hours for patients known to have ingested trichinous meat. Thiabendazole or metronidazole is recommended for the inflammation of dracunculiasis so that the worms themselves can be physically removed by rolling them on a stick during the course of a week. Filariasis is characterized by acute and chronic lymphatic inflammation eventually resulting in elephantiasis, hydrocele, and chyluria. There is no satisfactory treatment, but administration of diethylcarbamazine reduces the number of microfilaria. Diethylcarbamazine is also effective against *L. loa* and *O. volvulus*. *L. loa* is characterized by transient subcutaneous swellings (Calabar swellings). *O. volvulus* is the causative agent of river blindness, named for the blackfly that breeds in fast streams, which has caused blindness in whole African villages. The newer drug ivermectin is safer and more effective than diethylcarbamazine for onchocerciasis (but may be contraindicated for *L. loa*, which has been associated with encephalopathy¹). Albendazole is the newest of this group of medications (imidazoles) and produces greater tissue levels and a broader spectrum of activity.

Trematodes include the blood flukes, or schistosomes (*Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma haematobium*, and *Schistosoma mekongi*), which are one of the world's major public health concerns; the liver flukes (*Clonorchis sinensis* and *Fasciola hepatica*); the lung fluke *Paragonimus westermani*; and the intestinal fluke *Fasciolopsis buski*. Praziquantel is the drug of choice for all of these organisms (except *F. hepatica*, for which bithionol is used) and has revolutionized treatment. Metrifonate is effective against *S. haematobium*, and oxamniquine is effective against *S. mansoni*.

Cestodes, segmented worms or tapeworms, include the beef tapeworm (*Taenia saginata*), the pork tapeworm (*Taenia solium*, whose eggs cause human cysticercosis), the fish tapeworm (*Diphyllobothrium latum*), the dwarf tapeworm (*Hymenolepis nana*), and *Echinococcus granulosus*, the causative agent of echinococcosis, or hydatid disease. Niclosamide is the usual drug given to eradicate the adult tapeworms, but paromomycin and praziquantel are also effective. For human cysticercosis, praziquantel (with corticosteroids) is the drug of choice, and for hydatid cyst disease, albendazole with surgical removal is effective.

Other helminthic infections include visceral larva migrans (toxocariasis), cutaneous larva migrans (creeping eruption, caused by *Ancylostoma braziliense*, the dog or cat hookworm), and dirofilariasis. Most patients recover from visceral larva migrans without specific therapy. Thiabendazole has been used along with other agents for severe cases. Thiabendazole administered either orally or topically has also been used successfully for cutaneous larva migrans. *Dirofilaria immitis* is the causative agent of the dog heartworm. In humans, the immature filariae die, causing a local vasculitis in the pulmonary circulation. This may be seen occasionally as a coin lesion on the chest radiograph.

The drugs mentioned earlier are the most common anthelmintics used. Older drugs such as those in the antimony group—pyrantel pamoate, poquil, bephenium hydroxynaphthoate, and hycanthon—have special applications and may still be in use, especially in less developed countries and in veterinary medicine. Levamisole, related to mebendazole, and suramin, in use since 1920, have found newer uses as chemotherapeutic agents in the treatment of certain cancers.

In general, the older medications are more toxic to humans than the newer ones. The older medications have reported protean side effects, some of which are worse than the disease being treated. On other occasions, the side effects may be mistaken for progression or complications of the disease itself. It is important to remember that many of the side effects of treatment, such as with praziquantel for cysticercosis or with diethylcarbamazine for onchocerciasis (ivermectin is now used), are due to the large antigenic mass of dying worms released into the bloodstream. Similarly, many side effects are really not side effects of the medication because they probably would not occur if uninfected patients were given the same treatment. Pretreatment or concurrent treatment with corticosteroids is used in some cases, and slow progressive therapy is used in others. Medications that are not significantly absorbed (and thus have insignificant systemic toxicity), such as mebendazole, are ideal for susceptible helminths that are limited to the lumen of the gastrointestinal (GI) tract.

In the review that follows, the many agents available are divided into intuitive groups: imidazoles (mebendazole and related compounds), piperazines (diethylcarbamazine and piperazine), drugs identified for schistosomiasis (praziquantel, metrifonate, and others), and other important anthelmintics, such as ivermectin and suramin.

IMIDAZOLES

Mebendazole

Mebendazole is a drug commonly used in the treatment of intestinal nematodal disease, such as ascariasis, trichiuriasis, hookworm (*N. americanus* or *A. duodenale*), and enterobiasis (pinworm). Like the other benzimidazoles, it is thought to selectively and irreversibly block microtubular-dependent glucose uptake by nematodes and cestodes by binding to free β -tubulin and inhibiting tubulin polymerization.⁵ Only 5% to 10% of an orally ingested dose is absorbed from the GI tract. Most of what is absorbed is metabolized in the liver (P-450 system) with a significant first pass effect. Thus, adverse reactions attributable to the medication itself are practically nonexistent, although diarrhea and abdominal pain have been reported. The usual dose used is 100 mg twice daily for 3 days. For pinworm infection, one 100-mg tablet given once is sufficient. A repeat dose a week later is recommended to kill nematodes that were protected as eggs at the time of initial mebendazole administration. Treatment of all family members is also recommended.

Mebendazole has also been used to treat hydatid disease (echinococcal cysts); a reduction in cyst size has been demonstrated with prolonged treatment. Albendazole, a related imidazole with better absorption, has now replaced mebendazole for this use. Albendazole is given in 4-week cycles of 400 mg, twice daily, separated by 2-week rest periods. At least three cycles are given. When albendazole is given in these higher doses, pyrexia has been noted; it is thought to be due to tissue necrosis of the hydatid cyst.

Another reported side effect of mebendazole is agranulocytosis. In a Russian study, this complication was found in 2 of 75 patients with hydatid cysts treated with 50 mg/kg per day for 30 days, resulting in the death of one patient.⁶ Mebendazole has been shown to be teratogenic and embryotoxic in laboratory animals and so is contraindicated in pregnancy and in those younger than 2 years. Cimetidine, by inhibiting the P-450 system, may increase blood levels. There have been reports of contact urticaria and contact dermatitis from albendazole.⁷ An outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis among those treated with both mebendazole and metronidazole has been reported.⁸

Treatment of poisoning includes decontamination in cases of overdose and is otherwise symptomatic and supportive.

Albendazole

Albendazole is similar to mebendazole but is more completely absorbed from the GI tract. It has a broader spectrum of activity. Its absorption is enhanced by taking it with fatty meals.⁹ One of its main uses is in adjunctive treatment with surgery (or single-agent treatment without surgery) in hydatid cyst disease due to echinococci.¹⁰ Mebendazole is probably as effective for most nematodal diseases isolated to the lumen of the

GI tract. Albendazole appears to be more effective for hookworm.¹¹ It is also effective against intestinal tapeworms and neurocysticercosis, for which it is an alternative to niclosamide and praziquantel, respectively. In one trial, it was more effective than praziquantel in neurocysticercosis.¹²

Albendazole is rapidly metabolized by the liver into an active metabolite that has a terminal half-life of 8.5 hours. It is given in at least three 4-week cycles separated by 2-week rest periods at a dose of 400 mg twice daily (10 to 14 mg/kg/day) when used for hydatid cyst disease. Side effects are similar to those for mebendazole and usually do not require discontinuation. It, too, has been shown to be teratogenic in animals (rats and rabbits) and is not recommended in pregnancy or in infants younger than 2 years. In one review only GI side effects were seen, and only at the low rate of slightly over 1%.¹³ Treatment of poisonings is symptomatic and supportive (see also the later discussion of side effects in the section on Thiabendazole).

Thiabendazole

Thiabendazole, like albendazole, is also rapidly absorbed through the GI tract, metabolized by the hepatic P-450 system, and excreted by the kidneys in the first 24 hours. It is also available for topical application for cutaneous larva migrans. In addition to binding free β -tubulin, it inhibits the helminth-specific fumarate reductase enzyme system. It is the treatment of choice for strongyloidiasis, for which the dosage is 25 mg/kg twice daily (maximum, 3 g/day) for 2 days. In immunocompromised hosts (e.g., human immunodeficiency virus-infected patients or those with cancer), a hyperinfection syndrome from *S. stercoralis* can develop. Infective filariform larvae reenter the host via the lower GI tract or perianal regions in massive numbers. For this, thiabendazole is given at 25 mg/kg twice daily for 2 to 3 weeks.¹⁴

Thiabendazole has also been used for cutaneous larva migrans (creeping eruption, caused by *A. braziliensis*), visceral larva migrans, and trichinosis (*T. spiralis*), all of which have no proven therapy. Thiabendazole may serve only to decrease the load of growing organisms. It has also been used, at a dose of 25 mg/kg twice daily for 2 days, to treat *D. medinensis* infection (dracontiasis), when it helps to decrease inflammation, allowing slow removal of the helminth by winding it on stick during the course of a week.¹⁵ Metronidazole has also been used for this same purpose.

Numerous adverse reactions have been loosely attributed to thiabendazole. Most reactions are transient and not serious. These include GI effects such as anorexia, nausea, epigastric discomfort, and diarrhea; generalized complaints such as dizziness, drowsiness, weakness, and pruritus; and nervous system complaints such as headaches, tinnitus, and blurred vision. Also reported are hypotension, bradycardia, crystalluria, and malodorous urine. Self-limited abnormalities may be cholestasis, leukopenia, elevated liver transaminase levels, jaundice, and hyperglycemia. Nephrotoxicity has

been reported, as has inhibition of hepatic metabolism of theophylline, which would be expected because both drugs are metabolized by the hepatic P-450 system. In mice, subchronic exposure caused slight anemia (hemosiderosis and extramedullary hematopoiesis), liver injury (elevated transaminases), and kidney injury (tubular atrophy).¹⁶ Hypersensitivity reactions are also reported and include fever/chills, rashes, angioedema, erythema multiforme, Stevens-Johnson syndrome, and anaphylaxis. Allergy to topically applied medication has also been reported.¹⁷

Treatment for intoxication with this agent is supportive. Thiabendazole should be avoided by patients with liver and kidney disease. Levels of other hepatic P-450-metabolized medications should be monitored. Because of the possibility of drowsiness due to this drug, heavy machinery should not be operated by patients under treatment. Its safety has not been established in pregnancy or lactation.

Flubendazole

Flubendazole is the parafluoro analog of mebendazole. Interestingly, it is absorbed better from the GI tract when taken with or after a meal. It is also available in a slow-release parenteral preparation given subcutaneously or intramuscularly, which allows sustained release over 5 days. The usual dosage is 750 mg/wk for onchocerciasis. It is used to treat hookworm, *T. trichiura*, and *A. lumbricoides*. Side effects are vague and mostly abdominal, such as nausea, abdominal pain and rumbling, soft/loose stools, and dyspepsia. Also reported are fatigue and breathlessness. Unlike mebendazole, it has not yet been shown to be teratogenic in laboratory animals. Treatment of poisoning is supportive. If side effects are severe, flubendazole may have to be withdrawn.

Levamisole

Levamisole is the more nematocidal L-isomer of tetramisole. Its mechanism of action is thought to be rapid and reversible muscle paralysis of the helminth due to ganglionic stimulation. Like thiabendazole, at high doses, it also inhibits the helminthic fumarate reductase system. It is available as syrup or in a tablet, is rapidly absorbed from the GI tract, and is extensively metabolized. Its use is mainly for nematodal disease such as ascariasis, for which it can be given in a single 120- to 150-mg dose.

Today levamisole is used more in combination chemotherapy for cancer (e.g., with 5-fluorouracil in colon cancer) than as an anthelmintic. The doses when used in this manner are different, and more side effects have become evident. Agranulocytosis develops when levamisole is used for a prolonged period.¹⁸ Thrombocytopenia occurring as late as 2 years after its use has been reported.¹⁹ Many skin reactions have been reported, most recently a fixed toxic erythema with pigmentation.²⁰ Also reported are cases of multifocal inflammatory leukoencephalopathy when used with 5-fluorouracil.²¹ In patients taking warfarin, the international normalization

ratio has been reported to increase.²² This may be because of its competitive inhibition of hepatic P-450 system metabolism of warfarin.

Treatment of poisoning is supportive. Severe effects mandate discontinuation of its use.

Niridazole

Niridazole is also an imidazole (a substituted nitrothiazole), but it does not have the same uses as the others. It also has the distinction of suppressing cellular immunity and possibly being carcinogenic. Fifty percent of oral intake is absorbed. It is excreted in the feces and urine after it has been metabolized in the liver. It has a metabolite with a half-life of 40 hours, and this is responsible for the prolonged immune suppression encountered. It causes the urine to become very dark, and patients should be warned about this.

Its main uses are for *S. japonicum* and *S. mansoni* infections, amebiasis, and dracontiasis, in which it may be used like thiabendazole as an anti-inflammatory. It is not as effective against the other species of schistosomes. In general, its use has become obsolete.

Its toxicity includes nervous system problems such as seizures (usually limited to patients with a seizure disorder), subclinical electroencephalographic changes, headaches, dizziness, agitation, insomnia, and hallucinations (usually only in patients with a history of psychosis). In the treatment of schistosomiasis, it is possible that some of the central nervous system effects are due to high drug levels because of hepatic shunting. Other side effects include GI effects such as nausea, vomiting, and abdominal pain. Also reported are rash, slight electrocardiographic abnormalities, and hemolytic anemia in patients with glucose-6-phosphatase deficiency.

Treatment of the toxicity is supportive. It should not be used by patients with a seizure disorder, liver disease, or psychosis.

PIPERAZINES

Piperazine

Piperazine causes paralysis of the helminth and is thought to precipitate expulsion of the helminth from the GI tract. It is orally absorbed and is excreted unchanged in the urine within 24 hours. Its uses include treatment of enterobiasis (pinworm infection), 65 mg/kg/day (maximum 2.5 g) for 7 days; and ascariasis, 75 mg/kg/day (maximum 3.5 g) for 2 days. In cases of intestinal obstruction due to large worm burdens, it is recommended that piperazine syrup be given via nasogastric tube at a dose of 150 mg/kg then 65 mg/kg every 12 hours for 6 doses. It narcotizes the worm in the intestinal or biliary tract, allowing its passage distally.²³

Side effects are rare but can affect many organ systems. GI symptoms include nausea and vomiting, diarrhea, and abdominal pain. General symptoms include fever, weakness, and rash. Angioneurotic edema has been reported in sensitive patients.²⁴ Neurologic abnormalities include visual disturbances, seizures and electroen-

cephalographic abnormalities, and cerebellar ataxia, known as “worm wobble.”²⁵ The latter abnormalities are seen mainly in patients with overdoses or with renal failure in which the accumulated levels have become toxic.

Treatment of side effects and toxicities includes discontinuation of treatment and administration of antihistamines if the effects seem to be allergic in nature. Other side effects are treated symptomatically. Piperazine is not recommended for patients with hepatic or renal disturbance or with seizures. Its safety in pregnancy has not been established. There has been a report that it may be linked with cleft hand and foot.²⁶

Diethylcarbamazine

Diethylcarbamazine is still in use in many parts of the world. In the United States, it may be found in dog-owning households because it is a treatment for *D. immitis*, the dog heartworm. Ivermectin has become popular for prophylaxis of this condition (discussed later). Diethylcarbamazine is highly soluble in water and is well absorbed through the GI tract. Its renal clearance is reduced in alkaline urine. It is also available as a lotion for onchocerciasis. In addition to its canine use, it can be used to treat filariasis and *O. volvulus*. In filariasis, like thiabendazole, it may do no more than reduce the number of microfilariae of *W. bancrofti* and *B. malayi* (6 mg/kg daily for 2 weeks). Its effect on adult worms is uncertain, although a higher dose repeated monthly or weekly may be effective.²⁷ In the treatment of *L. loa*, it eliminates the microfilariae and may also kill the adult worms.

In the treatment of onchocerciasis (and also of filariasis to a lesser degree) with diethylcarbamazine, a severe reaction, probably an immune response to the mass of dying antigenic microfilariae, may develop 16 hours after treatment. It consists of severe pruritus, a fine papular rash, skin edema, fever, tachycardia, headache, swollen lymph nodes, and possibly hypotension. This reaction was first described in 1948 and is called the Mazzotti reaction.²⁸ For this reason, it is recommended that the diethylcarbamazine dose be gradually increased from 50 mg once per day on day 1, to 50 mg three times per day on day 2, to 100 mg three times per day on day 3, to the full 3 mg/kg three times per day on days 4 through 21. Levels of the immune mediator interleukin-6 correlate with the occurrence and severity of clinical symptoms after treatment. Tumor necrosis factors also are elevated in patients with reactions.²⁹ The Mazzotti reaction can also be used to test whether a rash is caused by *O. volvulus*. This is done by giving a test dose of 50 mg of diethylcarbamazine. If the rash worsens, it probably is due to a reaction against *O. volvulus*. Ivermectin (discussed later) has replaced diethylcarbamazine as the drug of choice in the treatment of onchocerciasis because it is safer and more effective. The Mazzotti reaction has also been seen with ivermectin treatment.³⁰

Other side effects include changes in the posterior segment of the eye (transient pigment lesions, optic disc leakage, and visual loss).³¹ *L. loa* encephalopathy may be aggravated. Pretreatment or concurrent treatment

with corticosteroids is helpful. A transient proteinuria, possibly resulting from circulating immune complexes, has also been described in patients.³²

ANTISCHISTOSOME MEDICATIONS

Praziquantel

The development of praziquantel has been a major advance in the control of schistosomiasis. It also has many other anthelmintic uses. It is readily absorbed through the GI tract and excreted by the kidneys. It can be detected in human breast milk. Its mode of action is not clearly understood. Bioavailability is limited by an extensive first pass effect through liver metabolism. This is exacerbated by dexamethasone and antiepileptic medication (through P-450 induction), often given concomitantly with praziquantel in patients with neurocysticercosis.^{33,34} Cimetidine, which inhibits P-450 metabolism, lengthens the drug's elimination half-life.³⁵

It is effective against all schistosomes as well as most of the other trematodes (flukes).³⁶ For *S. haematobium* and *S. mansoni*, it is given as a single 40 mg/kg dose, and for *S. japonicum* it is given as 20 mg/kg three times in 1 day. For *C. sinensis*, it is the treatment of choice. Surgery may be necessary for biliary obstruction. *Clonorchis* and intestinal flukes (*F. buski* and *Heterophyes heterophyes*) are treated with a dose of 25 mg/kg three times per day for 1 day. The lung fluke (*Paragonimus*) is treated with 25 mg/kg three times per day for 2 days. The only fluke not responsive to praziquantel is *F. hepatica*, for which bithionol must be used.

In addition to the trematodes, praziquantel is also effective against the cestodes (tapeworms). *T. saginata* (beef tapeworm), *T. solium* (pork tapeworm), and *Diphyllobothrium nana* (fish tapeworm) are treated with 10 mg/kg as a single dose, and *H. nana* (dwarf tapeworm) is treated with 25 mg/kg as a single dose. For human cysticercosis, infection with *T. solium* eggs, treatment is with 50 mg/kg per day in three divided doses for 2 weeks. This is usually given with corticosteroids to avoid the immunologic reaction common with the large antigenic load that is released. It may also have a role in the treatment of *Echinococcus*.

Side effects and toxicity from praziquantel are usually a result of the treatment of the infection rather than of the medication per se. When all inhabitants in an area of high prevalence of *S. mansoni* (61.8%) were treated, 27.2% had side effects (abdominal discomfort, fever, headache), mostly mild, disappearing in 24 hours, correlating with those that were infected.³⁷

Toxicity is rare. Mild toxicity does not require discontinuance of medication. If toxicity is from the rapid killing of worms, corticosteroids may be administered if not already given.

Metrifonate

Metrifonate, also called trichlorfon, is an organophosphorus compound that is selective for treatment of *S. haematobium*. It is nonenzymatically transformed into

dichlorvos and inhibits plasma cholinesterase activity. It inhibits erythrocyte cholinesterase to a lesser degree. The dose is 7.5 mg/kg (range, 5 to 15) every 2 weeks for 6 weeks.

Side effects include those of other cholinergic medications if taken in sufficient quantity. Suicide attempts among patients using metrifonate have been reported. Also reported have been cases of polyneuropathy.³⁸ Management of toxicity is similar to that with other cholinergic medication.

Oxamniquine

Oxamniquine is an antischistosomal quinoline compound selective for *S. mansoni*. Fifty percent of an oral dose is absorbed; most is excreted in the urine. A metabolite turns the urine dark orange or reddish on the second day. The dosage used varies from 60 mg/kg over 3 days in Egypt or East Africa to a low of 12 mg/kg as a single dose.

Side effects are frequent but usually mild and are likely due to immune reactions to the release antigenic load rather than the medication itself. They include dizziness, headache, vague abdominal pain, nausea, vomiting, and transient increases in results of liver function tests, especially in older patients. In one report, 38% had fever of 38° C to 39° C often 24 to 72 hours after completing a 3-day treatment. Six of 40 developed Löffler's syndrome with transient pulmonary infiltrates and eosinophilia.^{32,39} Treatment is supportive.

Hycanthone

Hycanthone (Etronol) has an unknown mechanism of action but is effective against *S. haematobium* and *S. mansoni*. It has good GI absorption and can also be given intramuscularly. It is not sold in the United States.

Side effects are frequent but mild and self-limited. The complaints usually are of GI origin (nausea, vomiting, and abdominal pain) or generalized (weakness, dizziness, headache, and myalgias). Very rarely a serious hepatic necrosis can occur. Hycanthone is mutagenic, carcinogenic, and teratogenic in animals and therefore should not be given to pregnant women until 1 month after delivery, nor to children or young adults. It should also be avoided by patients with liver disease. Treatment is symptomatic and supportive.

Niridazole was discussed earlier in the section on imidazoles.

OTHER ANTHELMINTICS

Other anthelmintics, such as ivermectin and niclosamide, are in common use around the world, and others are of primarily historical importance. Some of the latter are still used in developing countries.

Ivermectin

Ivermectin enjoys widespread use around the world. In the United States, it is used primarily for prophylaxis and

treatment of heartworm in dogs. It is often the object of calls to regional poison control centers.

Ivermectin is from a family of chemicals called avermectins. These are macrocyclic lactones from the fermentation broth of *Streptomyces avermitilis*. It is thought to work by opening chloride-sensitive channels. In the free-living nematode *Aeorhabditis elegans*, it binds to a glutamate-gated chloride channel.⁴⁰

It is active primarily in nematodes and is the drug of choice for the treatment of onchocerciasis. It kills the microfilariae of *O. volvulus* but not the adults. Sumarin (discussed later) is the only agent that kills the adults. It is also used to treat *D. immitis* (heartworm) in dogs. For onchocerciasis, it is given in a dose of 150 µg/kg as a single dose. It has been tried in the treatment of lymphatic filariasis (single dose), clearing microfilariae from the blood, but is not active against adult filarial worms in the lymphatic system.⁴¹ It can also be used as an alternative to mebendazole in the treatment of intestinal nematodes.⁴²

Adverse reactions are fairly numerous and may be related to the worm burden rather than the medication itself. Encephalopathy has been temporally related to ivermectin administration, most cases when the patients may have also had *L. loa*.⁴ In another report, 97% had side effects when ivermectin was used to treat *W. bancrofti*. These consisted of fever, headache, pruritic rash, weakness, myalgias, lymphatic nodules, cough, and elevated alkaline phosphatase levels, all of which subsided in 12 to 72 hours after treatment. Some patients with very dense infection developed serious pulmonary symptoms consisting of cough with production of blood-tinged sputum, shortness of breath, and patchy pneumonitis.⁴³ Some patients, however, had heavy worm burdens but did not develop side effects. Other reported side effects include facial edema and bullous skin disease.⁴⁴ Treatment is symptomatic.

Niclosamide

Niclosamide (Yomesan) is not absorbed through the GI tract and therefore has almost no side effects. It is used to treat cestodes (tapeworms), which include *T. saginata* (beef tapeworm), *T. solium* (pork tapeworm), *D. latum* (fish tapeworm), and *H. nana* (dwarf tapeworm). It is not effective against cysticercosis (eggs of *T. solium*) or *E. granulosus* (hydatid disease), because these require tissue penetration.

Patients occasionally complain of GI symptoms, such as abdominal cramping and nausea. Treatment is supportive and symptomatic.

Suramin

Suramin is an antiparasitic drug that is now used in cancer chemotherapy. It was introduced in 1920 for the treatment of African trypanosomiasis and began to be used in 1947 for the treatment of onchocerciasis. It is the only medication that kills the adult *O. volvulus*. It is not well absorbed orally, and intramuscular injection causes significant local skin irritation; thus, it is given

intravenously. Its elimination half-life is 36 to 54 hours. Nearly 100% (99.9%) is protein bound.

It is recommended for onchocerciasis only if the patient has recurrent skin disease after treatment with ivermectin and several courses of diethylcarbamazine or for patients with eye disease. A test dose of 100 mg is first given, and if this is tolerated, 1.0 g is given intravenously each week for 6 weeks. Treatment is stopped if proteinuria or casts appear in the urine or if exfoliative dermatitis develops.

Suramin toxicity can result in renal and adrenal insufficiency, coagulation factor abnormalities, immune suppression, and polyneuropathy.

Other side effects include a wide variety of skin eruptions,⁴⁵ including a lethal toxic epidermal necrolysis,⁴⁶ and weakness due to hypophosphatemia, mitochondrial myopathy,⁴⁷ or motor axonal polyneuropathy (some with sensory symptoms).⁴⁸ Treatment is supportive and symptomatic. The drug should be withdrawn if side effects occur.

Pyrantel Pamoate

Pyrantel pamoate is a depolarizing neuromuscular blocker. It results in spastic neuromuscular paralysis of the parasite, allowing its expulsion. It is poorly absorbed from the GI tract; 40% is excreted in the feces, and small amounts are detectable in the urine. It is used for enterobiasis (pinworm), ascariasis (giant roundworm), and *N. americanus* (hookworm) infections. The usual dose is 11 mg/kg orally once (maximum 1 g), repeated after 2 weeks.

Because most of an oral ingestion remains in the lumen of the GI tract, the medication itself has very few side effects. Most of the side effects are from the parasitic burden. These include nausea, vomiting, abdominal pain, tenesmus, headache, dizziness, insomnia, drowsiness, fever, rash, and nasal congestion. Liver transaminase levels may become transiently elevated. Use of pyrantel pamoate is contraindicated in pregnancy, in those younger than 1 year, and in patients with liver disease. Treatment is symptomatic and supportive.

Pyrvinium Pamoate

Pyrvinium pamoate, like pyrantel pamoate, is useful to eliminate certain intestinal parasites because of its minimal absorption from the GI tract. Patients should be warned of changes in stool color, which most often becomes red. It has been largely replaced by mebendazole for the treatment of enterobiasis (oxyuriasis).

It produces minimal side effects, with occasional nausea, vomiting, and abdominal pain. A photosensitive skin reaction has also been reported. Treatment is symptomatic.

Poquil

Poquil has been used for the treatment of enterobiasis (oxyuriasis) at a dose of 1.5 mg/kg per day for 8 days. Mebendazole treatment is simpler (one dose) and is the

agent of choice. Poquil is well tolerated, although occasional nausea and vomiting are reported. It causes a bitter taste in the mouth. Treatment of intoxication is symptomatic and supportive. If vomiting or other effects are severe, it should be discontinued.

Antimony

The trivalent antimonials act by inhibition of phosphofructokinase. They have to be administered intravenously because oral ingestion leads to significant GI irritation. They bind to erythrocytes and thus have slow renal excretion, on the order of weeks to months.

Trivalent antimony has been replaced by other medications for most helminthiasis, but on occasion they are used, mainly for schistosomiasis. *S. japonicum* responds to antimony potassium tartate and antimony sodium dimercaptosuccinate. *S. haematobium* and *S. mansoni* also respond to antimony sodium dimercaptosuccinate. *S. mansoni* also responds to stibophen.

The antimonials have many toxicities. They are contraindicated in hepatic disease, unless it is due to schistosomiasis, because they can cause worsening of liver function. They can rarely cause hepatitis. A host of immunologic reactions can occur, such as an anaphylactoid reaction and anaphylaxis, arthralgias, arthritis, myalgias, headache, fainting, skin rashes, and facial edema. Pulmonary symptoms include pneumonia (especially with tartrates), coughing, dyspnea, and apnea.

More specific side effects include fever, fainting, rashes, and vomiting with use of dimercaptosuccinate; hemolytic anemia, thrombocytopenia, vomiting, and albuminuria with stibophen; and phlebitis, cough, and death due to rapid injection with tartrates. Dimercaptosuccinate is contraindicated in the presence of bacterial infection or herpes (simplex or zoster) infection.

The medication should be withdrawn if the side effects are severe. Treatment is supportive and symptomatic.

Pentavalent antimony is used in the treatment of protozoan infections such as leishmaniasis.

Bephenium Hydroxynaphthoate

Bephenium hydroxynaphthoate is a quaternary ammonium used for the treatment of hookworm (*N. americanus*, 5 g twice per day for 3 days; and *A. duodenale*, 5 g twice per day for 5 days); and also for giant roundworm (*A. lumbricoides*). It has been replaced for the most part by mebendazole but is more effective than tetrachloroethylene.

Bephenium hydroxynaphthoate has minimal GI absorption. It does have a bitter taste, and this is what usually causes the nausea and vomiting. Treatment is symptomatic.

Bithionol

Bithionol may still be used for human fascioliasis (30 to 50 mg/kg on alternate days for 10 to 15 doses), for which it is the treatment of choice. It may be used for paragonimiasis (30 mg/kg every other day for 20 days),

but for the most part, treatment of this and other trematode infections has been replaced by praziquantel.

Side effects are skin reactions and GI irritation, which are rarely severe enough to discontinue medication. Treatment is symptomatic.

Paromomycin

Paromomycin can be used to eradicate the cestodes (tapeworms) *T. saginata*, *T. solium*, *D. latum*, and *H. nana*. It is given in a dosage of 1 g every 4 hours for 4 days. Treatment with paromomycin has largely been replaced by niclosamide.

ACKNOWLEDGMENT

The authors wish to thank Donald G. Barceloux, MD, for his thoughtful review and commentary on this chapter.

At a Glance...

- Isoniazid, which is structurally related to nicotinic acid, pyridoxine, and other pyridines, remains the most common treatment for tuberculosis.
- Isoniazid produces a broad range of adverse effects, including drug-drug interactions, hypersensitivity reactions, and hepatotoxicity.
- In overdose, isoniazid produces the pathognomonic triad of seizures, severe metabolic acidosis, and coma.
- Treatment of isoniazid overdose begins with supportive care that includes seizure control, which begins with administration of benzodiazepines.
- The specific antidote and treatment of choice for isoniazid-induced seizures is intravenous vitamin B₆ (pyridoxine), given in a gram-for-gram dose. If the ingested dose of isoniazid is unknown, 5 g (75 mg/kg in children) should be administered intravenously.

Isoniazid (INH) was introduced in 1952 and remains the antibiotic most commonly used in the treatment of tuberculosis. It is first-line treatment for both latent tuberculosis and in combination with other agents for active tuberculosis. Because the incidence of tuberculosis remains high worldwide, INH continues to be more widely prescribed.¹ With this expanded use has come a greater opportunity for INH adverse effects and poisoning. Fortunately, a greater understanding of the biochemical mechanisms underlying its effects has led to the development of effective strategies for the treatment of INH intoxication.^{2,3}

PHARMACOLOGY

INH, which contains a pyridine nucleus, is a structural analog of the nutrients nicotinic acid (niacin, vitamin B₃), nicotinamide-adenine dinucleotide (NAD), and pyridoxine (vitamin B₆) (Fig. 55-1). INH is also a congener of the monoamine oxidase inhibitor antidepressant isocarboxazid. Its complete name, isonicotinic acid hydrazide, identifies INH as a congener of nicotinic acid.³ INH has primary p*K*_a of 1.9.⁴

As monotherapy in latent tuberculosis, INH is given daily in 5 mg/kg (adult) or 10 mg/kg (pediatric) doses.⁵ Treatment regimens vary for active tuberculosis.⁶ Details about isoniazid pharmacotherapy go beyond the scope of this chapter; the reader is referred to sources specific for the treatment of tuberculosis.⁷ Isoniazid also may be given as an intramuscular injection and has been given intravenously in experimental settings.

INH is rapidly absorbed from the gastrointestinal tract (primarily the small intestine), and peak serum concentrations are achieved within 1 to 2 hours.^{3,4} Absorption is delayed by concomitant administration of antacids.³ Once absorbed, INH is distributed throughout body water and has an apparent volume of distribution of 0.6 L/kg.^{4,5} INH has negligible binding to plasma proteins.^{4,5}

The primary metabolic pathway for INH is acetylation by the enzyme *N*-acetyltransferase (NAT). This enzyme is located in the liver and intestinal mucosa. NAT has been identified as a polymorphic enzyme whose pharmacokinetic activity follows Michaelis-Menten (saturable) kinetics. Additionally, the activity of this enzyme is genetically controlled by autosomal-dominant inheritance.^{3,4} Phenotypically, slow and fast acetylators can be identified. The fast acetylation phenotype is found primarily among Eskimos and Japanese, and slow acetylation among Scandinavians, Jews, and North Africans. In the United States, the prevalence of slow acetylation is about 50% of the general population. Acetylation activity is responsible for a number of the clinical differences observed in slow versus fast acetylators: (1) slow acetylators have a smaller degree of hepatic clearance (first pass effect) than fast acetylators, (2) fast acetylators metabolize INH five to six times faster than slow acetylators, and (3) plasma INH concentrations are 30% to 50% lower in fast versus slow acetylators. Daily INH treatment regimens usually do not result in any differences in response rates between slow and fast acetylators. Fast acetylators may have a sub-optimal response in once-weekly regimens.⁵ It is thought that slow acetylators may be more prone to the hepatotoxic effects of INH.⁸

The elimination half-life of INH in fast acetylators is approximately 70 minutes, compared with a mean of 3 hours in slow acetylators. The primary metabolites after

FIGURE 55-1 Structural relationships of isoniazid.

INH biotransformation are acetylisoniazid and isonicotinic acid.^{3,4,9} Based on urinary concentrations of these metabolites and the parent compound, it is possible to determine acetylation status with a technique outlined by Kohno and colleagues.^{10,11} Both INH and its inactive metabolites are excreted in the urine, and 75% to 95% of a single dose is eliminated within 24 hours. Twenty-seven percent of INH is excreted unchanged in slow acetylators, in contrast to 11% in fast acetylators.⁴ The clearance of INH averages 46 mL/min.⁴ The half-life is especially prolonged in those with end-stage renal disease (up to 17 hours). Compliance with therapy may be measured using either urine or serum testing (colorimetric urine tests have been developed), but serum concentrations are not routinely monitored.

Hydrazine, a component of rocket fuel that is also touted as an alternative treatment for cancer, and monomethylhydrazine, the toxic component of *Gyromitra* mushrooms, are derivatives of INH. They produce neurotoxicity and hepatotoxicity in a similar manner.¹² Hydrazine is well-known as a human carcinogen. Isoniazid has not been demonstrated to be carcinogenic. INH is an inhibitor of several cytochrome P-450-mediated functions, particularly demethylation, oxidation, and hydroxylation.¹³ In vitro, INH has been shown to inhibit CYP2C19 and CPY3A4 isoenzymes at clinically relevant plasma concentrations; coadministration with substrates of these enzymes may result in drug interactions.¹⁴ INH appears to exert a biphasic effect on the CYP2E1 isoenzyme with inhibition followed by induction.¹⁵⁻¹⁷ Significant drug interactions exist with INH.^{1,2} Table 55-1 demonstrates the more clinically significant interactions. An effect on the anticonvulsant phenytoin has been well described; altered mental status (occasionally coma) has occurred in patients who were simultaneously prescribed INH and phenytoin, associated with the development of toxic serum phenytoin concentrations. Phenytoin toxicity results from INH inhibition of cytochrome P-450 hydroxylases.^{3,5} This decrease in phenytoin clearance tends to occur in the second week of combined treatment.¹⁸ Other drugs whose elimination is reduced by concomitant administration of INH are carbamazepine, valproate,¹⁹ coumarin anticoagulants, and rifampin.¹³

When coadministered with INH, serum theophylline concentrations are increased, resulting from inhibition of its metabolism.^{3,5} Case reports have suggested a significant adverse interaction between INH and acetaminophen,²⁰ the result of CYP2E1 enzyme induction. However, well-controlled clinical studies have failed to demonstrate a greater risk for hepatotoxicity when these two are taken simultaneously.¹⁶ The degree of acetaminophen toxic metabolite formation also may be dependent on the patient's acetylation phenotype.²¹

Certain herbal medications have been associated with fulminant hepatic failure when taken with INH.⁵ One case of central nervous system (CNS) depression and hemodynamic instability has been reported when INH was coadministered with meperidine, a serotonergic opioid.²² No cases of interactions with serotonin reuptake inhibitors have been reported.

INH has a significant effect on several biochemical pathways (Table 55-2). INH also affects the enzymes involved in the metabolism of the CNS neurotransmitter γ -aminobutyric acid (GABA). GABA is the primary neurotransmitter at the motor inhibitory neurons of the CNS. GABA levels are regulated by two enzymes, glutamic acid decarboxylase (GAD) and GABA aminotransferase. GAD catalyzes the synthesis of GABA, whereas GABA aminotransferase promotes GABA breakdown. Both enzymes require pyridoxal phosphate as a cofactor. INH is an inhibitor of both enzymes but has a greater inhibitory effect on GAD, leading to reduced GABA levels.^{8,23,24} Reduction in GABA has been directly associated with the development of seizures.^{23,24} Monomethylhydrazine has a similar pharmacologic action.

INH's effect on pyridoxine metabolism is pivotal in the drug's toxicity. Pyridoxine activity is markedly reduced by INH, and pyridoxine depletion ultimately results. At least two mechanisms are responsible for this loss of pyridoxine activity: (1) INH inhibition of the enzyme pyridoxine phosphokinase, which converts pyridoxine to its active form, pyridoxal phosphate,²⁶ and (2) INH binding to pyridoxal phosphate, which forms an inactive hydrazone complex that is excreted in the urine.^{4,25} Daily urinary excretion of pyridoxine is doubled with INH doses of 3 to 5 mg/kg and is quadrupled

TABLE 55-1 Drug Interactions with Isoniazid

DRUG	NATURE OF INTERACTION	CLINICAL EFFECT	REFERENCES
Phenytoin	Inhibition of parahydroxylation	Increased phenytoin level	3, 5, 18
Carbamazepine	P-450 inhibition (3A4)	Increased carbamazepine level	5
Valproic acid	Unknown; possible enzymatic inhibition	Increased valproic acid level	19
Coumarin anticoagulants	Unknown	Increased warfarin levels; increased prothrombin time	5
Rifampin	Possible enzyme induction by rifampin	Isoniazid hepatotoxicity	5, 13
Theophylline	Unclear; possible P-450 inhibition	Increased theophylline levels; tachycardia, neurotoxicity	5
Acetaminophen	P-450 2E1 inhibition	Hepatotoxicity	16, 20, 21
Meperidine	Monoamine oxidase inhibition	Coma, hemodynamic instability, possible serotonin syndrome	22

Binding of pyridoxal phosphate	↓ Pyridoxine activity	70
Replacement of nicotinic acid, producing inactive nicotinamide-adenine dinucleotide	Impaired glucose and fatty acid oxidation, metabolic acidosis	26, 66, 70

GABA, γ -aminobutyric acid.

with INH doses of 20 mg/kg.²⁶ The consequences of pyridoxine depletion include impaired activity of pyridoxine-dependent transaminases and decarboxylases (including GAD). Catecholamine synthesis also is affected by inhibition of these enzymes.

Because of INH's structural similarity to nicotinic acid, it may replace nicotinic acid in the synthesis of NAD, and an inactive compound may form.^{4,27}

INH readily crosses the placenta and enters breast milk. No teratogenic or mutagenic effects have been identified with INH use during pregnancy.⁴ The American Academy of Pediatrics has determined that it is safe to continue breast-feeding while a woman is taking isoniazid.²⁸

CLINICAL TOXICOLOGY

Adverse Events

Because of its many biochemical effects, INH is associated with a myriad of adverse reactions when taken in therapeutic doses. The overall incidence of adverse drug reactions with INH therapy is 5.4%.³ The most common of these are rash, neuropsychiatric abnormalities, and abnormal liver function with the appearance of jaundice. INH hepatotoxicity may result from the generation of hydrazines.^{3,12,29} INH-induced liver enzyme elevation occurs in up to 20% of patients and in most cases is asymptomatic.⁵ Approximately 0.6% of patients develop frank jaundice and hyperbilirubinemia, and approximately 0.4% go on to develop ongoing liver disease.⁵ Hepatotoxicity appears to occur more often in older patients and in slow acetylators.⁸ A study of health care workers found elevation of transaminases to levels requiring discontinuation of the drug in 9.6%.³⁰ A study of patients in a public health tuberculosis clinic found a hepatotoxicity incidence of 0.1% in those starting a regimen containing INH.^{30,31} A British study found mild aminotransferase elevation in 30% of children receiving triple therapy for tuberculosis disease, but treatment was discontinued in only one child.³² Fulminant hepatitis

occurs in an estimated 20.7 per 1000 persons; approximately 1 to 4.2 cases per 100,000 result in death.³³⁻³⁵ Liver transplantation may be necessary.³³ It is well established that the risk for hepatotoxicity is increased with multidrug antitubercular regimens. Other risk factors for INH-induced or -associated hepatotoxicity are alcoholism and active hepatitis B infection (as evidenced by positive hepatitis Be antigen).^{36,37} Hepatitis C seropositivity was not considered to be a risk factor for INH-induced hepatitis.³⁶ The Centers for Disease Control and Prevention has recommended discontinuation of isoniazid when transaminases reach elevations greater than three times the upper limit of normal and the patient is symptomatic, or an asymptomatic elevation greater than five times the upper limit of normal. The reader again should refer to these guidelines for more specific details of tuberculosis management.⁷

Acute pancreatitis has also been associated with INH use but is rare.^{38,39} Autoimmune phenomena ranging from an asymptomatic ANA seropositivity to frank lupus erythematosus occurs.⁴⁰ Approximately 25% of those taking INH develop antinuclear antibodies.⁴¹ The mechanism is unknown, although it may be related to the hydrazine structure of INH; slow acetylators may be at higher risk.^{8,40} Symptoms usually consist of fever, rash, arthralgias or frank arthritis, and pleuritis.⁸ Life-threatening complications such as pericardial tamponade have been reported.⁴¹ The syndrome usually resolves with discontinuation of the drug; corticosteroids and/or immunosuppressants may be required in some cases.^{40,42}

Peripheral or optic neuritis may also occur with INH use. Peripheral neuritis has been observed in up to 20% of those taking INH at doses greater than 6 mg/kg. Those at greater risk include patients with poor nutritional status, alcoholism, pregnancy, or hemodialysis-requiring renal disease. Children appear to be at lesser risk for neuropathy.^{3,8} Symptoms of peripheral neuritis include paresthesias in a stocking-glove distribution, which may progress proximally.² Although primarily a sensory neuritis, myalgias and weakness may occur.² Optic neuritis generally is manifested as decreased visual acuity (often unilateral).^{2,3,39,43-45} Less commonly, CNS toxicity

occurs, with manifestations of dysarthria, ataxia, and psychiatric disturbances.⁴⁵ Suicidal psychosis has been observed with therapeutic dosing and resolved with discontinuation of the drug.^{46,47} Neurologic complications are usually reversible and may be due to INH inhibition of the neuronal enzyme apotryptophanase.² Coadministration of pyridoxine with INH prevents their occurrence.³

INH may precipitate seizures in those with such a predisposition, even at therapeutic dosing.^{3,48} Patients receiving hemodialysis appear to be at greater risk.⁸ Pellagra in the setting of INH use has been documented. The result of vitamin B₃ (niacin) depletion, pellagra is characterized by a triad of dermatitis, diarrhea, and dementia or alteration in mental status. INH is thought to act as an analog for niacin in biochemical reactions and may precipitate pellagra in those with niacin depletion. Some investigators have attempted to treat INH-induced pellagra with pyridoxine (vitamin B₆), only to find it ineffective.^{49,50} However, when INH was discontinued, and in some cases, niacin supplemented, the pellagra resolved.⁴⁹⁻⁵² Patients with the slow acetylator phenotype may be at greater risk.⁵²

INH use also may have a significant effect on diet. INH is known to be a weak monoamine oxidase inhibitor. In fact, soon after the introduction of INH to the market, tuberculosis patients were noted to have improvement in their mood. One derivative of INH, isocarboxazid, was used as a monoamine oxidase inhibitor antidepressant. This property predisposes the patient to similar interactions with tyramine-containing foods (e.g., cheese, wine, aged sausages). Symptoms of a tyramine reaction include hypertension, flushing, and tachycardia. A syndrome similar to scombroid poisoning may occur after ingestion of certain fish due to INH inhibition of histaminase. Patients should be forewarned about the possibility of these food reactions.^{8,14,53-55} Isoniazid also has been linked to hematologic disturbances, including red cell aplasia, agranulocytosis, hemolytic anemia, sideroblastic anemia, thrombocytopenia, eosinophilia, and megaloblastic anemia.^{8,56} Skin disorders associated with INH use range from simple rash to exfoliative dermatitis to Stevens-Johnson syndrome.^{8,57,58}

Acute Intoxication

Acute ingestion of 2 to 3 g of INH leads to toxicity, whereas ingestion of more than 10 to 15 g or 80 mg/kg is usually fatal without aggressive treatment.^{5,59} Severe INH toxicity correlates with serum INH concentrations of greater than 30 mg/L.⁶⁰ Clinical manifestations of INH intoxication may appear as early as 30 minutes after ingestion.^{60,61-63} Early signs and symptoms include nausea, vomiting, slurred speech, dizziness, mydriasis, and tachycardia. A subsequent cascade of biochemical events soon leads to the striking clinical features that characterize INH intoxication, namely, recurrent seizures, severe metabolic acidosis, and coma. As described earlier, INH prevents pyridoxine-dependent synthesis of GABA, the major inhibitory neurotransmitter. A proposed mechanism for this sequence is shown in Figure 55-2.

Seizures after INH overdose are episodic and tend to occur at regular intervals; either hyperreflexia or areflexia precedes their onset.² Improvement in consciousness may occur between seizures.⁵⁹ Once they begin, seizures are difficult to control despite the administration of anticonvulsants. *Seizures refractory to conventional anticonvulsant therapy are a hallmark of INH intoxication.*

Severe metabolic acidosis is another prominent feature of INH overdose. Although pH ranges of 6.80 to 7.30 are common, surviving victims may present with a systemic pH as low as 6.49.⁶⁴ The etiology of metabolic acidosis appears to be an increase in the generation of lactic acid because of the muscular activity of recurrent seizures. Experimental data have demonstrated that paralyzed animals with INH intoxication do not develop severe metabolic acidosis.⁶⁵ Other theories of metabolic acidosis have been proposed, however, including (1) the generation of acidic INH metabolites, (2) an increase in keto acids (specifically, β -hydroxybutyric acid) due to altered fatty acid oxidation, and (3) the formation of inactive NAD, leading to impairment of both glucose and fatty acid metabolism. The last-named theory has led to the suggestion that nicotinic acid be administered in INH overdose, although no clinical studies have been performed to this end.^{4,27,66-68}

Coma may be protracted after overdose (lasting more than 24 hours) and may continue after seizures have abated and metabolic acidosis has been corrected. This profound CNS depression has been attributed to CNS catecholamine depletion.^{63,69}

Other clinical effects of acute INH intoxication are severe hypotension, hyperglycemia, acetonuria, abnormal results of liver function tests, and renal failure.^{2,69,70} INH-induced renal failure is often exacerbated by the myoglobinuria that develops from seizure-induced rhabdomyolysis.⁷¹

DIAGNOSIS

In the absence of a history of overdose, INH overdose may be suspected in patients who present with the characteristic symptom complex. The differential diagnosis of severe metabolic acidosis includes diabetic ketoacidosis and the ingestion of cyanide, methanol, ethylene glycol, iron, ibuprofen, or salicylates. Of these, only INH overdose has recurrent seizures as its hallmark.

The toxic screen generally does not detect the presence of INH, although serum INH concentrations can be measured if confirmation is required. These results likely will return well after the patient's acute toxicity has resolved. Other important laboratory tests are an arterial blood gas determination, electrocardiogram, electrolyte measurements, liver function tests, creatine phosphokinase determination, and urinalysis.

MANAGEMENT

The initial management of INH intoxication requires stabilization of vital signs with provision of a patent

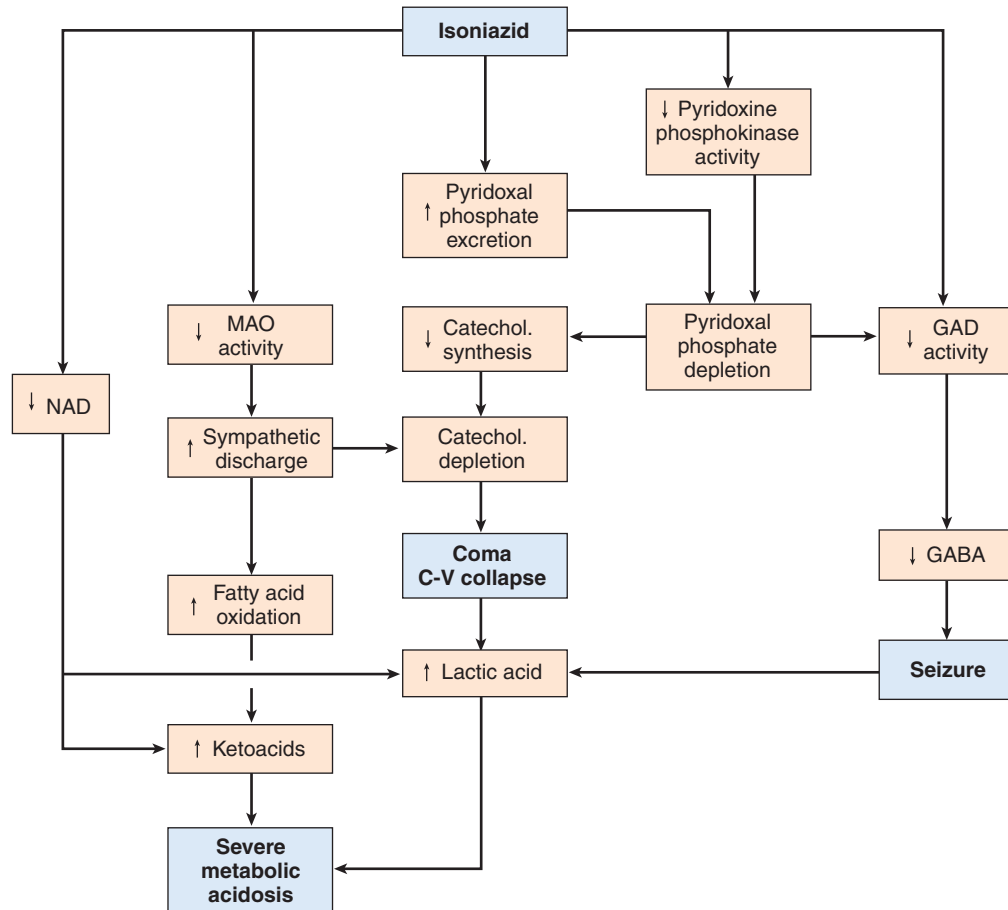

FIGURE 55-2 Proposed mechanisms of isoniazid toxicity.

airway, oxygen, cardiovascular support with intravenous fluids, and administration of sodium bicarbonate to treat metabolic acidosis (Box 55-1).

If emergency department arrival is within 1 hour of ingestion, administration of activated charcoal with a cathartic is indicated. Ipecac-induced emesis is contraindicated owing to the potentially rapid onset of seizures and risk for airway compromise. Delayed absorption of INH after an overdose has not been observed, and it is thus suggested that late gastrointestinal decontamination may be ineffective.

Intravenous pyridoxine has been shown to be highly effective for INH intoxication and should be administered to all symptomatic patients.^{60,72} The milligram dose of pyridoxine should equal the ingested dose of INH. Pyridoxine (given as pyridoxine hydrochloride) has been shown to terminate seizures, correct metabolic acidosis, and abbreviate the duration of coma.^{2,73} The efficacy of pyridoxine is directly correlated with the administered dose; in one study, recurrent seizures occurred in 60% of patients who received no pyridoxine, 47% of those who received 10% of the ideal pyridoxine dose, and none of the patients who received a full dose of pyridoxine.⁷³ When the quantity of ingested INH is unknown, a pyridoxine dose of 5 g (75 mg/kg in children) should be administered. Repeated doses of pyridoxine may be required based on the resolution of

signs and symptoms. Pyridoxine is commonly dispensed as 100 mg/mL solution with a pH ranging from 2 to 3.8. A relatively large volume of such an acidic solution may

BOX 55-1

SUMMARY OF TREATMENT STRATEGIES FOR ISONIAZID OVERDOSE

Supportive Care

Ventilatory support
Vascular access
Fluids, vasopressors

Gastrointestinal Decontamination

Activated charcoal plus cathartic

Pharmacologic Treatment

Sodium bicarbonate to correct metabolic acidosis
Benzodiazepines and/or barbiturates as anticonvulsants
Pyridoxine: gram for gram per dose ingested, 5 g (75 mg/kg for children) if isoniazid dose is unknown; may be repeated if necessary

Elimination Enhancement

Hemodialysis
? Multiple-dose activated charcoal

temporarily worsen a metabolic acidosis soon after administration. This transient decline in serum pH should resolve within approximately 30 minutes and should not be interpreted as a failure of treatment, nor should it be a contraindication to pyridoxine administration for INH overdose.^{74,75} A patient with significant INH overdose may deplete local supplies of pyridoxine. Santucci and colleagues suggest stocking at least 5 g of pyridoxine in the emergency department at all times.⁷⁶ Contingency plans should be created for access to pyridoxine in the event of multiple INH exposures within a brief period.^{76,77}

Conventional anticonvulsants remain important in the early treatment of seizures. The benzodiazepines are agents of choice because they have a synergistic effect with pyridoxine as well as inherent GABA agonist activity.^{2,73,78,79} Prophylactic administration of benzodiazepines has no proven efficacy. Several investigators have recommended against the use of phenytoin in INH overdose because of an apparent lack of efficacy and the potential for phenytoin intoxication.^{2,70} However, impaired phenytoin metabolism has been documented only in those ingesting INH continually, not after acute intoxication. Phenytoin may be an acceptable anticonvulsant, although its efficacy remains in question.⁷⁹ Phenobarbital, like the benzodiazepines, is a potent GABA agonist that may be effective in the treatment of seizures. Phenobarbital may worsen CNS depression, especially if administered after a benzodiazepine.

INH has a small volume of distribution and low protein binding, pharmacokinetic features that make it amenable to hemodialysis and peritoneal dialysis. Up to 75% of serum INH may be removed within 5 hours by hemodialysis, with clearance rates as high as 120 mL/min.^{4,8} Hemodialysis should be reserved for patients with severe acidosis or who develop renal failure. These same characteristics make isoniazid similar to theophylline and phenobarbital, two drugs whose elimination is enhanced by the “gut dialysis” effect of multiple-dose activated charcoal. While data are lacking, multiple-dose activated charcoal should be considered as a potential means of elimination enhancement in patients with severe intoxication.

A Chemotherapeutic Agents

RICHARD Y. WANG, DO

At a Glance...

- Overdoses from chemotherapeutic agents occur infrequently, but are associated with devastating outcomes.
- The majority of unintentional exposures occur iatrogenically, resulting from errors in either dosage regimen or drug preparation.
- Mucositis, emesis, pancytopenia, and alopecia are common clinical manifestations of toxicity.
- Management includes stabilization of life-threatening disorders, decontamination, prevention of overwhelming sepsis, the timely use of rescue agents, and enhanced elimination in specific instances.

The use of chemotherapeutic agents in the treatment of cancer stems from the discovery that mustard agents used during World Wars I and II caused bone marrow toxicity. Mustard gas (sulfur mustard) was first used in World War I as a chemical warfare agent at Ypres, Belgium, in 1917, and was later found to cause myelosuppression in animals and in sailors unintentionally exposed to this agent while on a U.S. naval vessel.¹ Upon further evaluation of this class of agents, it was demonstrated that they were effective against tumors in animals and the nitrogen mustards were less toxic to the host than sulfur mustard. These findings led to the production of mechlorethamine (Mustargen) for the treatment of lymphoma by Merck & Co, West Point, Pennsylvania, in 1943. The next class of chemotherapeutic agents developed for clinical use was the folate analogs. Pteroyltriglutamic acid was identified in 1946 as the active agent in the fermentation products of *Lactobacillus casei* that caused the remission of breast tumors in mice.² Since then, other folate analogs and several other classes of agents have been developed and used successfully in cancer therapy. These agents can be generally classified as antimetabolites, alkylating agents, antibiotics, and antimitotics. Certain tumor cells (e.g., prostate, breast, endometrial) are responsive to hormonal therapy, and these agents comprise another class. Unlike other classes of pharmaceutical agents, the chemotherapeutic agents are more likely to cause toxicity in people with exposures because of the unique mechanism of action and narrow therapeutic window of these agents.

The occurrence of toxicity from chemotherapeutic agents in patients during therapy was characterized in a review of the Surveillance, Epidemiology, and End Results (SEER) tumor registry of the hospitalizations of women with breast cancer from 1991 to 1996.³ There were 35,060 women diagnosed with breast cancer in this

period, and 4134 underwent chemotherapy that included doxorubicin, mitoxantrone, cyclophosphamide, fluorouracil, methotrexate (MTX), and paclitaxel. The observed frequency of hospital admissions for adverse effects attributed to chemotherapy (i.e., neutropenia, thrombocytopenia, fever, and unspecified adverse effects of systemic therapy) was 14%, which was higher than the 0.5% of women admitted for the same diagnoses who did not receive chemotherapy. Neutropenia accounted for about half of the admissions in the treated women, and the rate of hospitalizations for these adverse effects increased by about 2-fold with advancing stages of tumor. Chemotherapy was associated with a 10-fold higher mortality rate and a 6-fold higher likelihood for death in women admitted for health effects associated with treatment. The host factors that were associated with hospital admission for toxicity related to chemotherapy were advanced stage of tumor and type of chemotherapeutic agent. Women treated with anthracycline agents were two to three times more likely to be admitted for toxicity than those who were treated with cyclophosphamide, fluorouracil, MTX, or paclitaxel.

Unintentional exposures to chemotherapeutic agents may occur by confusing the amount to be administered, the route of administration, the dose frequency, or the agent itself. The following discussion is intended to familiarize health care providers with the clinical manifestations of toxicity and management of the commonly observed chemotherapeutic agents in therapy.

MECHANISMS OF ACTION AND TOXICITY

Chemotherapeutic agents cause cell death by primarily disrupting DNA synthesis or function during cell replication. These agents can alter DNA structure, impair DNA synthesis, or inhibit chromosomal separation by a variety of mechanisms. The alkylating agents interact through reactive intermediates with electrophilic DNA side groups to form a covalent bond by nucleophilic substitution. The alkylated DNA can form inter- or intrastrand cross-linkages, which can promote errors in base pairing during DNA replication or transcription and lead to cell death. The 7 nitrogen in the imidazole ring of guanine is a favored substitution site because it can alter the DNA structure by either forming the unfavorable enol tautomer or disrupting the imidazole ring complex. The nitrogen mustard agents are most

likely to form cross-linkages because each molecule contains two reactive 2-chloroethyl side chains. The reactive intermediates of the alkylating agents can be formed by spontaneous hydrolysis or an enzymatic-dependent process. The anthracycline antibiotics impair DNA structure by causing breaks in the strand, which can result from any one of several mechanisms. The planar structures of these agents allow them to intercalate with DNA to cause single-strand breaks. Similar results can occur from the generation of oxygen free radicals from the formation of a semiquinone intermediate during the hepatic metabolism of these agents. The anthracyclines can bind and inhibit topoisomerase II to cause permanent double-strand breaks in DNA, which are more damaging to the cell than single-strand breaks.

The antimetabolites indirectly disrupt DNA synthesis by serving as inhibitory analogs to either cofactors or nitrogenous bases of nucleic acids. These agents can be categorized as folate analogs (e.g., MTX), pyrimidine analogs (e.g., 5-fluorouracil, 5FU), and purine analogs (e.g., mercaptopurine). The antimetabolic agents, such as vinca alkaloids, disrupt chromosomal separation during cell division by impairing microtubule function. These agents bind to tubulin, which is a protein subunit of microtubules, and cause cells to stop at metaphase during mitosis.

In recent years, hormonal active agents have become part of chemotherapy because of their ability to alter gene transcription and to cause cell death. Topotecan and irinotecan belong to a new class of chemotherapeutic agent that inhibits topoisomerase I, which is responsible for reversible DNA breaks and is necessary for DNA replication. These agents are derived from camptothecin, which is isolated from the tree *Camptotheca acuminata*. Bone marrow suppression with resultant overwhelming sepsis and death can occur from an overdose with topotecan.⁴

PHARMACOLOGY

The chemotherapeutic agents can be administered by a variety of routes, including intravenous (IV), intra-arterial, intravesicular, intracavitary (pleural, peritoneal), intralésional, topical, and oral. The majority of chemotherapeutic agents are administered by the IV route, and only a few are given orally. The intrathecal (IT) route of administration is limited to MTX and cytarabine (cytosine arabinoside). These three routes are the common ones associated with overdoses. The selection of the route of administration depends on drug stability and the intended site of action. Some medications poorly penetrate the blood-brain barrier and must be given intrathecally for them to be effective in cases of existing (or the potential for) brain metastasis. The agents available as tablets and associated with overdoses in the literature include MTX, busulfan, and melphalan. MTX is rapidly absorbed from the gut, with peak serum levels achievable within 1 to 2 hours after oral administration. Gut bacteria metabolize about 5% of MTX to 2,4-diamino-*N*(10)-methylptericoic acid (DAMPA), which is

inactive at the dihydrofolate reductase (DHFR) site, but will cross react on the clinical TDx assay (Abbott Laboratories, Abbott Park, IL) to contribute to the overall serum MTX level. In an oral overdose of 4 mg/kg busulfan tablets, the peak plasma busulfan level was observed at 4 hours after ingestion.⁵ Typically, busulfan does not distribute well into the cerebrospinal (CS) space, but at doses higher than 16 mg/kg, appreciable CSF levels can be achieved to result in seizures. A similar situation occurs when a high dose of vincristine is administered. Unique to paclitaxel is its 49.7% ethanol diluent, which can cause its own toxicity in the overdose setting.

Many of the chemotherapeutic agents distribute in the body according to a multicompartiment model based on the decay of the plasma level. The initial plasma half-life for these agents ranges from minutes to hours and the terminal half-life ranges from hours to days (Table 56A-1). Several agents have high plasma protein or tissue binding capacities and large volumes of distribution, which would limit their ability to be removed by hemodialysis. MTX can distribute into third space fluids (e.g., peritoneal, pleural) to prolong the terminal half-life, which is associated with increased host toxicity. Bowel obstruction can also increase MTX's terminal half-life by allowing for the re-uptake of MTX by enterohepatic circulation.

The majority of the chemotherapeutic agents are metabolized in the liver and the metabolites are eliminated by the kidneys through either glomerular filtration or active tubular secretion. For some agents, they are eliminated unchanged in the urine and require their dose adjusted in patients with diminished renal function. Biliary elimination accounts for a small amount of total drug elimination for certain agents, such as MTX. Some agents (e.g., mechlorethamine, cisplatin) undergo spontaneous hydrolysis and quickly become reactive intermediates upon the administration of the drug. Cisplatin's chloride molecule is replaced by a hydroxyl molecule to form monohydroxy monochloro *cis*-diammine platinum, which contributes to renal tubular toxicity. This hydrolytic reaction is limited in the presence of a high chloride concentration, which is why sodium chloride diuresis is performed during high-dose cisplatin therapy. For some agents, additional drug metabolism occurs intracellularly. MTX undergoes polyglutamation inside the cell by the enzyme folyl polyglutamate synthetase. This prolongs MTX's duration in the cytosol and activity at the DHFR site.

Some of the metabolites of the chemotherapeutic agents can contribute to host toxicity. For example, cyclophosphamide is metabolized by a series of hepatic and intracellular enzymatic reactions to phosphoramidate mustard and acrolein, which are both renally eliminated and biologically active. Phosphoramidate mustard is the active alkylating intermediate, and acrolein is a by-product. Acrolein is a highly reactive aldehyde because of the close proximity between the carbonyl and vinyl groups in its structure, and is highly irritating to epithelial cells. The latter effect may result from acrolein's ability to bind to sulfhydryl groups, which can

TABLE 56A-1 Pharmacologic Parameters Pertaining to Selected Chemotherapeutic Agents Discussed in This Chapter.

AGENT	MOLECULAR WEIGHT (Da)	ROUTE OF ADMINISTRATION	VOLUME OF DISTRIBUTION (L/kg)	PLASMA PROTEIN BINDING	METABOLISM (PRIMARY)	METABOLITES	ELIMINATION	TERMINAL PLASMA HALF-LIFE (hr)
Alkylating								
Busulfan	246	PO, IV*	0.6–1.0	3%–32%	Hepatic	Methanesulfonic acid	Renal	2–3
Chlorambucil	304	PO	0.14–0.29	99%	Hepatic	Phenylacetic acid mustard (PAM)*	Renal	2 (PAM)
Cisplatin	300.1	IV	0.17–1.47	90%	Nonezymatic hydrolysis	Hydroxylated derivatives Hydrolytic derivatives* (e.g., Monohydroxymonochloro cis-diammine platinum [III])	Renal	1.5 (parent) 58–73
Cyclophosphamide	279.1	PO, IV	0.34–1.2	12%–14%	Hepatic	4-Hydroxycyclophosphamide (HC), Phosphoramide mustard (PM)* 4-Ketocyclophosphamide Carboxyphosphamide Acrolein*	Renal	3–12 (parent) 9 (PM) 7 (HC)
Ifosfamide	261.1	IV	0.34–0.9	Not appreciable	Hepatic	4-Hydroxyifosfamide Ifosfamide mustard* Dechloroethylifosfamide derivatives 4-Ketoifosfamide 4-Carboxyifosfamide Acrolein*	Renal	4–15
Melphalan	305.2	PO, IV	0.5	90%	Nonezymatic hydrolysis	Hydrolytic derivatives	Biliary > renal (10%–15% unchanged)	2 (parent)
Antibiotic								
Daunorubicin	563.9	IV	20–40	50%–60%	Hepatic	Daunorubicinol (DNL)*	Biliary > renal	55 (parent) 25 (DNL)
Doxorubicin	543.5	IV	25	70%–85%	Hepatic	Doxorubicinol (DXL)*	Biliary	30 (parent) 29 (DXL)
Idarubicin	533.9	IV	25	94%–97%	Hepatic	Idarubicinol (IDL)*	Biliary > renal	15–24 (parent) 45 (IDL)
Mitoxantrone	517.4	IV	1000–2000 L/m ²	80%	Hepatic	Mono- and dicarboxylic acid derivatives	Biliary > renal	20–200
Antimetabolite								
5-Fluorouracil	130.1	Topical, IV	0.25	8%–12%	Hepatic	Fluorodeoxyuridine monophosphate* Alpha-fluoro-beta-alanine	Respiratory, renal	16 min (parent)
Methotrexate	454.5	PO, IV, IT	0.4–0.8	50%	Hepatic	Polyglutamated derivatives* 7-hydroxymethotrexate* 2, 4-diamino-N(10)-methylptericoic acid	Renal > biliary	8–15 (parent)
Antimitotic								
Vinblastine	923.1	IV	27	40%–99%	Hepatic	Desacetylvinblastine*	Biliary > renal	23
Vincristine	923	IV	8.4	44%	Hepatic	Uncharacterized	Biliary > renal	20–150
Paclitaxel	853.9	IV	2	90%–98%	Hepatic	6-hydroxypaclitaxel	Biliary > renal	3–20

lead to the disruption of cellular protein activity. In the urinary bladder and in high concentration, acrolein can cause a hemorrhagic cystitis. This is prevented by hydrating the patient to promote urinary flow and to lower the urinary acrolein level and by administering the thiol agent sodium 2-mercaptoethane sulfonate (MESNA) during high-dose cyclophosphamide therapy (>120 mg/kg) before bone marrow transplantation. Another example of a toxic metabolite is when MTX is administered at a dose higher than 1 g/m². MTX is metabolized by aldehyde oxidase to 7-hydroxymethotrexate (7OHMTX), which is not active as a folate analog and is eliminated uneventfully in the urine. However, this metabolite is less soluble than MTX and tends to precipitate in acidic pH. During high-dose MTX therapy, appreciable levels of 7OHMTX can be achieved to cause precipitation in the renal tubules with resultant necrosis and renal failure.

TOXICOLOGIC MANIFESTATIONS

The toxicologic effects of the chemotherapeutic agents in the body are most apparent in cells with a high turnover rate, such as those in the epithelium, bone marrow, and hair follicle. This is because these agents were designed to limit cancerous cell growth by exploiting their high rate of mitosis. Thus, patients with toxicity will present with mucositis, alopecia, and leukopenia. The occurrence of these events post-treatment will vary by agent, but can be expected at about 3 to 5 days for mucosal epithelial loss and 7 to 13 days for the nadir effect of leukopenia. The mucosal epithelial loss can lead to gastrointestinal bleeding and serve as a source for sepsis from the entry of gut bacteria into the systemic circulation. MTX, 5FU, bleomycin, and doxorubicin are highly associated with mucosal ulcerations during therapy. The white blood cell count usually returns to baseline at 21 to 24 days. For some agents, the nadir of the leukopenia can be delayed by weeks (e.g., carmustine) or the duration of bone marrow suppression is much more sustained and can last for months to years after the exposure (e.g., busulfan). During this period of myelosuppression, patients may require blood product replacement, use of granulocyte colony-stimulating factors,^{6,7} reverse isolation, and antibiotic therapy to protect them from overwhelming sepsis. Granulocyte colony-stimulating factor has been demonstrated to improve neutrophil count response, improve rate of recovery from neutropenia, decrease duration of febrile neutropenia, and decrease hospital length of stay in patients undergoing chemotherapy. Additional findings common to overdoses of chemotherapeutic agents include nausea, vomiting, and hyperuricemia. The onset of nausea and vomiting is within 6 hours of exposure, and the effect can last for as long as 24 hours.

Chemotherapeutic agents are highly emetogenic, especially cisplatin, mechlorethamine, and doxorubicin because of their ability to stimulate the emetic center located in the medulla from various pathways. These

include the chemoreceptor trigger zone (CTZ), which can be affected by constituents in the blood or CSF, and the solitary tract nucleus, which receives vagal and sympathetic innervation by the enterochromaffin cells in the intestinal mucosa. The vagal and sympathetic afferents can stimulate the emetic center by way of the CTZ as well. Because serotonin is involved in many of these pathways, ondansetron is an effective antiemetic agent for chemotherapeutic agent-induced vomiting. In order to assist patients with protracted emesis from these agents, the pharmacologic inhibition of the other neurotransmitters involved in these pathways (e.g., dopamine) is often necessary, requiring combination drug therapy. Certain chemotherapeutic agents cause unique toxicologic manifestations and they are further discussed in the advancing sections.

Cardiac

The chemotherapeutic agents causing cardiotoxicity in a dose-dependent fashion are cyclophosphamide and the anthracycline antibiotics. The pyrimidine analog 5FU appears to be associated with manifestations consistent with coronary vasospasm during high-dose continuous infusion therapy.⁸ Doxorubicin and daunorubicin are the original anthracycline agents, and their use is limited by their oxidative-induced damage to myocardial tissue, which can lead to irreversible congestive cardiomyopathy. Cardiomyopathy is a significant and consequential effect of anthracycline therapy because it is irreversible, can lead to congestive heart failure, and is associated with a 48% mortality rate.⁹ The availability of structural analogs (e.g., epirubicin and idarubicin) and liposomal encapsulated formulations of the original anthracyclines allows for the continued use of this class of agents with less toxicity to the host. For example, the cumulative dose for doxorubicin and epirubicin to cause a 20% incidence of congestive cardiomyopathy is 550 mg/m² and 720 mg/m², respectively.^{10,11} Daunorubicin and mitoxantrone are associated with a 2% incidence at the cumulative doses of 600 mg/m² and 140 mg/m², respectively. In addition to cardiomyopathy, which is a delayed effect, the anthracycline agents can cause immediate manifestations of cardiac toxicity. These immediate effects, occurring within 24 hours of administration, include dysrhythmias, ST segment and T wave changes on the electrocardiogram, diminished left ventricular ejection fraction leading to congestive heart failure, pericarditis, myocarditis, and sudden death.¹²⁻¹⁵ The repolarization changes on the electrocardiogram are observed in about 40% of patients receiving doxorubicin therapy, and are transient and not associated with either total dose or peak serum levels.^{13,16,17} The onset of cardiomyopathy is heralded by manifestations consistent with biventricular heart failure and its timing, since the last course of treatment can be quite variable, ranging from months to years. Although this period is usually 1 to 4 months, it tends to be longer for the less toxic anthracycline analogs.¹⁸⁻²⁰

Cyclophosphamide's toxic effects on the heart are described in patients receiving high-dose therapy for

bone marrow transplantation and in the overdose setting.²¹ These patients can develop congestive heart failure, hemorrhagic pericarditis, or cardiac tamponade resulting in death within days of exposure.^{22,23} Patients receiving a mean cyclophosphamide dose of 174 mg/kg were observed to have greater reductions in QRS voltage and increases in left ventricular mass index compared with patients treated at a lower dose.²⁴ These findings were attributed to myocardial swelling from either edema or hemorrhage.²⁵ Patients at increased risk for cardiac effects from cyclophosphamide therapy include those who are older than 50 years, have a history of cardiac dysfunction,²⁶ or received treatment with anthracycline agents or thoracic radiotherapy.

5FU is associated with myocardial ischemia and cardiogenic shock when administered as a high-dose continuous infusion.²⁷ The incidence of cardiac symptoms in patients receiving high-dose continuous infusion therapy was observed to be about 10%, which was 10-fold higher than patients receiving bolus therapy.⁸ In some of these patients, diminished QRS voltage and ventricular wall motion normalized within 48 hours of discontinuation of 5FU treatment. These manifestations are attributed to increased myocardial oxygen demand²⁸ and coronary vasospasm,²⁹ which may be a response to endothelial damage caused by the metabolite fluoroacetate.³⁰ Patients with coronary artery disease or prior thoracic radiotherapy are at risk for these events during 5FU therapy, and they should be treated by discontinuation of 5FU and with coronary artery vasodilators (e.g., nitrates, calcium channel blockers) for myocardial ischemia.

Neurologic

The chemotherapeutic agents can cause a variety of neurologic effects, including central nervous system (CNS) and peripheral nervous system disorders, from the systemic administration of an excessive dose. Altered mental status and seizures are commonly observed during overdoses from the nitrogen mustards, MTX, and vincristine. The inappropriate IT administration of vincristine or MTX (by dose) can result in seizures as well. The putative neurotoxin from chlorambucil and ifosfamide overdoses is chloroacetaldehyde, which is produced by *N*-dechloroacetylation in the liver.³¹⁻³³ The seizures from chlorambucil overdoses typically present within 6 hours of exposure and are generalized tonic-clonic activity, which can last for 24 hours.^{34,35} Vincristine-induced seizures occur much later than those caused by the nitrogen mustards; typically at 1 to 7 days after exposure. Patients with underlying seizure disorders, delayed drug elimination,³⁶⁻³⁹ or altered drug pharmacokinetics (e.g., nephrotic syndrome) (salloum) are at risk for seizures during treatment with these agents. Vincristine toxicity can cause hypothalamic stimulation as well as central autonomic instability. The former can lead to fevers and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).⁴⁰ The duration of the fevers can be protracted, lasting for 1 week after the exposure, and serum electrolyte abnormalities may not present until 10 days after drug

exposure. The manifestations of central autonomic instability include bowel ileus, constipation, atony of the urinary bladder, hypertension, and hypotension.³⁸ Other chemotherapeutic agents associated with altered mental status include L-asparaginase, 5FU, and procarbazine.⁴¹ 5FU is associated with cerebellar ataxia in less than 5% of treated patients, and the mechanism remains to be determined.⁴²

The neurologic effects from MTX toxicity are variable and depend on the nature of the exposure. Chemical arachnoiditis occurs within hours of IT treatment and manifests as cephalgias, meningismus, pleocytosis, sterile CSF, and increased CSF protein and CSF MTX levels. The early administration of systemic steroids may limit the inflammatory response that is believed to occur during this process. A CSF MTX level higher than 100 $\mu\text{mol/L}$ during IT therapy suggests either an excessive amount of MTX administered or a CSF outflow obstruction.⁴³ Transverse myelopathy can occur from the lumbar subarachnoid administration of MTX and is typically not a reversible process, which is unlike that of chemical arachnoiditis. Neurobehavioral disorders and depressed mental status presenting months to years after treatment is characteristic of MTX-induced leukoencephalopathy. The overall incidence of this disorder is variable, ranging from 10% to 70%, and patients with increased age, intraventricular or IT administration of MTX, or prior cranial radiation appear to be at risk for developing this finding.⁴⁴ Computed tomography scan and magnetic resonance imaging of the brain can demonstrate findings consistent with demyelination and necrosis of the white matter.⁴⁵

IT overdoses with MTX occur infrequently and are associated with devastating outcomes, including permanent neurologic deficits and death. IT therapy is used to prevent CNS spread of cancerous cells in patients with acute lymphoblastic leukemia. The common cause of IT errors is confusing IV for IT medication, which can occur with similarly named drugs, multiple medications at the bedside, or when varying doses by different routes of administration are available for the same medication.⁴⁶ This latter reason accounts for some MTX IT overdoses because the higher IV dose was administered as the IT dose. The manifestations of toxicity present within minutes of the drug's administration, and include pain in the lower extremities, cephalgia, meningismus, and depressed level of consciousness. An electroencephalograph can demonstrate diffuse alterations in electrical activity.⁴⁷ IT overdoses with vincristine also have occurred, and the clinical outcome is more devastating than other chemotherapeutic agents administered in a similar manner.⁴⁸⁻⁵⁰ Patients present with findings consistent with an ascending myelopathy, and the outcome is typically fatal or includes permanent neurologic sequelae.

Peripheral neuropathies are observed with cisplatin and vincristine toxicities and occur in a dose-dependent fashion. The neuropathy is classic in its clinical presentation, ascending in nature, and can involve both sensory and motor components. The incidence of paresthesia with vincristine therapy is about 60% at a dose of 12 to 25 $\mu\text{g/kg}$ and increases sixfold at a dose of

75 µg/kg.⁵¹ The occurrence of neuropathies is higher for vincristine than vinblastine. The onset of symptoms during therapy ranges from 2 to 8 weeks after treatment, and limits the dosing regimen for vincristine.⁵² For the vinca alkaloids, the loss of the Achilles tendon reflex is an early finding that can be expected to resolve within 7 weeks upon discontinuation of further therapy.⁵³ Cranial nerve (III–VII and X) and laryngeal nerve involvement have been described in association with the vinca alkaloids.^{41,54} In comparison to vincristine, paclitaxel (taxol)-induced neuropathies have more of a sensory deficit and a shorter recovery period. This may be related to the difference in the mechanism of activity of these two agents on microtubule synthesis. The peripheral neuropathy associated with cisplatin toxicity is primarily a sensory disorder, and it is potentiated by the concomitant use of other neurotoxic agents, such as paclitaxel. The patient will present with paresthesia, and loss of vibratory sense and proprioception. Other clinical findings associated with cisplatin toxicity include tinnitus, high-frequency hearing loss, and retinopathy.⁵⁵

Renal

Chemotherapeutic agents can cause renal toxicity either directly or indirectly, resulting from the accumulation of breakdown products of cell death (i.e., uric acid). Acute uric acid nephropathy is commonly observed during the use of these agents for the treatment of leukemia or lymphoma. MTX is associated with renal insufficiency at doses higher than 500 mg/m² (100 mg/kg). Prior to the institution of prophylactic measures, such as hydration and urinary alkalinization, MTX was associated with renal insufficiency in 30% of the patients receiving therapy, and mortality in patients with severe renal failure.⁵⁶ The cause is the precipitation of the 7OHMTX metabolite in the renal tubules to cause acute tubular necrosis. This metabolite is less soluble than MTX and crystallizes in renal tubules in an acidic environment. The solubility of 7OHMTX at pH 5.5 is 2 mmol/L and increases at a higher pH. Cisplatin is another agent that causes renal tubular necrosis in a dose-dependent manner, and when repeat doses are administered in close succession. Protein unbound cisplatin freely enters into renal tubular cells, accumulating in the corticomedullary region of the kidney to cause distal and proximal tubular necrosis. Pretreatment with sodium chloride reduced the level of cisplatin and cisplatin metabolites in the kidney tissue and urine of treated animals.⁵⁷ When the cisplatin dose is higher than 50 mg/m², the frequency of renal failure is about 30%. The time of onset for the increase in serum blood urea nitrogen (BUN) and creatinine is about 1 to 2 weeks after treatment, which is slightly delayed compared to MTX. Hypomagnesemia and hypocalcemia are observed during cisplatin toxicity and may be attributed to renal loss from tubular injury.⁵⁸ Patients at risk for renal toxicity from these agents include the elderly, those with underlying renal disease, and those receiving concomitant therapy with nephrotoxic agents (e.g., aminoglycosides).

DIAGNOSIS

The diagnosis of a patient with an overdose from a chemotherapeutic agent is based on the presence of clinical manifestations consistent with the toxicity of the agent, historic evidence of the exposure, and laboratory findings supporting the exposure or toxicity. In most instances, the event will be clearly evident based on the history alone because these agents are typically administered in the controlled setting of a hospital. However, for agents associated with delayed onset of clinical toxicity or toxicity from chronic exposure, a heightened level of awareness will be necessary to establish the relationship between exposure and clinical findings.²⁰

The mechanisms responsible for the unintentional administration of chemotherapeutic agents involve either errors in dosage regimens or drug preparations, and they should be investigated in situations where the exposure is not apparent but suspected.⁵⁹ Some of the reasons for the dosage regimen errors include inappropriate dosage, misinterpretation of the protocol, and incorrect number for current treatment cycle. Such occurrences result from the lack of familiarity with the treatment protocol, errors in prescribing, errors in administration, errors in interpretation of the written order, and lack of familiarity with the patient's medical background. Two common examples of errors in administration include doxorubicin (correct, 100 mg/m² for over 4 days in divided doses; incorrect, 100 mg/m² daily for 4 days) and vincristine (correct, IV dose [0.06 mg/kg]; incorrect, administered IT). A systemic approach to prevent medical errors with chemotherapeutic agents is discussed elsewhere.⁶⁰ Patient risk factors for toxicity from these agents need to be considered during the assessment because these may explain the clinical findings. These include inability to eliminate or metabolize the drug (i.e., renal or hepatic insufficiency), pre-existing disorder (e.g., seizures, congestive heart failure, coronary artery disease) of the target organ of toxicity, the presence of third space fluid compartments (e.g., peritoneal, pleural) that can sequester the drug or metabolite, and concomitant treatments (e.g., medications or radiotherapy) that can potentiate the target organ's toxicity.

Drug levels for this class of agents are not routinely available in the clinical setting to assist in confirming the diagnosis of toxicity. However, analytical assays to measure MTX, busulfan,⁵ cisplatin (platinum),⁵⁸ and vincristine⁶¹ are available, and the levels of these agents can be used to assess for exposure. Some of the chemotherapeutic agents are associated with unique manifestations of toxicity such that when these are present, the agents should be suspected. For example, the anthracyclines are associated with congestive heart failure and cardiomyopathy; cisplatin with renal insufficiency, ototoxicity, and peripheral neuropathy; the vinca alkaloids with peripheral neuropathy, SIADH, and central autonomic instability; and ifosfamide with seizures.

Certain studies can assist the diagnostic process by either confirming the findings on clinical examination

or by evaluating for other disorders that may present with similar findings. For example, myocardial biopsies can evaluate for infectious and ischemic causes of cardiomyopathy when anthracycline toxicity is being considered. Although this procedure is infrequently used for this purpose, it is still used in conjunction with the left ventricular ejection fraction to determine the course of anthracycline treatment in select cases. The electroretinogram can identify retinal disorders of the post-photoreceptor neural function that is described in patients with visual loss and color aberrations from cisplatin toxicity.⁵⁵ Other studies include audiometry to evaluate for high-frequency hearing loss from cisplatin toxicity; brain computed axial tomography or magnetic resonance imaging to evaluate for leukoencephalopathy from MTX, hemorrhage, and metastatic lesions; and nerve conduction studies to evaluate for sensorimotor deficits attributed to a peripheral neuropathy. Drug-induced peripheral neuropathies in cancer patients need to be differentiated from paraneoplastic syndromes.⁶²

MANAGEMENT

The initial approach toward the patient with a chemotherapeutic agent overdose requires the stabilization of immediate life-threatening findings. These include dysrhythmias, congestive heart failure, seizures, and complications of pancytopenia (e.g., sepsis). Furosemide, inotropic agents, and fluid restriction can be used to treat heart failure. Uncontrolled hypertension can be managed with a peripheral vasodilating agent, such as a calcium channel blocker. This may be necessary because vincristine toxicity central autonomic instability can occur in this setting. Seizures can be treated with benzodiazepines, barbiturates, and phenytoin. For busulfan, phenytoin is used in a prophylactic manner during high-dose therapy (>16 mg/kg). Methylene blue (50 mg IV as a 1% solution) is used to treat encephalopathy from ifosfamide, and it was attributed to an improved patient outcome in a small case series.⁶³ Blood product replacement may be necessary because of either anemia or thrombocytopenia. In order to protect febrile neutropenic patients from overwhelming sepsis, granulocyte colony-stimulating factor, reverse isolation, and broad-spectrum antibiotics will be necessary.

There are two events when decontamination is important, and they are oral and IT exposures. The application of gut decontamination is limited to only a few chemotherapeutic agents because of their availability as oral formulations. These include MTX, busulfan, melphalan, and chlorambucil. The oral administration of activated charcoal is indicated when patients present in a timely manner following the ingestion. Repeat doses of activated charcoal can be used in the setting of delayed MTX elimination (e.g., renal failure) to limit enterohepatic recirculation of the drug.⁶⁴ As for IT overexposures, it is imperative to decontaminate immediately the cerebrospinal space so that the maximal amount of drug can be removed. IT decontamination consists of CSF drainage, lavage of the cerebrospinal

space, and ventriculolumbar perfusion.⁴⁷ The volume of CSF that can be safely removed at one time is dependent on the age of the patient. For an adult, up to 75 mL can be removed and replaced with an equal volume of Ringer's lactate. Cerebrospinal space lavage is accomplished by exchanging CSF with isotonic saline or lactated Ringer's mixed with fresh-frozen plasma to minimize protein loss from the CSF.

Patients need to be adequately hydrated to promote renal perfusion because they are at risk for volume depletion from gastrointestinal fluid loss. Specific approaches to limit renal toxicity by stabilizing either parent drug or metabolite are recommended for cisplatin and MTX. Sodium chloride promotes the anionic state of cisplatin and decreases urine platinum concentrations to limit renal toxicity.^{65,66} Therapy with 0.9% saline hydration and osmotic diuresis with mannitol to achieve a urinary output of 1 to 3 mL/kg/hr for 6 to 24 hours is recommended. It is important to maintain urinary output because platinum renal elimination is dependent on urine flow and not on creatinine clearance.⁶⁷ For MTX, the patient needs to be adequately hydrated and the urine alkalized to limit renal toxicity from the precipitation of drug metabolite.⁶⁸ The urine pH should be maintained at >7.0, which can be accomplished with a sodium bicarbonate infusion.

Baseline studies should be obtained upon initial evaluation of the patient, and they include complete blood count, serum electrolytes, BUN, creatinine, liver function tests (i.e., aspartate transaminase, alanine transaminase, lactate dehydrogenase, alkaline phosphatase, bilirubin), prothrombin time/partial thromboplastin time, urine analysis, and electrocardiogram. If the woman may be pregnant, a pregnancy test is necessary to evaluate the consequences of the exposure to the pregnancy. Trace elements such as magnesium should be monitored in the setting of cisplatin toxicity because renal wasting can lead to hypomagnesemia. In general, hematologic indices should be followed weekly for up to 2 weeks after hospital discharge of the patient because myelosuppression may not present until weeks after the exposure. For many of the chemotherapeutic agents, patients with an excessive exposure will require intensive management for their condition. This will include close and constant monitoring for existing and evolving toxicities (e.g., cardiac, CNS, renal), or treatment with either rescue agents or the use of enhanced elimination therapy. Thus, these patients need to be admitted to the area in the hospital that can provide them with the appropriate level of care.

Drug levels are infrequently monitored during chemotherapy and thus are not available in the routine clinical setting. However, MTX is an exception, and drug levels are monitored to assist patient management in the course of therapy. A serum MTX level should be obtained initially and repeated at 24 and 48 hours to determine the risk for toxicity and the duration of leucovorin treatment. An MTX half-life greater than 3.5 hours within the first 24 hours of exposure or a serum MTX level greater than 5 $\mu\text{mol/L}$ at 28 hours post-exposure is associated with increased risk for toxicity.

MTX CSF levels can assist in evaluating symptomatic patients at risk for neurotoxicity (e.g., prior meningeal disease) from either an overdose or a CSF outflow obstruction. In both cases, the CSF MTX level would be elevated. The common clinical method for measuring MTX is the fluorescence polarization immunoassay (TDx), which has a level of sensitivity of 0.01 $\mu\text{mol/L}$ and can accept various biologic specimens (e.g., plasma, serum, urine, and CSF). The notable interferents with this method are MTX metabolites, such as 7OHMTX and DAMPA.

Rescue Agents

Rescue agents or chemoprotectants⁶⁹ are medications that limit host toxicity from the effects of drugs used in chemotherapy. The role for rescue agents in the management of patients with chemotherapeutic agent toxicity is limited because of the few drugs available and the need to use them in a timely manner. These rescue agents were designed for pretreatment and not post-treatment therapy. Thus, when an exposure is recognized, it is important to administer the rescue agent immediately once the decision is made to use it. Rescue agents are available for MTX (folinic acid, carboxypeptidase), cisplatin (amifostine, thiosulfate), and the anthracycline antibiotics (dexrazoxane). Although glutamic acid is not considered a rescue agent because of its nonspecific activity, it has been used during vincristine therapy to limit peripheral neuropathy based on animal evidence.⁷⁰ Patients treated with glutamic acid were observed to have improved deep tendon reflex and sensory responses,⁷¹ and a shorter duration of myelosuppression.⁷² The therapy is benign and should be offered to overdosed patients. The dose for glutamic acid is 500 mg every 8 hours, by mouth or IV.

Folinic acid (leucovorin) is used to limit the toxic effects of MTX on host cells by allowing for the continuation of biochemical processes that are dependent on tetrahydrofolate. Tetrahydrofolate is necessary for single carbon transfer reactions that are critical to the formation of certain amino acids, purine nucleotides, and thymidylate. The latter two products are necessary for the synthesis of DNA and RNA. MTX blocks the reduction of dihydrofolate to tetrahydrofolate by inhibiting DHFR. The addition of reduced folate analogs (e.g., folinic acid [5-formyl-5,6,7,8-tetrahydro-folic acid]) allows for continued cell function and survival by bypassing this enzymatic blockade. The beneficial effects of folinic acid have been demonstrated to decrease gastrointestinal mucosal disruption and bone marrow-suppressive effects during high-dose MTX therapy. The use of folinic acid is indicated when the serum MTX level is anticipated to be greater than 0.01 $\mu\text{mol/L}$, which can occur during high-dose MTX therapy, in the overdosed patient or in a patient with delayed MTX elimination. Although the effective MTX concentration to inhibit DHFR is 0.5 $\mu\text{mol/L}$, it is generally accepted that a level of 0.01 $\mu\text{mol/L}$ is not likely to have any toxicologic effects, and folinic acid rescue treatment is recommended until this level is achieved. The IV route of administration is

preferred for folinic acid in the acute setting or in the patient with toxic manifestations. This is because of the efficiency of drug administration and the limitations associated with the oral route in this setting. These include incomplete gut absorption⁷³ and lack of compliance, which can result in the patient with mucosal ulcerations. The dose of folinic acid is from 15 to 25 mg orally, and up to 1000 mg/m² IV, and is administered every 6 to 8 hours. When 100 mg/m² folinic acid was administered IV over 4 hours, it achieved a steady-state reduced folate level of 4 $\mu\text{mol/L}$.⁷⁴ Folinic acid should be administered IV during IT MTX overexposures to limit systemic toxicity from the distribution of MTX from the cerebrospinal space to the systemic circulation. Folinic acid is not to be administered intrathecally for IT MTX overdoses because this route of administration was associated with a fatal outcome.⁷⁵ Serum MTX levels should be monitored daily to determine adjustments in dose and therapeutic end point during the use of folinic acid. Folinic acid therapy is benign, and treatment should not be delayed in anticipation of a serum MTX level in patients with an MTX overdose.

Carboxypeptidase (NSC-641273) is a bacterial enzyme that effectively deactivates MTX by cleaving the glutamyl residue. This rescue agent is under investigatory use to degrade MTX during situations of host toxicity. Carboxypeptidase has been used systemically (i.e., IV) and in the cerebrospinal space for IT overdoses with success.⁴³ This agent is made available through the National Institutes of Health, and the indications for use include renal failure and an elevated serum MTX level⁷⁶ or IT overdoses (protocol number 92-C-0137). The contact information is as follows: Clinical Studies Support Center/National Cancer Institute, telephone (888) 624-1937, fax (301) 881-8239, website <http://ccr.ncicrf.gov/trials/cssc/patients/search.asp>, and e-mail address ncicssc@mail.nih.gov. A limitation to the use of carboxypeptidase is host sensitization, which has not been previously described.

Amifostine (Ethyol, MedImmune Oncology, Inc., Gaithersburg, MD), and sodium thiosulfate are thiol agents that have been clinically used to limit cisplatin-induced nephrotoxicity. Although only amifostine is approved by the Food and Drug Administration to protect against nephrotoxicity, the mechanism by which these thiol agents work to counteract cisplatin are different. Thiol agents have long been studied for their protective effects from cisplatin toxicity. Several mechanisms are proposed by which these agents elicit their protection, and they include binding to reactive cisplatin intermediates, scavenging for free radicals, or regenerating intracellular glutathione.⁷⁷ Amifostine is an organic thiol agent and is activated by intracellular alkaline phosphatase. It is most effective when administered prior to cisplatin, and may offer additional beneficial effects by limiting myelosuppression, mucositis, and neuro-toxicity.^{78,79} Amifostine administration can cause hypotension; thus, the patient needs adequate hydration and frequent blood pressure monitoring during the use of this drug. Sodium thiosulfate works by binding to extracellular protein unbound platinum species, which limits the metal's

deposition in the renal tubules to cause damage.⁵⁸ There is some evidence that thiosulfate may limit neurotoxicity from cisplatin as well.^{80,81} Thiosulfate needs to be administered soon after cisplatin exposure to obtain maximal benefit, and as an infusion because of its short plasma half-life (approximately 20 minutes). When thiosulfate was administered as an IV bolus of 4 g/m² and continued as an infusion of 12 g/m² over 6 hours, it was shown to limit renal toxicity in patients receiving cisplatin at a dose as high as 270 mg/m².^{82,83} BNP7787 is a disulfide of MESNA and is being investigated as another thiol rescue agent for cisplatin toxicity. In controlled animal trials, BNP7787 was shown to limit cisplatin-induced nephrotoxicity and myelosuppression.⁸⁴

Dexrazoxane is used to limit cardiotoxicity during doxorubicin therapy of women with breast cancer and who are receiving doses higher than 300 mg/m². This agent is a cyclic analog of ethylenediaminetetra-acetic acid (EDTA) and forms an intracellular intermediate to chelate iron to interrupt the formation of free radicals responsible for cardiotoxicity. Dexrazoxane treatment is associated with improved left ventricular ejection fraction and decreased incidence of congestive heart failure following doxorubicin therapy.⁸⁵ During chemotherapy, dexrazoxane is administered 30 minutes prior to doxorubicin treatment, and in a dose ratio of 10:1. Although further investigations are necessary to define the role of this rescue agent in the overdose setting, its use may benefit patients with doxorubicin overdoses, and the oncologist should be consulted on this topic. Amifostine⁸⁶ and monohydroxyethylrutoside⁸⁷ are being considered as new rescue agents to protect patients from the cardiotoxic effects of the anthracycline agents.

Enhanced Elimination

The application of enhanced elimination for patients with chemotherapeutic agent overdoses is based on the limited experience and variable success with a few agents. These include busulfan, ifosfamide, cisplatin, doxorubicin, mitoxantrone, MTX, and vincristine. The factors significantly contributing to the effectiveness of these approaches include timeliness of intervention and the extent of either tissue binding or tissue distribution by the chemotherapeutic agent. The protein-binding capacity of the agent is important when hemodialysis is being considered. Hemodialysis has been used to enhance the elimination of busulfan in renal failure patients during therapy^{88,89} and in an overdosed patient. This procedure may be effective for ifosfamide exposures⁹⁰ as well. In a 4.6-kg infant who received a four fold overdose of busulfan tablets, hemodialysis was instituted at 9 hours following exposure and continued for 3 hours at a flow rate of 68.3 mL/min.⁵ During hemodialysis, the plasma half-life for busulfan was 1 hour and the clearance was 61 mL/min/kg, which were improved from the pretreatment values of 1.6 hours and 41 mL/min/kg, respectively.

Hemoperfusion is the preferred method for the enhanced elimination of MTX because of its greater efficiency compared to hemodialysis.⁹¹ Hemodialysis

should be reserved for patients with both an elevated serum MTX level and renal failure because MTX is efficiently eliminated by normal functioning kidneys.^{92,93} At 24 hours, about 85% of MTX administered IV is eliminated by the body. Delayed endogenous clearance of MTX occurs when the creatinine clearance is less than 60 mL/m²/min. Hemoperfusion may be effective in removing doxorubicin because it was shown to increase doxorubicin clearance by 20-fold in animal experiments,⁹⁴ and to rapidly decrease serum drug levels in patients with doxorubicin overdoses.⁹⁵ However, hemoperfusion was less successful in removing mitoxantrone in an overdosed patient even though it was initiated within hours of the drug's administration.⁹⁶ The lack of efficacy in this latter situation may be attributed to this drug's extensive tissue-binding capacity or tissue distribution.

Plasmapheresis is best used to enhance the elimination of chemotherapeutic agents with a high capacity for protein binding. Plasmapheresis is the preferred approach to remove cisplatin because it was shown to be more effective than hemodialysis,^{52,97-99} and associated with improved symptoms following a decline in plasma drug level.⁵² In an event where a patient received 400 mg/m² of cisplatin, plasmapheresis was initiated the day after drug exposure and continued for 12 days for a total of nine sessions. The plasma cisplatin level declined from 2470 ng/mL to 216 ng/mL, and the patient's mental status improved after the fifth session.⁵² Plasmapheresis should be initiated soon after the exposure to limit further distribution of cisplatin into the intracellular space, but can still be of benefit when administered days after the initial exposure.⁶⁷ For vincristine overdoses, plasmapheresis^{100,101} and exchange transfusion⁷² have been demonstrated to lower plasma drug levels and, possibly, shorten the duration of toxicity. Plasmapheresis and exchange transfusion were initiated at 6 hours post-exposure, and drug levels decreased from pretreatment levels by 23% and 65%, respectively. It is important to institute these procedures soon after exposure to maximize removal of the drug while it remains in the blood compartment.

SUMMARY

Chemotherapeutic agent overdoses are associated with high morbidity and mortality because of the cell-specific mechanism of action and the narrow therapeutic window of the drugs in this class. The causes of the exposure are typically iatrogenic and involve several mechanisms that can be categorized as errors in either dosage regimen or drug preparation. The manifestations of toxicity common to these agents include pancytopenia, nausea, vomiting, mucositis, and alopecia. The presence of additional clinical findings, such as cardiac dysrhythmias and failure, renal insufficiency, seizures, peripheral neuropathies, and electrolyte abnormalities will vary by the chemotherapeutic agent. The management of these patients includes stabilization of immediate life-threatening disorders, decontamination,

administration of rescue agents, and institution of enhanced elimination. Despite all of these modalities, prevention remains the best treatment for these patients.

B Thalidomide

MICHAEL W. SHANNON, MD, MPH

At a Glance...

- Thalidomide has many useful clinical properties, possessing sedative-hypnotic, antibiotic, anti-inflammatory, anti-angiogenesis, and immunomodulatory effects. It consequently has a wide range of potential clinical uses.
- Thalidomide is also a very potent teratogen, capable of producing birth defects after a single dose. The limb deformity phocomelia is the best characterized of thalidomide's effects.
- Adverse effects of thalidomide when taken therapeutically include somnolence, rash (including Stevens-Johnson syndrome), peripheral neuropathy, and hepatotoxicity.

Thalidomide is one of the most notorious drugs ever created. The agent was used around the world for approximately 5 years before its role as a potent teratogen was recognized. Banned after producing a generation of children with severe birth defects, the drug began making a surprise comeback in the 1980s. In 1998, thalidomide was approved by the Food and Drug Administration (FDA) for use in erythema nodosum leprosum. Since that time, the drug's list of clinical indications has proliferated as its broad range of pharmacologic actions are exploited to treat leprosy, multiple myeloma, leprosy, and many other disorders.

HISTORY

Thalidomide was first released in Germany as the drug Contergan in 1956 and in England in 1958 as Distaval. Originally developed to be an antibiotic, it was found to have a useful sedative effect. It was approved as a sedative-hypnotic, safer than barbiturates and other central nervous system (CNS) depressants of its era. Its liquid form was often given to crying children, earning it the title "West Germany's baby sitter."¹ Proving to be effective in hyperemesis gravidarum, it became a popular

drug for the nausea of pregnancy, with the added benefit of offering women a full night's sleep. Having an excellent safety profile, its use rapidly grew; it quickly became the third largest selling drug in Europe; at its peak it was sold in 48 countries.² In North America, it was used briefly in Canada as the drug Kevadon; for a brief period Kevadon was distributed illegally in the United States. However, when a new drug application to market Kevadon in the United States was filed with the FDA in 1960, the drug's approval was deferred by Dr. Frances O. Kelsey because reports of thalidomide-associated peripheral neuropathy had begun to appear and because animal safety data seemed inadequate. As the FDA continued to seek more data, in November 1961 thalidomide's role in causing phocomelia ("seal limb") in the offspring of women who used the drug during pregnancy was reported almost simultaneously by Drs. Lenz in West Germany and McBride in Australia. The drug was promptly removed from the market. By 1962, phocomelia, amelia, and other birth defects in more than 12,000 children in 46 countries were attributed to thalidomide; at least 17 cases of phocomelia occurred in the United States.³ While phocomelia, an obvious and debilitating birth defect, became synonymous with thalidomide, cardiac defects and other anomalies were also found in the progeny of pregnant women who used thalidomide.⁴ Birth defects were associated with ingestion of as little as a single dose.

After its worldwide withdrawal in 1961, the drug was shunned for only a few years. In 1965 its efficacy in the treatment of erythema nodosum leprosum (ENL) was discovered. After years of growing scientific interest, and drug research and development, in July 1998 the FDA approved thalidomide for the treatment of ENL, a debilitating condition associated with lepromatous leprosy. Soon thereafter it was shown to be valuable as a treatment for aphthous ulcers, leading to its approval for this indication in 2001. Once clinical and experimental data indicated that thalidomide was also a potent angiogenesis inhibitor, its clinical role expanded even

more. Thalidomide is now used for a broad range of conditions (Box 56-1).

PHARMACOLOGY

Thalidomide is a glutamic acid derivative. Its structure is shown in Figure 56-1. The agent is available in 50-, 100-, and 200-mg capsules. For most of its clinical uses, thalidomide is prescribed in a dose of 3 to 6 mg/kg/day, taken in one to four divided doses. Customary doses are 200 to 800 mg daily. Absorption of thalidomide from the gut is slow but extensive; a 200-mg dose produces a peak concentration of 1 to 2 mg/L at 3 to 4 hours.⁵ Distribution characteristics include plasma protein binding of approximately 60% and an apparent volume of distribution (Vd) of approximately 1 L/kg.^{5,6}

Thalidomide is primarily biotransformed through spontaneous, nonenzymatic hydrolytic cleavage.⁵ The drug also undergoes metabolism by the cytochrome P-450 isoenzyme CYP2C19. Multiple metabolites have been identified; certain drug effects (e.g., antiangiogenic activity) are attributed to its metabolites rather than to the parent drug.

FIGURE 56-1 Thalidomide structure.

genesis activity) are attributed to its metabolites rather than to the parent drug. The drug's elimination half-life is approximately 6 hours. Thalidomide metabolites are eliminated in urine and feces within 48 hours of a dose; there is little excretion of unchanged drug. Drug pharmacokinetics are not altered by repeat dosing. Thalidomide possesses no significant drug interactions.

Having a broad range of clinical effects, thalidomide has unclear cellular mechanisms of action. However, on a macroscopic level, the drug appears to have four primary actions: (1) immunomodulatory, (2) anti-inflammatory,^{7,9} (3) antiangiogenesis, and (4) hypnosedative. Thalidomide is an immunostimulant, producing an increase in total lymphocyte count and CD8⁺ T cells. It also increases interferon- γ production² while significantly lowering levels of circulating tumor necrosis factor- α (TNF- α , also referred to as cachectin). For many conditions, its efficacy is based on this action. For example, ENL is associated with high circulating levels of TNF- α ; thalidomide's efficacy correlates with falling TNF- α concentrations. Recurrent aphthous ulcers and Behçet's disease, other conditions for which thalidomide is useful, are also associated with elevated circulating TNF- α .^{10,11} Sedative effects of the drug appear to have a mechanism different from barbiturates; rather than enhancing γ -aminobutyric acid (GABA)-mediated neurotransmission, thalidomide appears to activate sleep centers in the forebrain.⁵ Recent data also suggest that thalidomide is an inhibitor of nitric oxide synthase.¹²

Although thalidomide is FDA approved only for the treatment of recurrent aphthous ulcers and erythema nodosum leprosum, the range of disorders for which it has been used, with reported clinical benefit, is extensive (see Fig. 56B-1). It has been used successfully to treat infectious conditions such as HIV-associated wasting syndrome and tuberculosis-associated weight loss. It has also been used to treat chronic graft-versus-host disease. However, its most rapidly expanding use has been as a chemotherapeutic agent for select cancers, including multiple myeloma,¹³⁻¹⁶ prostate cancer, myelofibrosis, renal cell carcinoma, lymphoma, Kaposi's sarcoma, and thyroid cancer.¹⁷ It has also been used to treat a number of autoimmune or idiopathic disorders, including ankylosing spondylitis, sarcoidosis,¹⁸ and inflammatory bowel disease.^{19,20}

TOXICITY

The mechanisms of thalidomide toxicity are equally unclear. By whatever mechanisms, the drug is associated with a very broad range of adverse effects (Box 56-2). These toxicities are found in those taking the drug chronically; acute single overdose of thalidomide appears to produce only mild sedation; ingestions of as much as 14 g have led to minimal toxicity.⁵

The adverse effects associated with chronic thalidomide use include somnolence, rash, fatigue, constipation, abdominal pain, Stevens-Johnson syndrome, elevated liver enzymes, and peripheral edema.⁸ Endocrine effects are also multiple and include hyperprolactinemia (with

Peripheral neuropathy has been a recognized adverse effect of thalidomide since it was first released. The neuropathy characteristically affects sensory rather than motor neurons and lower more than upper extremities.²⁴ Victims often complain of distal lower extremity painful paresthesias. The neuropathy seems to be dose related, although dose-unrelated occurrences have also been reported.²⁵ At-risk groups are females rather than males and the elderly. The neuropathy is partially reversible and can be either an axonal length-dependent neuropathy or a ganglionopathy.²⁶

Other clinical toxicities include sinus bradycardia, particularly in those taking other medications that decrease heart rate,²⁷ deep venous thrombosis, pulmonary embolus, and other thromboembolic events.^{28,29}

As many as 30% of subjects must cease thalidomide use due to unacceptable adverse effects.³⁰

TERATOGENICITY

Thalidomide is a powerful teratogen, producing effects when taken during much of pregnancy, particularly days 34 to 50 after the final period. The main categories of thalidomide embryopathy include limb deformity, craniofacial defects (microtia or anotia, eye defects, choanal atresia), cardiac disturbances (ductus arteriosus, conotruncal defects, septal defects), intestinal disorders (duodenal atresia, anal atresia, pyloric stenosis), genitourinary tract abnormalities (ectopic kidney, vaginal duplication, renal/testicular agenesis), and lung abnormalities. Limb deformities such as phocomelia occurred

when women took any amount of thalidomide during the 20th to the 36th day of pregnancy. Most birth defects, including phocomelia, have been attributed to the drug's antiangiogenesis effects. Thalidomide does not produce second-generation birth defects.³¹

When it approved thalidomide, the FDA and drug manufacturer instituted severe controls over the drug. To minimize the risk for birth defects, the FDA has mandated that physicians prescribing thalidomide be registered in the System for Thalidomide Education and Prescribing Safety (STEPS) program. Patients taking the drug must receive drug education and acknowledge that they received this education. Women must agree in writing to have no intercourse or to use two methods of birth control should they engage in intercourse. Women must also undergo periodic pregnancy tests.

MANAGEMENT

Acute overdose of thalidomide should be treated with initial stabilization and supportive care. Sedation can be anticipated. Activated charcoal adsorbs thalidomide and is a potentially valuable intervention, particularly if administered within 1 to 2 hours of ingestion. There are no specific laboratory data that would be useful in the diagnosis and management of thalidomide toxicity. An electrocardiogram and an arterial blood gas or pulse oximetry with end-tidal CO₂ monitoring can be useful adjuncts in management. Other tests (e.g., toxic screen testing) may be useful to rule out coingestions. There is no known method of enhancing the elimination of thalidomide; elimination enhancement should not be necessary since patients quickly recover without sequelae. A pregnancy test should be considered in women of childbearing age since thalidomide ingestion during pregnancy has grave implications that may require pregnancy counseling. Patients with acute overdose who are asymptomatic or who have only transient lethargy can be safely discharged from the emergency department with close follow-up.

SHARITA E. WARFIELD, MD, MS ■ MATTHEW W. HEDGE, MD

At a Glance...

- Transplant agents and other immunosuppressives are being used increasingly as the prevalence of solid organ and cell transplant recipients increases.
- All transplant agents have important drug–drug or drug–food interactions, requiring careful dosing and close monitoring.
- Tacrolimus and cyclosporine, the most common transplant agents, are metabolized by CYP3A3. Their metabolism can be significantly slowed in the presence of CYP3A inhibitors, leading to elevated concentrations and resulting toxicity.
- The major toxicity resulting from tacrolimus and cyclosporine overdose is renal injury.

Transplantation of vital organs such as the kidney, liver, pancreas, heart, and bone marrow is efficiently used as a form of treatment for end-stage organ disease. It is the role of the body's immune system to discriminate between self and nonself cells in the body and destroy the nonself cells. When an organ transplant is introduced to the body, it is recognized as foreign. It is this response that leads to transplants being rejected. Historically, immunosuppressive agents have been used to ensure the success of organ transplantation. However, the use of these agents was not without consequence. Older agents used in single and multiple drug protocols had many undesirable effects. The discovery and refinement of current conventional immunosuppressive agents, which function in a nonspecific manner to suppress the immune system, has helped revolutionize the field of transplantation.

Until recently, these agents provided the mainstay of clinical immunosuppression with antiproliferative activity. They included antimetabolites, alkylating agents, and irradiation. The current belief is that T lymphocytes are primarily responsible for graft rejection. The introduction of agents that specifically act on T lymphocytes (cyclosporine, tacrolimus [FK506], and azathioprine) dramatically changed the outcome after transplantation.

The use of immunosuppressive agents extends beyond organ graft protection. Many newer agents have shown efficacy in the treatment of dermatologic disorders including seborrheic dermatitis, cutaneous lupus erythematosus, vulvar lichen sclerosis, and vitiligo.¹⁻⁴ Some older agents have shown efficacy in the treatment of the vasculitides, rheumatoid arthritis, and multiple sclerosis.^{5,6} In general, overdose of transplant agents is rare. However, increasing indications for the newer agents coupled with the occasional dosing errors with

the older agents have sparked an interest in better understanding the toxicity and adverse effects of these drugs.

TACROLIMUS (FK506)

Pharmacology

Tacrolimus (FK506) is a macrolide immunosuppressant derived from *Streptomyces tsukubaensis*. It has been used in liver, heart, kidney, and other experimental forms of transplantation. It is similar to cyclosporine in its mode of action, efficacy, and toxicity profile. The exact mechanism by which tacrolimus produces immunosuppression remains unknown. It is proposed that tacrolimus inhibits T-lymphocyte activation by binding to an intracellular protein, FKBP-12. A complex is formed between tacrolimus and FKBP-12, calcium, calmodulin, and calcineurin. This complex inhibits the phosphatase activity of calcineurin. The inhibition of calcineurin is believed to prevent the dephosphorylation and translocation of nuclear factor of activated T cells (NF-AT), which is the cellular component thought to initiate gene transcription for the formation of lymphokines such as interleukin-2 (IL-2) and interferon- γ . Tacrolimus also inhibits the transcription for genes that encode IL-3, IL-4, IL-5, granulocyte-macrophage colony-stimulating factor (GM-CSF), and tumor necrosis factor- α (TNF- α), all of which are involved in the early stages of T-cell activation. In addition, it inhibits the release of preformed mediators from skin mast cells and basophils, as well as potentiating the effects of corticosteroids.

Pharmacokinetics

The pharmacokinetic profile of tacrolimus has been studied extensively in adults and children. Bioavailability after oral administration averages 17% to 22%. The presence of food, particularly a high-fat meal, decreases the rate and extent of tacrolimus absorption. Peak whole-blood levels are achieved within 1.5 to 3 hours after oral dosing.^{7,8} Tacrolimus is highly protein bound and also binds to erythrocytes and lymphocytes. The volume of distribution in adults is 1.4 to 1.9 L/kg; in children, it is 2.6 L/kg. Tacrolimus is primarily metabolized in the liver via cytochrome P-450 isoenzymes CYP3A4 and CYP3A5. The metabolites are eliminated in the bile at a rate of 0.04 to 0.08 L/kg/hr in adults and 0.14 L/kg/hr in children. The elimination of tacrolimus is not affected by renal or mild hepatic dysfunction; however, in patients with severe hepatic dysfunction or hepatitis C, the clearance rate is prolonged.⁷⁻¹¹

Tacrolimus is available in the United States and Canada in three formulations: oral, parenteral, and a topical ointment. Dosage varies and is based on body weight. Typically for adults, teenagers, or children, the oral dose will be 0.1 to 0.3 mg/kg/day. The parenteral dose is 0.01 to 0.05 mg/kg/day.

DRUG INTERACTIONS

The metabolism of tacrolimus by CYP3A increases the risk of drug interactions when it is used with drugs that are also metabolized via the cytochrome P-450 enzyme system. A variety of drug classes cause increased tacrolimus concentrations, including antifungal agents, corticosteroids, calcium channel blockers, macrolide antibiotics, and gastrointestinal (GI) prokinetic agents. Other substances such as cyclosporine, metronidazole, cimetidine, and grapefruit juice may lead to decreased tacrolimus concentrations. Nephrotoxicity has been reported in patients taking tacrolimus; the concomitant use of other nephrotoxins such as amphotericin, aminoglycosides, cisplatin, or nonsteroidal anti-inflammatory agents (NSAIDs) may place the patient at increased risk for this adverse effect.^{7,8}

Toxicology

CLINICAL MANIFESTATIONS

Data are limited on cases of overdoses with tacrolimus. However, chronic overdose is known to cause nephrotoxicity. This usually is manifested early in therapy as an increase in serum creatinine and a decrease in urine output. Dosage adjustment or discontinuation of therapy will usually reverse the nephrotoxic effect. Neurotoxicity, which appears more commonly in patients with elevated tacrolimus concentrations or hepatic dysfunction, has also been reported. In severe cases, it may manifest as seizures, delirium, or coma. Some individuals may have a genetic predisposition to developing tacrolimus-induced neurotoxicity.⁶

ADVERSE EFFECTS

The most common adverse effects associated with tacrolimus are listed in Box 57-1. Type 1 diabetes mellitus develops in approximately 20% of patients taking tacrolimus. It appears to be more common in African Americans, in patients receiving high-dose corticosteroids, and in patients with elevated tacrolimus levels.^{7,8}

Management

Supportive care is the mainstay of therapy. A single dose of charcoal should be given after an acute overdose to help decrease absorption. Benzodiazepines can be used to treat agitation and seizures if they develop. Currently, no robust data support the use of multiple-dose activated charcoal or hemodialysis as treatment for tacrolimus overdose.

AZATHIOPRINE

Pharmacology

Azathioprine was originally approved by the Food and Drug Administration (FDA) in 1968 for use as an adjunct immunosuppressant agent. It was often used in combination with corticosteroids for solid organ transplantation. In recent years, azathioprine use has markedly declined and has been replaced by mycophenolate. Azathioprine is a pro-drug that is converted in the body to 6-mercaptopurine (6-MP). 6-MP is a purine analog that acts as an antimetabolite immunosuppressive agent inhibiting T-cell proliferation by interfering with the synthesis of nucleotides. Azathioprine is also used to treat Crohn's disease, lupus nephritis, rheumatoid arthritis, psoriasis, myasthenia gravis, and other autoimmune diseases.

Pharmacokinetics

Orally, azathioprine is well absorbed. Azathioprine is rapidly eliminated from the blood and converted in the liver by xanthine oxidase to 6-MP, which is then metabolized to 6-thiourate and several other metabolites. These metabolites are excreted in the urine; no azathioprine or 6-MP can be detected in the urine after 8 hours. The plasma half-life of azathioprine is less than 15 minutes, and the half-life of 6-MP is 1 to 3 hours. Azathioprine is 30% protein bound and only partially dialyzable.

The drug is available in two forms: an oral 50 mg tablet and an injectable solution of 100 mg/20 mL vial. The intravenous and oral doses are equivalent. Intramuscular injection is not advised. The initial recommended dose is 3 to 5 mg/kg once a day, and the maintenance dose is reduced to 1 to 2 mg/kg once a day. Dose reduction is necessary in patients with impaired renal function.

DRUG INTERACTIONS

The use of azathioprine with drugs including cotrimoxazole, carbamazepine, and ganciclovir affects leukocyte production and thus may induce hematologic toxicity in patients. The use of angiotensin-converting enzyme (ACE) inhibitors in patients taking azathioprine has been reported to cause anemia and severe leukopenia.¹² Severe leukopenia can develop particularly in renal transplant patients. Allopurinol inhibits xanthine oxidase, the enzyme responsible for the inactivation of 6-MP to 6-thiouric acid and other metabolites. The use of azathioprine and allopurinol in combination causes 6-MP to accumulate and places the patient at risk for marked immunosuppressive effects from azathioprine. Therefore, the dose of azathioprine should be reduced by 50% when used with allopurinol.¹³ Prolonged use of azathioprine with corticosteroids may cause muscle wasting. Azathioprine also is known to impair fertility by reducing sperm counts in males. When azathioprine is used with tubocurarine, it decreases the effect of tubocurarine and other nondepolarizing neuromuscular blocking agents.¹²

Toxicology

CLINICAL MANIFESTATIONS

The principal and potentially serious toxic effects of azathioprine are hematologic and gastrointestinal. There also is an increased risk of secondary infection and cancer. Large overdoses of azathioprine may acutely cause abdominal pain, nausea, vomiting, and diarrhea. In general, patients undergoing azathioprine therapy experience nausea and vomiting for the first few months. Vomiting and abdominal pain may also be associated with hypersensitivity pancreatitis that rarely develops in these patients. Hepatotoxicity, manifested by elevated serum transaminases, alkaline phosphatase, and bilirubin, also is known to occur. Discontinuation of azathioprine therapy usually reverses the hepatotoxic effects. A rare but life-threatening hepatic veno-occlusive disease associated with chronic use of azathioprine has been reported.¹² Periodic measurements of serum transaminases, alkaline phosphatase, and bilirubin are indicated to detect hepatotoxicity early. Leukopenia and thrombocytopenia are dose dependent but may occur with chronic therapy. Dose reduction or temporary withdrawal will reverse these toxicities. In addition, macrocytic anemia and bleeding are known to occur with azathioprine therapy. A single case has been reported of a renal transplant patient who ingested a large dose (7500 mg) of azathioprine. The immediate toxic reactions were nausea, vomiting, and diarrhea, followed by mild leukopenia and mild abnormalities in liver function. The white blood cell count, serum glutamic oxaloacetic transaminase (SGOT), and bilirubin returned to normal 6 days after the overdose.¹⁴

ADVERSE EFFECTS

The most common adverse effects associated with azathioprine are listed in Box 57-2.

BOX 57-2

MOST COMMON ADVERSE EFFECTS ASSOCIATED WITH AZATHIOPRINE

Hematologic	Dermatologic
Leukopenia	Rash
Pancytopenia	Alopecia
Macrocytic anemia	Skin cancer
	Jaundice
GI	Bruising
↓ Appetite	Systemic
Nausea	Fatigue
Vomiting	Fever
Diarrhea	Serum
Pancreatitis	Sickness
Renal	
Interstitial nephritis	

Management

Overdose with azathioprine is rare; therefore, data regarding management in overdose are lacking. Supportive care seems to be the mainstay of treatment for GI manifestations. Protection from falls or injury seems prudent to avoid bruising or bleeding. Alanine transaminase (ALT), aspartate transaminase (AST), bilirubin, and alkaline phosphatase should be monitored. Hemodialysis may serve as an adjunct to supportive care with large ingestions, since it has been shown to remove up to 45% of azathioprine.¹² No data support the use of multiple-dose activated charcoal for azathioprine overdose. Single-dose activated charcoal may prove useful but may be complicated by the GI manifestations that preclude its successful administration.

CYCLOSPORINE

Cyclosporine is an 11-amino acid cyclic polypeptide produced by *Beauveria nivea* and *Tolyocladium inflatum* Gams. The amino acids at the 1, 2, 3, and 11 positions form an active site; experimental modifications of the drug have resulted in decreased immunosuppressive activity. Cyclosporine was introduced in the early 1980s and brought with it significant improvements to the field of organ transplantation. It has improved both initial and long-term allograft survival. The use of cyclosporine has also decreased the initial length of stay and the rate of readmission after transplantation. Cyclosporine is used in solid organ transplantation of heart, liver, and kidney as well as for treatment of rheumatoid arthritis and psoriasis. Minimal change, focal segmental, and immunoglobulin A (IgA) nephropathy may also be treated with cyclosporine.¹⁵ It has shown benefit in the initial treatment of type 1 diabetes mellitus. There have been reports of significant decreases in the patient's insulin requirement if cyclosporine therapy is initiated within the first 2 months.¹⁵

Pharmacology

Cyclosporine reversibly inhibits the proliferation of immunocompetent lymphocytes in G_0 and G_1 phases of the cell cycle, specifically, the T-cell lines. This inhibition of immune activity is accomplished by cyclosporine forming a complex with cyclophilin that binds to and inhibits the activity of the phosphatase, calcineurin. This in turn inhibits the production of the lymphokine, IL-2. IL-2 is a growth factor for the immune system and stimulates the replication of activated immunocompetent lymphocytes. This inhibition is greater in T-helper cells than in T-suppressor cells. The immunosuppressant activity of cyclosporine is largely due to the parent compound, because its metabolites have little pharmacologic activity.

Pharmacokinetics

Two forms of cyclosporine are currently available: Neoral, a microemulsion formulation, and Sandimmune, the conventional formulation. Neoral has significantly better bioavailability and less variability in absorption, both intra- and interindividual. It allows for more consistent dosing. The interindividual oral biovariability can still be quite significant, between 20% and 50% of the area under the curve. This great variability in absorption necessitates frequent drug monitoring to establish and maintain a stable dosing regime. Both forms of cyclosporine are highly lipid soluble, with absorption significantly affected by diet; high-fat meals increase absorption. Cyclosporine has a large volume of distribution, between 3 and 5 L/kg, and is up to 90% protein bound. Cyclosporine is metabolized by the cytochrome P-450 system, specifically CYP3A4, with 94% of metabolites excreted in the bile. A small portion, 6%, is excreted by the kidney, and 0.1% is excreted unchanged. Because excretion mainly is via the bile, there is a potential for enterohepatic recirculation. Cyclosporine has approximately 25 metabolites, none with significant immunosuppressive activity.

SPECIAL POPULATIONS

The pediatric population is notably different from the adult population in the metabolism and excretion of cyclosporine. Clearance has been reported to be enhanced significantly in the pediatric population—up to 40% greater.¹⁵ This difference in clearance may be related to differences in body composition and an apparent decrease in the volume of distribution (Vd) in children. Cyclosporine is classified by the FDA as pregnancy class C but has been used during pregnancy. Placental transfer is estimated to be between 37% and 64%. There is little evidence that cyclosporine adversely affects fetal outcome. Although there does seem to be an increased rate of prematurity and a trend toward fetal malformation and low birth weight, only prematurity reached statistical significance in one meta-analysis.¹⁶

Cyclosporine clearance is decreased in the geriatric population. It is unclear whether this decrease relates to a decrease in hepatic function or a change in Vd or lipid

transport.¹⁵ Cyclosporine clearance has also been found to be decreased in patients with decreased levels of low-density lipoproteins. This most likely represents a decrease in the ability to transport the drug to the liver for metabolism and excretion. Since there is minimal renal excretion of cyclosporine, patients with poor but stable renal function do not require dose adjustment. Greater than 90% of cyclosporine is metabolized in the liver, particularly the cytochrome P-450 system, and then excreted in the bile. A patient with significantly decreased hepatic function requires changes in the dosing regime.

DRUG INTERACTIONS

Owing to the extensive number of drugs that are metabolized via the cytochrome P-450 system, the potential interactions are numerous. Many commonly prescribed therapeutics are metabolized at CYP3A, increasing the risk of potential drug–drug interactions. The macrolides, azole antifungals (e.g., fluconazole), antiretroviral protease inhibitors, and many calcium channel blockers are also known inhibitors of CYP3A. These drugs have the potential to elevate a patient's cyclosporine level either through competition for the active site as a competitive inhibitor or through inhibition of the cytochrome via a secondary allosteric site as a noncompetitive inhibitor.¹⁷ Carbamazepine, a substrate of CYP3A, potentially acts as a competitive inhibitor. Many anticonvulsants such as carbamazepine, phenobarbital, phenytoin, and the glucocorticoids also interact with this cytochrome as inducers, increasing the amount of the enzyme and potentially leading to decreased cyclosporine levels and ineffective immunosuppression. Aminoglycosides, antineoplastics, antifungals such as amphotericin B, NSAIDs, and colchicines are known to cause renal dysfunction; concomitant use with cyclosporine may increase this risk.

Toxicology

Generally, acute toxicity from an oral ingestion is minimal. However, neonates and patients who receive unintentional parenteral overdoses are of concern, for they can develop significant toxicity. Parenteral overdose produces significant morbidity although the number of reported cases is limited. Reported effects, mainly in premature neonates, include worsening renal failure, metabolic acidosis, cyanosis, coma, hyponatremia, and hyperbilirubinemia.¹⁸ There is also a case report of cerebral edema with uncal herniation due to an intravenous cyclosporine overdose.¹⁹ When cyclosporine is used with other drugs that cause nephrotoxicity, synergistic effects could lead to rejection of an allograft. The pattern of nephrotoxicity has been broken down into three classes, all defined by a decrease in glomerular filtration rate (GFR) of 25%. The three classes are defined by the time course as acute (onset within the first 7 days of initiation of treatment), subacute (onset within 7 to 60 days of initiation of treatment), and chronic (onset >30 days after initiation of treatment). Increased serum creatinine, reduced glomerular filtration, and

decreased renal plasma flow rates are believed to be secondary to alterations in intrarenal hemodynamic function. Cyclosporine is thought to cause increases in Ca^{2+} influx in response to vasoconstrictors, particularly in the afferent arteriole. Cyclosporine also increases levels of thromboxane A_2 . Thromboxane A_2 increases vascular tone in the renal arterioles and myocyte proliferation in the intima of the vessel wall. Alternatively, an alteration in the ratio of thromboxane A_2 to prostacyclin could cause this effect, since thromboxane A_2 is a vasoconstrictor and prostacyclin is a vasodilator.

Many patients taking cyclosporine report neurologic side effects. The complaints consist mainly of paresthesias and numbness, although visual disturbances and coma have been reported. Many symptoms improve upon discontinuation of cyclosporine; however, they often recur upon rechallenge. GI disturbances including nausea and vomiting have been reported. Dysfunction of the biliary tree has been observed, with patients developing cholestasis, cholelithiasis, and hyperbilirubinemia.

Multiple endocrine effects have been noted with cyclosporine use, particularly hyperglycemia. The hyperglycemia is not associated with ketosis, and there is no change in the amount of secreted insulin or in the number of insulin receptors. Hyperglycemia is thought to be related to impaired glycogen synthesis with resulting accumulation of substrate.

Management

Decontamination of the GI tract with activated charcoal is suggested following acute toxic ingestion, particularly since cyclosporine has limited oral bioavailability. Some case reports suggest that multiple-dose activated charcoal decreases the half-life of cyclosporine although it is unclear whether these reported declines in serum levels represent redistribution to the tissues or elimination of the drug.^{20,21} In the setting of parenteral overdose, various therapies have been attempted, some being more effective and having a better rationale than others. Plasmapheresis was used in an adult who developed hyperbilirubinemia after a 30 mg/kg unintentional intravenous overdose.²² Although this therapy would help eliminate drug that was either free or bound to serum proteins, most of the circulating cyclosporine is bound to red blood cells (up to 50%) and 10% is bound to lymphocytes. Consequently, there appears to be little theoretic benefit to this intervention. Exchange transfusion has been used to treat neonatal cyclosporine overdose. In one case report, it produced a 30% reduction in cyclosporine level. In another case report, exchange transfusion was unsuccessful in changing the clinical outcome, and the patient died.¹⁸ The timing of the transfusion in relation to the overdose was unclear. At autopsy, there was significant tissue accumulation of cyclosporine, suggesting sufficient time had elapsed for redistribution to the tissues to occur.

LABORATORY MONITORING

Several methods are used to measure serum cyclosporine concentration. High-performance liquid chromatography

(HPLC) and radioimmunoassay techniques are the most common; these tests have variable sensitivity for the detection of cyclosporine metabolites. Little evidence suggests that measuring acute serum cyclosporine concentrations is helpful in management, particularly since peak levels can be delayed by up to 4 hours. The value in serial cyclosporine levels is more to determine when to resume immunosuppression than to aid in acute management. Serum blood urea nitrogen (BUN), creatinine, transaminases, and bilirubin should be monitored in patients with underlying renal or hepatic dysfunction.

ELIMINATION

Cyclosporine is not effectively removed by hemodialysis or hemoperfusion. It is not known whether charcoal, either in single or multiple doses, is effective in enhancing elimination although multiple-dose activated charcoal has been suggested as an effective means of elimination enhancement. It has also been suggested that CYP3A inducers might be useful therapeutic adjuncts, but little evidence supports its efficacy.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil is a prodrug that is rapidly metabolized to the active metabolite mycophenolic acid (MPA). MPA is a reversible, noncompetitive inhibitor of inosine monophosphate dehydrogenase, an essential enzyme in the production of purines. B and T lymphocytes have a greater reliance on the de novo pathway of purine synthesis, while other cell lines can use scavenger pathways to meet their metabolic needs. MPA is thus cytostatic in respect to lymphocytes.

Pharmacokinetics

Mycophenolate mofetil is rapidly absorbed and converted to MPA. MPA has a large V_d —3.6 to 4 L/kg—and is up to 97% protein bound. MPA is then metabolized to the phenolic glucuronide (MPAG) form. MPAG is largely excreted by the kidney; 93% is eliminated either by glomerular filtration or secretion from the renal tubule. The remaining MPAG is eliminated in the GI tract via biliary excretion, or it is excreted unchanged. MPAG that has been secreted in the bile and eliminated into the GI tract undergoes enterohepatic recirculation.

The absorption, metabolism, and area under the curve for children are similar to those of adults. Pharmacokinetics have not been studied in the geriatric population.

Because mycophenolate mofetil requires metabolic activation, patients with significantly impaired hepatic function have lower levels of the active form of the drug and less immunosuppressive activity.

Renal elimination is required for the excretion of the inactivated metabolite, and patients with impaired renal function have a prolonged exposure to the active form of the drug. Patients with significantly decreased renal excretion have similar peak drug levels but a decreased

rate of excretion, leading to an enlarged area under the curve compared with that of patients with normal renal function.

Although mycophenolate mofetil has been shown to be teratogenic in animal experiments, it is classified as pregnancy class C.²³

DRUG INTERACTIONS

Only a few drug–drug interactions have been studied with this agent. Antacids with magnesium and aluminum hydroxides decrease the amount of MPA absorbed. Cholestyramine lowers the area under the curve by interrupting the enterohepatic recirculation, leading to increased drug excretion. MPA decreases the amount of hormone absorbed from oral contraceptives, but what effect that has on suppression of ovulation is unknown. MPAG is excreted through glomerular filtration and tubular secretion; drugs that block this secretion such as probenecid will increase the area under the curve. Alterations in gut flora have the potential to alter the enterohepatic circulation and change the absorption and excretion characteristics of the drug, with less hydrolysis of MPAG, leaving less MPA for reabsorption. There are no reported significant drug interactions with cyclosporine, acyclovir, or ganciclovir. In patients with renal dysfunction, trimethoprim-sulfamethoxazole may compete with MPAG in the renal tubule for secretion into the tubular lumen.

Toxicology

Toxic manifestations of MPA are exaggerated therapeutic effects, consisting primarily of neutropenia.

Adverse effects that have been noted include an increased incidence of GI disturbance, GI bleeding, herpesvirus infection, and neutropenia.

Determination of drug levels is made either by enzyme-mediated immunofluorescence or HPLC.

Management

There are currently no case reports of acute MPA overdose in humans. Rats have been able to tolerate up to 4 g/kg and monkeys up to 1 g/kg; typical adult dosing is 2 to 4 g/day. Since many of therapeutic effects are dose dependent, the toxic manifestations would most likely be exaggerated clinical responses.

As for any overdose, supportive care is essential, with protection of the airway and evaluation of other toxic co-ingestants. Activated charcoal as a single dose may be useful in decreasing absorption of the drug. Evaluating serum drug concentration probably has more utility in determining when to restart MPA than in acute management. Secondary to the large V_d and protein binding of the drug, it is unlikely that either hemodialysis or hemoperfusion would be of significant benefit in enhancing elimination. There is significant enterohepatic recirculation, and animal studies suggest that cholestyramine can interrupt this circulation and

possibly enhance elimination. There is also a theoretic rationale for the use of multiple-dose activated charcoal to interrupt enterohepatic recirculation.

Digitalis

FRÉDÉRIC LAPOSTOLLE, MD, DMC ■ STEPHEN W. BORRON, MD, MS

At a Glance...

- Digitalis glycosides (digoxin and digitoxin) are drugs with small therapeutic indices.
- Digoxin is eliminated primarily via the kidneys, digitoxin by hepatic metabolism.
- Symptoms of toxicity may be vague, particularly in the elderly, and may involve multiple organ systems.
- Patients presenting with hyperkalemia, underlying cardiac disease, and advanced age have a poor prognosis.
- Digitalis Fab fragments may be lifesaving and should be administered early in case of serious poisoning or in the presence of poor prognostic factors.
- Cardiac conduction abnormalities, gastrointestinal disturbances, and both hypokalemia and hyperkalemia associated with digitalis toxicity are rapidly corrected by the administration of Fab fragments, obviating the need for other therapy.

Digitalis was introduced into clinical medicine by William Withering in 1785, after his investigation of a home remedy used by herbalists in the English countryside.^{1,2} He reported therapeutic efficacy and toxicity of leaves of *Digitalis purpurea*, commonly named foxglove. He recommended that digitalis “be continued until it acts either on the kidneys, the stomach, the pulse, or the bowel . . . let it be stopped upon the first appearance of any of these effects and I will maintain that the patient will not suffer from its exhibition, nor the practitioner be disappointed in any reasonable effects.”

Thereafter, cardiac glycosides, including digoxin, digitoxin, and ouabain, were extracted from plants and largely prescribed. Nowadays, indications for cardiac glycosides are restricted to the treatment of heart failure with or without associated supraventricular arrhythmia.

Due to a narrow therapeutic index (40% to 60% of the lethal dose is required to achieve the maximal therapeutic effect), digitalis toxicity remains frequent in patients with chronic heart diseases.³ Less frequently,

digitalis toxicity results from acute overdose in suicide attempts. Digitalis poisoning treatment strategy has been dramatically modified since 1976, with the introduction of digoxin-specific Fab fragments by Smith and colleagues.⁴

SCOPE OF PROBLEM

Digitalis intoxication was once considered the most common adverse drug reaction in U.S. medical practice. Studies from the 1960s and 1970s showed that as many as 15% of all patients in medical admissions were taking digitalis, and 20% to 30% of these patients would have signs of toxicity.⁵ Prescribing habits and the incidence of toxicity have begun to change because of (1) better appreciation of digitalis pharmacodynamics and drug interactions, (2) more appropriate maintenance dosage, (3) easy and rapid availability of serum digoxin determinations, and (4) expanded drug therapy for congestive heart failure, eliminating the need to push digitalis to higher, more potentially toxic concentrations. Nevertheless, the number of patients receiving maintenance digitalis therapy remains high, and the numerous common untoward effects still demand attention and understanding. Recently, toxicity associated with chronic digoxin treatment has been reported in 6% to 23% of patients, especially in the elderly.^{3,6}

The mortality rate of poisoned patients is poorly documented in cases of chronic intoxications but reaches 25% in cases of acute overdose.⁷ Neither pacing nor antidotal treatment has significantly reduced this mortality rate.^{7,8}

PHARMACOLOGY

The preparations of cardiac glycosides now used in clinical practice were initially derived from the leaves of plants from the species *D. purpurea*. Other plants that contain cardiac glycosides (e.g., strophanthus, red squill,

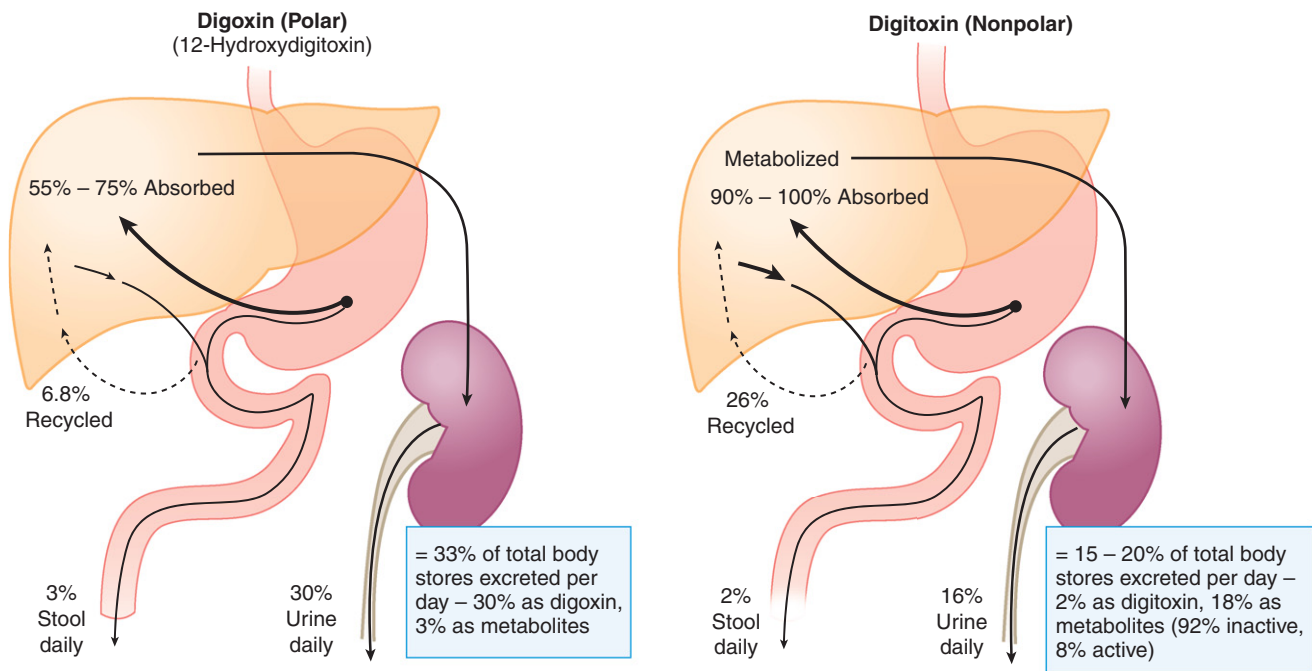

FIGURE 58-1 Digoxin and digitoxin pharmacokinetics, showing average values for absorption, excretion, enterohepatic circulation, and half-life. (From Doherty JE: Digitalis glycosides: pharmacokinetics and their clinical implications. *Ann Intern Med* 1973;79:229.)

TABLE 58-1 Digoxin and Digitoxin Main Pharmacologic Characteristics

	DIGOXIN	DIGITOXIN
Absorption	55%–75% for tablets 90%–100% for liquid or encapsulated liquid	90%–100%

Protein binding	25%	95%
Half-life	33–34 hr	6–7 days
Clearance	Renal	Hepatic

and derivatives) have occasionally led to unsuspected cardiac complications. Recently, accidental contamination of dietary supplements by *Digitalis lanata* has been reported.⁹

Several preparations of digitalis are available. However, because of their ease of oral administration and duration of action, only two preparations are used in clinical practice today: digoxin and digitoxin. Their main pharmacologic characteristics are reported in Figure 58-1 and Table 58-1. Digoxin and digitoxin are both passively absorbed from the small intestine. Detailed pharmacodynamic studies have shown that drug action depends on tissue concentration, which is relatively constant in relation to serum concentrations, and that the major depot in humans is skeletal muscle.^{10,11} These findings lead to two conclusions: (1) the constant relationship of myocardial digoxin concentration to serum concentration supports measuring serum concentrations to monitor patients' compliance

and toxicity, and (2) dosage requirements and the likelihood of toxicity can be anticipated on the basis of muscle mass and not overall body weight. Digoxin and digitoxin are eliminated differently (see Fig. 58-1). Digoxin is excreted primarily via the renal route, whereas digitoxin is eliminated primarily via metabolic inactivation. Because enterohepatic circulation has a role in the metabolism of both drugs, biliary production affects digitalis elimination. Bioavailability of the drug may vary with different manufacturing processes and malabsorption syndromes and because of inactivation of gut flora, which can be altered by antibiotics.¹² Furthermore, digoxin is one of the breakdown products of digitoxin metabolism (about 8%) (Figs. 58-1 and 58-2).

Basic Mechanism

Digitalis acts at the subcellular level by altering the sodium/potassium-adenosine triphosphatase (Na^+/K^+ -ATPase) transport system (Fig. 58-3). The effect is an intracellular gain of Na^+ and loss of K^+ and a corresponding extracellular gain in K^+ . Through interaction with Na^+ and Ca^{2+} membrane transporters, an associated intracellular gain of Ca^{2+} is observed. In short, the net effect is a decreased intracellular K^+ concentration and an increased Na^+ and Ca^{2+} concentration. The increased Ca^{2+} augments myofibril interaction in cardiac muscle and leads to positive inotropic action responsible for digitalis's usefulness in clinical practice.¹³

In an intact heart, the effects of digitalis can be separated into mechanical and electrophysiologic actions, with toxicity related to its excessive therapeutic effects and the status of the patient at the time of drug administration.

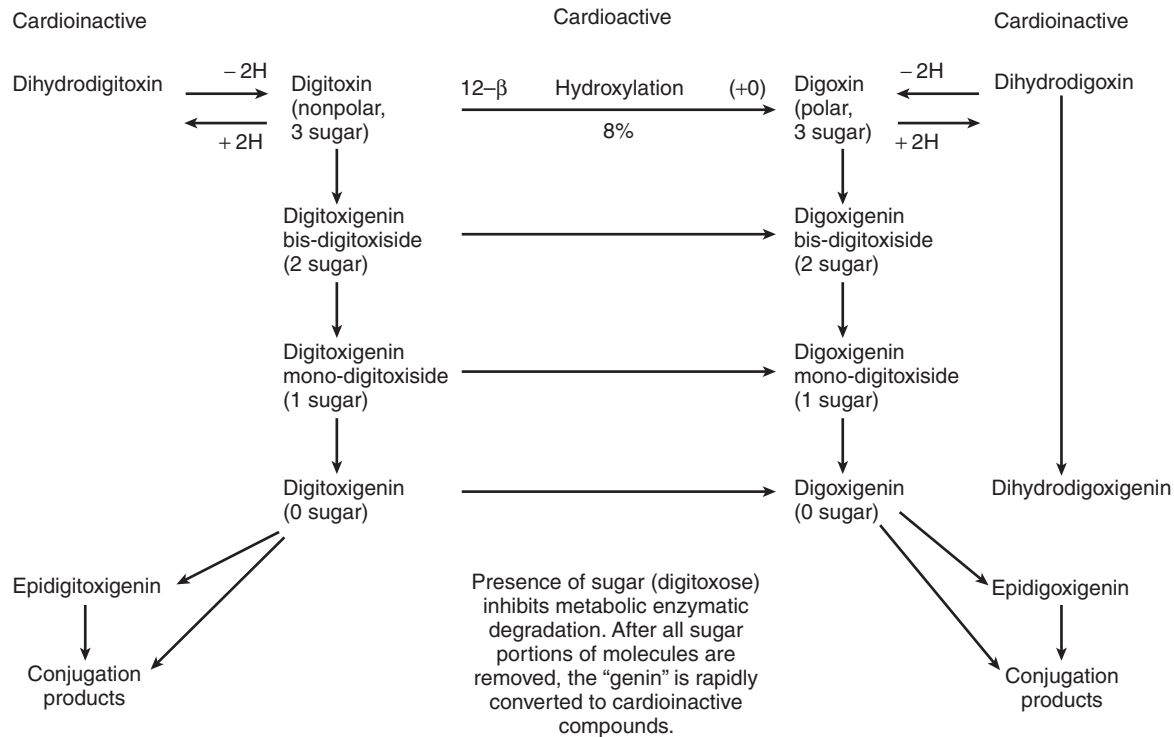

FIGURE 58-2 Metabolic pathways of digoxin and digitoxin. Note that digoxin is part of the metabolic pathway of digitoxin. (From Doherty JE: Digitalis glycosides: pharmacokinetics and their clinical implications. *Ann Intern Med* 1973;79:229.)

FIGURE 58-3 Cellular interactions between Na⁺/K⁺-ATPase pump and digoxin. Digitalis alters the Na⁺/K⁺-ATPase transport system. The net effect is an intracellular loss of K⁺ and gain of Na⁺ and Ca²⁺. The increased Ca²⁺ augments myofibril interaction in cardiac muscle and leads to positive inotropic action.

Normal Therapeutic Effects on Intact Heart (Summary of Actions)

DIGITALIS INOTROPIC EFFECT

A major therapeutic use for digitalis is for its inotropic effect. Digitalis augments the force of myocardial contraction by increasing the velocity of shortening and the velocity of developed tension of cardiac muscle.¹³ Therefore, there is less encroachment on compensatory mechanisms, allowing greater cardiac reserve. In patients with heart failure, digitalis causes a decrease in end-diastolic pressure and volume, increasing cardiac

output and stroke work. The usefulness of digoxin for congestive heart failure in patients in sinus rhythm has been the subject of some controversy. However, most conclude that digoxin is a weak inotropic agent.^{14,15} The Digitalis Investigators' Group trial and the study by Krum and colleagues demonstrated the usefulness of digoxin in congestive heart failure.^{16,17} More precisely, in 1997, The Digitalis Investigators' Group trial¹⁷ showed that although, in comparison with placebo, digitalis treatment did not reduce the mortality rate, it did reduce the rate of hospitalization, including hospitalization for worsening heart disease. In a nonfailing heart, the effects

of digitalis are more controversial. Positive inotropic action may occur, but it is not manifested by a measurable change in cardiac output or by a decrease in left ventricular filling pressure.¹⁸

DIGITALIS CHRONOTROPIC EFFECT

The negative chronotropic effect of digitalis is primarily central, mediated through an increase in vagal tone associated with decreased sympathetic activity. Thus, effects of digitalis may vary, depending on the interaction of drug concentration and autonomic tone.

Digitalis decreases the refractory period of both atrial and ventricular cells and tends to increase action potential amplitude and V_{max} . This improves conduction within the muscle, as reflected in a shortened QT interval. The same mechanism accounts for the increased atrial rate in atrial flutter or atrial flutter-fibrillation.¹³

Digitalis decreases the rate of sinoatrial (SA) node depolarization. Digitalis increases the refractory period of the atrioventricular (AV) node and the bundle of His. It prolongs phase 3 of the action potential, accounting for decreased ventricular response in atrial fibrillation. Some AV nodal effects are independent of vagal tone and affect phase 0, thus decreasing conduction velocity.¹ Most if not all effects of digitalis on the Purkinje system and ventricular muscle are direct effects and do not depend on autonomic interaction.¹³

Digitalis causes significant effects on myocardial automaticity (ability of tissue to undergo spontaneous depolarization) and excitability (ability of tissue to respond to a given stimulus). Inhibition of the Na^+ pump leads to an influx of Na^+ into the cell (see Fig. 58-3). This Na^+ influx increases phase 4 depolarization in all cardiac tissue except the SA node and leads to the appearance of new or latent pacemakers, thus increasing automaticity. This influx also lowers the resting membrane potential threshold, thus increasing excitability.¹⁹

Na^+ influx also causes delayed afterpotentials (oscillations in transmembrane potentials that follow full repolarizations of the membrane), and this effect provides a logical basis for understanding digitalis-induced arrhythmias.^{1,13}

Digitalis Toxicity

The toxic effects that occur when blood concentrations exceed the therapeutic range are almost uniformly a consequence of excessive normal physiologic responses. They can occur in any condition that increases the amount of digitalis in the body or modifies the cardiac sensitivity to digitalis. Drug interactions and other factors, such as electrolyte abnormalities, renal or hepatic failure, ischemia, or inflammation, predispose to digitalis toxicity.

INTERACTION WITH OTHER DRUGS

The importance of drug interactions in the development of digitalis toxicity was not truly appreciated until reliable assays of digoxin concentrations became widespread. Such interactions are important to consider, because introducing or discontinuing these drugs without changing the digoxin dose may lead to a digitoxic state. The most common interactions are listed in Table 58-2.

By far, the most important and dangerous drug interactions with digoxin are caused by the antiarrhythmics. Quinidine²⁰ causes an increase in serum digoxin in up to 90% of patients. The magnitude of the increase varies but is often twofold. The serum digoxin concentration begins to increase with the onset of quinidine therapy, and the concentration remains elevated as long as both drugs are continued. The adverse effects of elevated digoxin concentrations caused by quinidine are similar to those experienced with an overdose of digoxin.

There is no evidence that other antiarrhythmics similar to quinidine in their action (type I) interact with digoxin.²¹⁻²³ Procainamide, disopyramide, lidocaine, mexiletine, and flecainide do not increase serum digoxin concentrations.

Another major antiarrhythmic drug that interacts with digoxin is amiodarone.²⁴ Digoxin concentrations increased by 25% to 70% within 24 hours after adding amiodarone. The effect is mediated via a decrease in renal and nonrenal clearance. The result is more frequently bradyarrhythmias or heart block rather than tachyarrhythmias.

TABLE 58-2 Agents Affecting Digitalis Pharmacology

ALTERATION	AGENTS
Decreased absorption	Antacids, antibiotics (neomycin, sulfasalazine, p-aminosalicylic acid), bran, cholestyramine, cytotoxic, kaolin-pectin
Increased absorption (less of a problem when the capsule form is used) ¹²	Antibiotics inhibiting gut flora (erythromycin and tetracycline), anticholinergics
Inhibited protein binding	Clofibrate, phenobarbital, phenylbutazone, prazosin, warfarin
Increased renal excretion	Hydralazine, levodopa, nitroprusside
Decreased extra renal clearance	Diazepam, quinidine, verapamil
Decreased volume of distribution	Quinidine
Increased serum digitalis concentration	Amiodarone, aspirin, bepridil, diltiazem, flecainide, ibuprofen, indomethacin, nefedipine, nifedipine, nicardipine, nisoldipine, nitrendipine, propafenone

From Mooradian AD: Digitalis: an update of clinical pharmacokinetics, therapeutic monitoring techniques and treatment recommendations. Clin Pharmacokinet 1988;15(3):165-179.

The interaction between Ca^{2+} channel–blocking drugs and digoxin varies greatly.^{20,22} The dihydropyridines (nifedipine, amlodipine, isradipine, nifedipine) have minimal or no effect, and diltiazem has such a small effect that toxicity is unlikely. On the other hand, verapamil increases serum digoxin concentrations as much as 70% by altering renal and extrarenal clearance, which can lead to lethal cardiac toxicity.^{21,25}

Other antiarrhythmics, such as sotalol, aprindine, ajmaline, and moricizine, do not affect digoxin concentrations.^{21,22}

Potentially toxic interaction may also occur with potassium-sparing diuretics (such as spironolactone), which inhibit tubular secretion of digoxin; with anti-hypertensive agents, which can significantly alter renal reperfusion and glomerular filtration rate; and with anti-inflammatory drugs, especially indomethacin, in neonates or patients with renal dysfunction.

Some antiadrenergic agents, such as clonidine, methyldopa, reserpine, and β blockers, in combination with digitalis, may lead to severe bradyarrhythmias, especially in patients with SA node disease.^{21,22}

Reports have shown toxicity in patients with myocarditis when cyclosporine is added to digoxin in patients who have heart failure.²⁶ Aside from the drug interactions discussed earlier, renal dysfunction leading to decreased renal excretion of digitalis is the major factor leading to the increased total of digitalis throughout the body. Neither dialysis nor cardiopulmonary bypass causes much body loss of digitalis.

ALTERING SENSITIVITY TO DIGITALIS

Toxicity from digitalis is not limited to situations that increase total body concentration of the drug but can develop with any condition that modifies the cardiac sensitivity to digitalis. These include myocardial infarction or ischemia, myocarditis, cardiomyopathy, amyloidosis, and other trauma, including surgery. A healthy heart tolerates large amounts of digitalis, whereas diseased myocardium appears to develop arrhythmias at lower serum concentrations.²⁷ The myocardial disease leads to local areas of altered electrophysiology, which in turn can cause variation in digitalis uptake by cardiac tissue. The concentration differences and local ischemia lead to variation of cellular recovery times and set the stage, once again, for reentry phenomena. Intrinsic cardiac disease alone may produce similar rhythm disturbances, several of which are common in acute myocardial infarction. These rhythm disturbances have no specific distinguishing feature. However, digitalis toxicity can be implicated in most instances when withdrawal of the drug is followed by resolution of the arrhythmia. This increased sensitivity does not preclude careful use of digitalis when clinically indicated.²⁸

ALTERING METABOLISM

Metabolic factors are important in myocardial sensitivity to digitalis.^{22,29} Electrolyte abnormalities, especially hypokalemia and hypocalcemia, are well known, but aberrations of magnesium are important to consider. Other metabolic abnormalities, including acidosis,

alkalosis, hypoxemia, and hyperthermia, may alter digitalis's effect but are probably not independent risk factors. Diseases of other organ systems, especially chronic lung disease and hypothyroidism, predispose patients to digitalis toxicity. Acute cerebrovascular events may lead to toxicity by large sympathetic discharge, which may lower the arrhythmia threshold. Boxes 58-1 and 58-2 contain a more complete list.

CLINICAL PRESENTATION

Pathophysiology

Digitalis toxicity represents the result of the interactions of the drug on the transmembrane potentials and ionic current flows of the cardiac cells (direct effects) and those effects related to the autonomic nervous system (indirect). These interactions have various results depending on which cells are affected; they are expressed as abnormalities of atrial, AV nodal, or ventricular pathology. The mechanism of digitalis cardiotoxic rhythms may result from depression of conduction or alteration of impulse formation, with increased heterogeneity of refractory periods.

Manifestations

CARDIAC

Cardiac manifestations are frequent and dangerous presentations of digitalis toxicity.^{7,29} A healthy heart rarely has any signs of toxicity unless the ingested quantity is high. Therefore, accidental overdoses, especially in children, rarely present any cardiac findings but may show AV conduction disturbances. On the other hand, a diseased heart is prone to lethal arrhythmias. No arrhythmias are pathognomonic of digitalis toxicity because similar rhythms may represent underlying disease. A change in the rhythm, especially decreased pulse rate, may be the most important clue. Never-

theless, toxicity should be suspected in any patient receiving the medication and exhibiting evidence of depressed conduction, alteration of impulse formation (automaticity), or both.

Depressed conduction is related to slowing of SA and AV nodal conduction and prolonged nodal refractoriness from high vagal tone, but at high concentrations, digitalis may directly prolong AV nodal refractoriness. Thus, blocks of all types may be observed³⁰ (Box 58-3).

SA nodal block is relatively common since impulse-forming alterations from digitalis toxicity are often manifested as suppression of atrial pacemakers,

primarily the SA node. SA nodal block may range from sinus pauses to the SA nodal Wenckebach phenomenon or to total SA nodal exit block. The resultant arrhythmia is frequently sinus bradycardia, which may be quite severe, especially in elderly patients and in those with SA node disease (Fig. 58-4).

First-degree AV block (i.e., with prolonged PR interval), from digitalis is indistinguishable from other causes (Fig. 58-5).

Second-degree AV block, with intermittent dropped beats, may be Mobitz type I (Wenckebach) or Mobitz type II (see Fig. 58-5). The resultant heart rhythm may be complicated by accelerated junctional escape beats.

Third-degree block, or complete AV dissociation, is usually associated with a narrow QRS escape focus at adequate rates, and hemodynamic alterations are rare in the absence of other cardiac abnormalities (Fig. 58-6).

Alterations of impulse formation may be divided into those that suppress higher pacemakers or those that excite lower pacemakers. Suppression of higher pacemakers is limited primarily to direct effect on the sinus node. Excitation is due to increased frequency of discharge of junctional or ventricular pacemakers, taking the form of accelerated junctional or accelerated ventricular tachycardias. The combination of suppressant and excitant effects should be considered digitalis toxicity until proven otherwise (Fig. 58-7). However, as

FIGURE 58-4 The electrocardiogram of an 82-year-old woman recently begun on digitalis shows sinus rhythm with sinus arrest and atrioventricular dissociation with slow atrial escape and faster junctional escape rhythm.

the number of older patients with intrinsic cardiac disease increases, these arrhythmias are not specific for digitalis toxicity. Digitalis toxicity results in an exacerbation of the drug's normal effects on refractory periods of the conduction system and myocardial cells. Increased heterogeneity of the refractory periods allows for the development of reentry phenomena, which are the probable mechanisms for the development of tachyarrhythmias. Myriad extrasystoles may be seen, such as premature ventricular contractions (PVCs) (see Fig. 58-7), ventricular parasystole, or ventricular or bidirectional tachycardia. The PVCs may be multiformed, bigeminal, paired, or in couplets. Before more current therapy, ventricular tachycardia related to digitalis toxicity carried a 50% mortality rate. Bidirectional tachycardia was almost always fatal.

Conduction and rhythm disturbances can be seen in combination, resulting in various electrocardiographic presentations. The rhythms are usually manifested by an increased sinus rate with block or second-degree AV block with accelerated lower pacer. Examples are atrial fibrillation with slow ventricular response rate resulting in irregular bradycardia, or Wenckebach block with accelerated junctional escape beats (Fig. 58-8). Even

though nonspecific, digitalis toxicity should always be considered when this type of arrhythmia is encountered.

NONCARDIAC

Digitalis intoxication induces noncardiac as well as cardiac clinical effects.^{3,31,32} Gastrointestinal manifestations are present in both acute and chronic intoxication. Anorexia, nausea, and vomiting are common. These symptoms often occur early and may be the presenting complaint. In patients on chronic digitalis treatment, onset of these symptoms has to be considered a possible overdose symptom. Other gastrointestinal complaints are less common. Neurologic and visual manifestations are also frequent and range from headache and fatigue and weakness, to depression, confusion, disorientation, aphasia, delirium, and hallucinations. The visual disturbances of blurring and alteration in color are less common. A more complete list and incidence can be found in Table 58-3. In this study, vigorous attempts were made to establish digitalis as the cause of these symptoms.³¹ Digitalis intoxication should always be considered in patients, particularly in the elderly, who are receiving digitalis therapy and present with vague gastrointestinal complaints, malaise, or altered mental status.^{6,32}

FIGURE 58-5 An 82-year-old man was referred for slow pulse. An electrocardiogram (ECG) 1 day before the present ECG showed 2:1 heart block. The patient was taking digoxin, 0.25 mg/day. Strips show first-degree atrioventricular (AV) block and 5:4 AV nodal block with a narrow QRS complex.

LABORATORY DERANGEMENTS

As previously mentioned, the mechanism of cellular digitalis toxicity directly induces hyperkalemia, which is significantly correlated with digitalis poisoning severity and mortality. Mortality rates are greater in patients with serum potassium greater than 4.5 mEq/L, approaching 35% in patients with serum potassium greater than 5 mEq/L, and 100% in patients with concentrations greater than 6.4 mEq/L.³³ A recent retrospective review has confirmed the importance of hyperkalemia as a poor prognostic indicator in digitalis poisoning.³⁴

DIAGNOSIS

Acute overdose may result from accidental or suicidal overdose in patients, whether or not previously treated

by digitalis.^{7,35,36} In such cases, the main challenge is early detection of digitalis toxicity. Recognition of chronic digitalis toxicity requires a high index of suspicion among patients manifesting any of the cardiac or non-cardiac symptoms mentioned earlier. In both cases, definitive diagnosis is via serum digitalis determinations.

Digitalis Concentrations

The concentration of digitalis in the serum is the net result of whole body absorption, distribution, and excretion. Measurement of serum concentrations is currently the cornerstone of digitalis poisoning diagnosis.

The range of therapeutic concentration is 0.5 to 2.0 ng/mL for digoxin and 10 to 30 ng/mL for digitoxin. Due to the lack of specificity of digitalis poisoning symptoms, serum concentrations must be liberally obtained

FIGURE 58-6 Electrocardiogram (ECG) of a 79-year-old woman admitted with shortness of breath and weight loss. She was receiving maintenance digoxin therapy. The ECG shows atrioventricular (AV) dissociation secondary to a high-grade AV block with a narrow QRS complex.

in chronically treated patients who experience gastrointestinal symptoms, malaise, or any change from baseline rhythm disturbances. However, serum concentrations are not always diagnostic; major problems remain in diagnosing toxicity.

Assays of different digitalis preparations often overlap, and accurate interpretation of results is possible only if the exact preparation is known.

False-positive elevations may occur for several reasons. For example, spironolactone and hyperbilirubinemia interfere with the test. Far more frequent is a false-positive assay result in patients with chronic renal failure. This elevation is thought to be caused by an endogenous circulating digoxin-like substance, which has been reported in more than 60% of patients with chronic renal insufficiency.³⁷

Clinical correlations of therapeutic and toxic concentrations all have been made at steady-state concentrations. These concentrations are reached 6 to 8 hours after administration, and any measurements made before this time may give values two to three times greater than at steady-state concentrations. Digoxin undergoes bimodal elimination; thus, measurements made in the first few hours of administration (α elimination phase) do not correspond with toxicity. As the

α elimination phase begins, concentrations more closely approach steady-state concentrations and correspond better with toxicity.

Defining a toxic digitalis concentration is difficult because serum concentrations of patients with and without clinical toxicity overlap considerably. Figure 58-9 demonstrates this problem in an older study, but a more complete list is found in the review by Smith.³⁸

Multiple factors, previously detailed, predispose patients to toxicity at concentrations well below 2 ng/mL, usually considered the upper limit of normal. Hypokalemia is the most important of these. Hypoxia caused by chronic pulmonary disease or advanced forms of heart disease is also important. Factors enhancing digitalis sensitivity are listed in Boxes 58-1 and 58-2.²²

In summary, serum concentrations should be used as a guide to appropriate therapeutic doses and as an indication of toxicity. Serum concentrations also may verify drug compliance and aid dose regulation in patients with changing renal function, those who have undergone cardiac surgery, or those with severe congestive heart failure. It must be emphasized that toxicity cannot be diagnosed from serum concentrations alone. Special consideration must be given to those patients with underlying problems. In general, an

A

B

FIGURE 58-7 A, Admission electrocardiogram of an 89-year-old with a digoxin level of 2.4 ng/mL. B, One day later.

increased serum digitalis concentration indicates digitalis toxicity in patients chronically treated with digitalis who are manifesting cardiac or noncardiac symptoms.

THERAPY OF DIGITALIS INTOXICATION

Successful therapy of digitalis intoxication depends not only on early recognition but also on early and, at times, aggressive management. Physicians must maintain a high index of suspicion about digitalis intoxication if they are to make this diagnosis, especially in patients with predisposing factors, such as old age, renal disease, chronic lung disease, or quinidine use. Most of these patients suffer from chronic overdose, rather than severe suicidal or accidental acute ingestion. In unusual circumstances, such as involuntary plant poisoning or poisoning through herbal supplements, the diagnosis may be particularly elusive.^{9,32,39-42} It should be remembered that gastrointestinal manifestations, such as anorexia, nausea, or vomiting, are often the first clinical signs in these rare poisonings. In these circumstances, electrocardiographic manifestations and hyperkalemia should strongly increase the suspicion of digitalis poisoning, calling for measurement of serum digitalis concentrations.

When digitalis poisoning is diagnosed, precocious treatment, including antidotal therapy, should be considered.

Conventional Therapy

GASTROINTESTINAL DECONTAMINATION

A single dose of activated charcoal should be used in patients with acute poisoning if the patient has ingested a potentially toxic dose of digitalis and if charcoal can be administered during the first 2 hours following ingestion.⁴³ Neither repeated charcoal administration in acute poisoning nor single-dose charcoal administration in patients with chronic overdose has been demonstrated to be of value.⁴⁴

FIGURE 58-8 This rhythm strip shows atrial tachycardia with block. There is an atrial rate of approximately 150 beats/min with a 3:1 block.

TABLE 58-3 Noncardiac Symptoms of Digitalis Toxicity

	DEFINITE INTOXICATION (%)	POSSIBLE INTOXICATION (%)	NO INTOXICATION (%)
Vomiting	48	30	27

Modified from Mahdyoon H, Battilana G, Rosman H, et al: The evolving pattern of digoxin intoxication: observations at a large urban hospital from 1980 to 1988. *Am Heart J* 1990;120:1189

FIGURE 58-9 Results of 100 serum digoxin radioimmunoassay measurements. Sixteen patients were believed to be clinically toxic; their mean serum level was 3.0 ng/mL. Seven patients thought to be nontoxic also had serum levels of more than 3.0 ng/mL. Overlap of normal toxic values does occur; therefore, judgment must be used when evaluating results. (From Doherty JE: Digitalis glycosides: pharmacokinetics and their clinical implications. *Ann Intern Med* 1973;79:229.)

EXTRACORPOREAL REMOVAL TECHNIQUES

There are no data to support the use of any extracorporeal removal techniques in acute or chronic digitalis poisoning.

CORRECTION OF ELECTROLYTE DISORDERS

Correction of hypokalemia and dehydration are important in cases of chronic toxicity. However, the pathophysiologic mechanism of hypokalemia should be kept in mind, and care should be taken to avoid secondary hyperkalemia. It is generally recommended that calcium be avoided in the treatment of hyperkalemia in digitalis poisoning, due to concerns that intracellular calcium concentrations are already elevated and that administration of further calcium may lead to life-threatening dysrhythmias. This notion has been called into question by Kuhn, who cites a study by Nola and colleagues in dogs, which demonstrated that calcium could safely be administered in digitalis toxicity, so long as the serum calcium did not exceed 20 mg/dL.⁴⁴ A more recent paper by Hack and colleagues⁴⁵ demonstrated that calcium can be safely administered in a pig model of acute digitalis intoxication. Caution should be exercised, however, in overinterpretation of these studies, which involved acute contemporaneous digitalis and calcium administration, rather than administration of calcium in a model with extant digitalis intoxication (with sufficient time to observe poisoning of the Na/K-ATPase pump). More importantly, it should also be remembered that antidotal treatment with Fab

fragments corrects hyperkalemia,³⁵ so that administration of calcium for hyperkalemia should probably be reserved (if ever used) for those situations in which digitalis Fab fragments are not available.

TREATING BRADYCARDIA OR OTHER BRADYARRHYTHMIAS

Severe bradycardia and bradyarrhythmias are often related to increased vagal tone. Treatment is crucial, because bradyarrhythmias increase the risk for life-threatening ventricular arrhythmias.

Atropine is the treatment of first choice. A trial of 0.5 mg atropine may be given intravenously and repeated up to a total dose of 2.0 mg. Large cumulative doses of atropine may lead to anticholinergic encephalopathy.

Adrenergic agonists, such as isoproterenol, should be avoided, because the risk for precipitating more severe arrhythmias is high due to their dromotropic effects.

TREATING ECTOPY

One half to three fourths of patients developing high-grade ventricular tachyarrhythmias from digitalis toxicity will die. Early, aggressive therapy is essential in these situations. The following agents should be considered:

Cardiac pacing. Cardiac pacing can be used to treat bradycardia and bradyarrhythmias and to prevent ventricular arrhythmias.^{7,8} But pacing is not immediately available everywhere and is associated with life-threatening ventricular arrhythmias and with other nonfatal complications, such as infection. As a rule, it should be performed only if treatment by Fab fragments is not rapidly available. A recent article by Chen and colleagues suggests that pacing can be safely performed in patients with chronic digitalis poisoning. The authors caution against its use in digitalis intentional overdose.⁴⁶

Magnesium. The use of intravenous magnesium sulfate in digitalis toxicity has theoretical indications, especially if the magnesium concentration is low. Magnesium may be considered even when the magnesium concentration is normal or high if, as is often the case, the potassium concentration is elevated.⁴⁷ Magnesium potentiates Na/K-ATPase activity without affecting binding of proteins. Hypermagnesemia and related side effects may occur, particularly in patients with renal dysfunction. It is unlikely to appear, however, with an initial bolus of 10 to 20 mmol. Magnesium sulfate generally is packaged as 1.5 to 3 g of magnesium sulfate in 10 or 20 mL. Intravenous use for a cardiac emergency is 3 g diluted to 100 mL and given over 10 minutes. This is often repeated once, followed by maintenance intravenous drips, while monitoring the magnesium and potassium concentrations.

Other antiarrhythmic drugs, such as lidocaine and phenytoin, quinidine, procainamide, disopyramide, calcium channel blockers, and β blockers, have been previously used. Efficacy was poor and

the risk for side effects high. Nowadays, antidotal treatment is the first-line treatment for digitalis poisoning.

Cardioversion. Direct current countershock should be the last resort in life-threatening arrhythmias, and if used, the lowest effective energy level for cardioversion is suggested. Even at low energy levels, the highest mortality rates for direct current cardioversion occur in digitalis toxicity. It should be performed only if treatment by Fab fragments is not rapidly available.

ANTIDOTAL THERAPY

The most immediate decision for the physician treating suspected digitalis overdose concerns the need for antidotal therapy. Digitalis in massive doses may be lethal after suicidal or accidental overdoses, which are not uncommon. Resultant ventricular arrhythmias are responsible for a high mortality rate, reaching 25% in recent studies.^{4,35,36} The end result is asystole and finally a complete loss of any cardiac electric activity.

The best method for treating very high concentrations of digitalis poisoning is the use of digoxin-specific polyclonal antibody fragments (Fab). The first report of their use appeared in 1976 (Fig. 58-10).⁴ Efficacy and safety have since been clearly demonstrated

in acute and chronic poisonings in adults and in children. The fragments (molecular weight 50,000 Daltons) neutralize digoxin and digitoxin toxicity by reversing tissue binding of digitalis. Bound digitalis reaches high concentrations in the plasma, but the relatively small molecular size allows glomerular filtration and rapid excretion.

Two methods of antidotal treatment with Fab fragments have been proposed,⁴⁸ equimolar neutralization in patients with life-threatening poisoning and semiequimolar neutralization in patients with less severe intoxication and/or poor prognostic risk factors, although the latter has not been subjected to clinical trial. In effect, survival of patients who experience cardiac arrest due to digitalis poisoning is very poor. Smolarz and colleagues first suggested "prophylactic" neutralization to prevent secondary ventricular life-threatening arrhythmias.⁴⁹ Woolf and colleagues recommended the same strategy in poisoned children.⁵⁰ Taboulet and colleagues recently suggested the following approach. Once again, it should be emphasized that "semimolar neutralization" has not been subjected to controlled clinical trials, although it has been routinely employed in France for several years.⁴⁸

In patients with life-threatening intoxication, immediate equimolar neutralization:

FIGURE 58-10 Sequential electrocardiograms recorded before, during, and after treatment with digoxin-specific Fab fragments. **A**, In the tracing recorded immediately before the start of Fab infusion, serum potassium level is 8.7 mEq/L; the escape interval when pacer stimulus is reduced below threshold is 4.60 seconds. **B**, In the tracing recorded 15 minutes after the start of Fab infusion, serum potassium level is 8.0 mEq/L; the escape interval is 3.96 seconds. **C**, In the tracing recorded 30 minutes after the start of Fab infusion, the escape interval is 2.76 seconds. **D**, In the tracing recorded 2 hours after the start of Fab infusion, the serum potassium level is 7.4 mEq/L; a sinus mechanism is present at a rate of 75 beats/min, with first-degree atrioventricular block (P-R interval of 0.24 second). (From Smith TW, Haber E, Yeatman L, Butler VP Jr: Reversal of advanced digoxin intoxication with Fab fragments of digoxin-specific antibodies. *N Engl J Med* 1976;294:797.)

1. Asystole
2. Ventricular arrhythmia (fibrillation or tachycardia)
3. Bradycardia: heart rate less than 40 beats/min (after atropine venous infusion)
4. Serum potassium greater than 5.0 mmol/L

In patients with severe intoxication and/or bad prognostic risk factors, semimolar neutralization:

1. Patients older than 55 years
2. Patients with cardiac disease
3. Bradycardia: heart rate less than 60 beats/min (after intravenous atropine)
4. Second- or third-degree SA or AV blocks
5. Serum potassium greater than 4.5 mmol/L

Antidotal treatment is efficacious in the treatment of digitalis-induced cardiac as well as noncardiac disturbances. Hyperkalemia is best treated by Fab fragments. All other symptoms, including gastrointestinal symptoms, disappear after Fab fragment infusion.

The dose of Fab fragments to administer is determined by calculating digitalis body load.^{7,8} Digitalis body load may be estimated, based on supposed ingested digitalis amount (in acute poisoning) or by measured digitalis blood concentrations. When these data are not available, in cases of acute toxicity, empirical dosing recommendations are that 20 vials (760 mg) of Digibind (GloxoSmithkline, Research Triangle Park, NC) is adequate to treat most life-threatening ingestions in both adults and children. However, in children it is important to monitor for volume overload. The physician may consider administering 10 vials, observing the patient's response, and following with an additional 10 vials if clinically indicated.

In cases of chronic intoxication, for adults, six vials (228 mg) usually is adequate to reverse most cases of toxicity. This dose can be used in patients who are in acute distress or for whom a serum digoxin or digitoxin concentration is not available. In infants and small children (weighing less than or equal to 20 kg), a single vial usually should suffice.

Total digitalis body load is calculated in Box 58-4. The rate of Fab fragment administration is determined on the basis of the presence of life-threatening toxicity: the fragments are given over a few minutes in cases of ventricular disturbances and over 1 hour in cases of prophylactic indications. Resolution of digitalis poisoning symptoms after Fab fragment infusion is rapid. Reversal, including correction of serum potassium concentration, has been obtained in 75% of the patients within 1 hour.³⁵ Vital signs, electrocardiogram, and serum potassium monitoring during Fab fragment infusion are means of assessing treatment efficacy and safety. It is important to understand that serum digitalis concentrations measured by routine methods rise dramatically after administration of digitalis Fab fragments. Free digitalis concentrations may be measured to distinguish bound from unbound fractions, but such measurements are technically more difficult to perform and generally less available.

Prior history of allergy after Fab fragment administration is the sole contraindication to Fab fragment

BOX 58-4**CALCULATION OF DIGITALIS FAB FRAGMENT DOSAGE**

Calculation of digitalis body load based on ingested digitalis amount:

$$\text{Digoxin body load (mg)} = 0.8 \times \text{suspected ingested amount (mg)}$$

$$\text{Digitoxin body load (mg)} = 1 \times \text{suspected ingested amount (mg)}$$

NB: 0.8 and 1 are digoxin and digitoxin bioavailability. In case of elixirs and gel tablets, the value is 0.95.

Calculation of digitalis body load based on serum digitalis concentration:

$$\text{Digoxin body load (mg)} = [\text{digoxin serum concentration (ng/mL)}] \times 5.6 \text{ (L/kg)} \times \text{weight (kg)/1000}$$

$$\text{Digitoxin body load (mg)} = [\text{Digitoxin serum concentration (ng/mL)}] \times 0.56 \text{ (L/kg)} \times \text{weight (kg)/1000}$$

NB: 5.6 and 0.56 (L/kg) are digoxin and digitoxin's respective volumes of distribution

NB: Digoxin serum concentration (nmol/L) \times 0.781 = digoxin serum concentration (ng/mL or $\mu\text{g/L}$)

Digitoxin serum concentration (nmol/L) \times 0.765 = digoxin serum concentration (ng/mL or $\mu\text{g/L}$)

Thus, the dose of Fab fragments to administer is determined as follows:

One vial of 40 mg of Fab fragments (Digibind) neutralizes 0.6 mg of digitalis (digoxin or digitoxin).

One vial of 80 mg of Fab fragments (Digidot) neutralizes 1 mg of digitalis (digoxin or digitoxin).

To obtain equimolar neutralization, dose of Fab fragments to administer equals the total body load of digitalis: 1.7 vials of Digibind or 1 vial of Digidot for 1 mg of digitalis body load.

administration. Adverse effects associated with Fab fragment administration are rare and minor. The adverse effects potentially observed are (1) exacerbation of congestive heart failure, resistant to digoxin administration; (2) allergy; and (3) "overshoot" hypokalemia. Allergic reactions are reported in less than 1% of cases.³⁵

SUMMARY

Digitalis intoxication is a common problem in medicine today. Toxicity is manifested by many systemic symptoms, the most important of which, clinically, are cardiac arrhythmias. Virtually every known arrhythmia has been reported to be caused by digitalis excess. Finally, the most important aid in the successful treatment of digitalis intoxication is prevention through patient education. Patients' awareness of potential problems enables them to recognize problems early. Patient education is especially important in view of the length of digitalis use.

When prevention fails, in patients with chronic treatment experimenting digitalis toxicity and in patients with acute poisoning, early diagnosis is crucial in order to rapidly undertake appropriate treatment measures. Antidotal treatment using Fab fragments is the first-line treatment. Fab fragments can be used to obtain equimolar neutralization in patients with life-threatening symptoms in order to prevent life-threatening symptom complications.

STEVEN D. SALHANICK, MD

At a Glance...

- Calcium channel antagonist overdose can cause severe and prolonged toxicity resulting in a high degree of morbidity and mortality.
- Calcium channel antagonists are structurally diverse and vary greatly with regard to central versus peripheral cardiovascular effects.
- Toxicity is primarily an extension of therapeutic effects.
- Many xenobiotics interact with calcium channel antagonists, particularly those that are oxidized by the cytochrome P-450 system including grapefruit juice and digoxin. Care should be exercised when prescribing calcium channel antagonists in association with other xenobiotics.
- Early aggressive decontamination is warranted given the severity of toxicity.
- Virtually all forms of supportive care have been successful.
- Antidotes include calcium salts, but their effectiveness is debated.
- A promising recent development is high-dose insulin therapy, which is thought to be effective owing to correction of insulin deficiency and to its effects on myocardial energy metabolism.

Cytosolic calcium increase due to influx of calcium from the extracellular matrix has important physiologic consequences in both cardiac and vascular smooth muscle. As early as the 1960s, the negative chronotropic, inotropic, and vasodilatory effects of drugs that blocked calcium influx through cell membrane calcium channels was recognized, leading to the development of these pharmaceuticals as antiarrhythmic and antihypertensive agents.¹ Subsequently, a wide variety of indications for calcium channel antagonists has been realized, including tocolysis and cerebral vasospasm following aneurysmal subarachnoid hemorrhage. Given the prevalence of hypertensive disease, as well as the variety of indications that have been found for antagonists of calcium channels, these drugs are widely prescribed. Furthermore, given the lethal nature of these drugs in overdose, they are a frequent cause of morbidity and mortality.² Consequently, clinicians caring for patients exposed to overdose or potential overdose of calcium channel antagonists need to be familiar with the management of such patients.

STRUCTURE

Calcium channel antagonists are a structurally diverse group of drugs (Fig. 59-1). They are organized on the basis of structure and pharmacologic activity into five classes.

Phenylalkylamines

Verapamil is the prototypical phenylalkylamine. Verapamil depresses sinoatrial and atrioventricular

conduction, decreases myocardial contractility, and decreases peripheral vascular resistance. Verapamil is widely prescribed for the treatment of hypertension and is frequently used to control supraventricular tachyarrhythmias. It is often prescribed in extended-release form. Verapamil undergoes *N*-demethylation by CYP3A3 to norverapamil, which has approximately 20% of the activity of the parent compound.

Benzothiazepines

Diltiazem is the prototypical benzothiazepine. Diltiazem is notable for its depressive effects on cardiac chronotropy and contractility. Diltiazem relaxes peripheral vascular smooth muscle to a lesser extent than do other calcium channel antagonists. It is metabolized to desacetyldiltiazem, which has 25% to 50% of the pharmacologic activity of the parent drug. Diltiazem is frequently sold as a sustained-release preparation.

Dihydropyridines

Nifedipine is the prototypical dihydropyridine. Dihydropyridines are the largest group of calcium channel antagonists in clinical use. Dihydropyridines are notable for their predominant effect on vascular smooth muscle. They generally have little effect on cardiac inotropy or chronotropy. They uniformly decrease peripheral vascular resistance and coronary artery blood flow. Because of its high lipid solubility, nimodipine is indicated for the prevention of cerebral artery vasospasm following aneurysmal subarachnoid hemorrhage. Nisoldipine is marketed as an antihypertensive agent.³ It is notable for low bioavailability and marked peripheral vascular selectivity. Amlodipine, felodipine, and isradipine are remarkable for delayed time to peak plasma level and delayed onset of action. Dihydropyridines frequently cause reflex tachycardia owing to their peripheral vascular selectivity.

Diarylaminopropylethers

Bepridil is the prototypical diarylaminopropylether. It reduces blood pressure and heart rate in patients with stable angina. An adverse side effect profile including rate-related QT_c prolongation and torsades de pointes limits its use to refractory cases of angina.^{4,5}

Tertraline Derivatives

Mibefradil is the prototypical tertraline derivative. Mibefradil is unique in that it has effects on the T-type as well as the L-type calcium channel, which is the site of action of other calcium channel antagonists.^{6,7} T-type channels are thought to be involved in the control of

supraventricular arrhythmias. They have been identified in cardiac pacemaker cells but are rare in myocytes.^{6,8,9} They are involved in growth regulation of fibrosis and hypertrophy following myocardial infarction, and animal data suggest that mibefradil has beneficial effects on cardiac remodeling following myocardial infarction.¹⁰⁻¹² Mibefradil also binds at the verapamil binding site, but it has effects similar to those of dihydropyridines, affecting

vascular smooth muscle without exhibiting negative inotropic effect.^{7,13} Mibefradil also acts at coronary vascular smooth muscle to increase coronary blood flow.¹³

Mibefradil has high oral bioavailability and a long serum half-life (17 to 25 hours); it does not produce precipitous hemodynamic changes.⁷ It is metabolized by the cytochrome P-450 (CYP) 3A4 and 2D6 isoenzymes. Consequently, it interacts with many other drugs

including several cardiovascular agents. Because of the large number of potential and actual drug interactions, mibefradil was voluntarily removed from the market in the United States in 1998, despite its desirable profile.¹⁴

PHARMACOLOGY

Calcium flux across cell membranes provides electrical signaling in cells and coupling of these signals to changes in cytosolic calcium.¹⁵ Given the multitude of functions of cytosolic calcium, transmembrane calcium channels are of tremendous physiologic importance.

Several types of calcium channel have been described. They are primarily distinguished as low voltage activated or high voltage activated. Low-voltage-activated channels are poorly understood and found primarily in cells exhibiting repetitive electrical change. They are involved in pacemaker activity of cells, including the inflow of calcium into cardiac pacemaker cells during the first phase of depolarization.¹⁶

High-voltage-activated channels respond to relatively larger changes in the transmembrane potential. They function to couple electrical signals with increases in intracellular calcium. Five types of high-voltage channels have been described; classification is based on pharmacologic properties. The first described were the L-type channels classified on the basis of their sensitivity to dihydropyridines. Later, N-type channels were described in nervous tissue based on sensitivity to ω -conotoxin, a peptide isolated from the venom of the cone snail.¹⁷ The

P-type channels of cerebellar Purkinje neurons, Q-type channels, and aforementioned T-type channels have all been subsequently identified.

Molecular structures of the different types of calcium channels have been identified and correlate well with the pharmacologic classification (Fig. 59-2). All calcium channels (low and high voltage) share the α_1 subunit that contains the calcium pore and voltage sensors. The α_1 subunit contains four homologous domains, each with six transmembrane subunits that come together to form a pore in the cell membrane. There are six known α_1 subunits among the various types of channels. Other protein subunits include at least four β subunits and α_2 , γ , and δ subunits.^{18,19} The β subunits are nonlinked cytoplasmic proteins that affect ionic gradients, rates of activation and inactivation, and dihydropyridine binding affinity of the L-type channels.²⁰ The α_2 and δ subunits are linked to one another and affect the rate of channel activation as well as increasing the ionic gradient across the channel. The function of the γ subunit may be to amplify the actions of the β subunit.²⁰ Because of the complex nature of the L-type calcium channel, multiple receptor sites exist for the structurally diverse calcium channel antagonists.²¹

The calcium channel antagonists currently available act on the L-type channels of cardiac and vascular smooth muscle cells. While L-type channels exist in skeletal muscle, the current classes of calcium channel antagonists have not shown an effect on skeletal muscle. The intracellular release of relatively large amounts of calcium from mitochondrial and sarcolemmal stores in

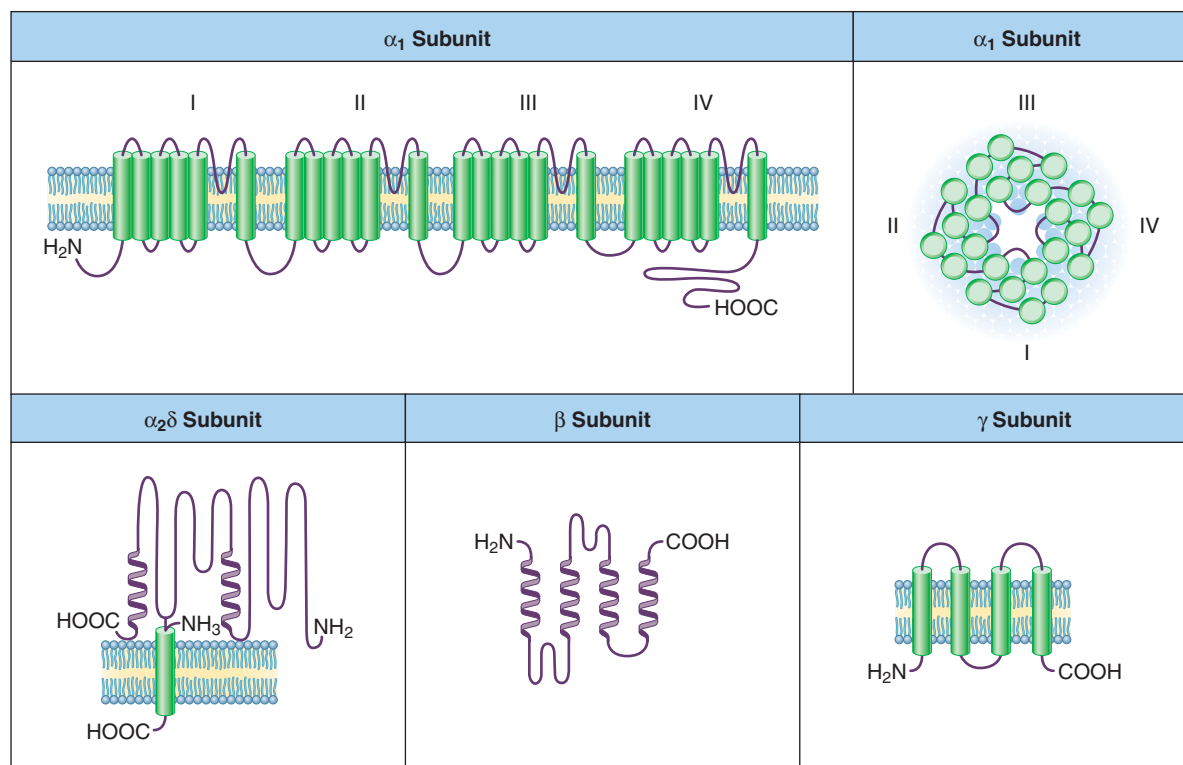

FIGURE 59-2 Molecular structure of the L-type calcium channel. (From Salhanick SD, Shannon MW: Management of calcium channel antagonist overdose. *Drug Saf* 2003;26[2]:65–79.)

skeletal muscle is less dependent on a transmembrane calcium increase as a signaling mechanism.²² L-type channels are also found in nervous tissue, but their function there is not well understood.²³

Antagonism of susceptible L-type channels results primarily in effects on the heart and peripheral vascular smooth muscle. Cardiac effects include negative inotropy due to a decrease in available calcium to facilitate excitation-contraction coupling in the myocardial cells as well as negative chronotropy due to blockade of L-type channels in pacemaker cells in the sinoatrial and atrioventricular nodes. Relaxation of vascular smooth muscle results in decreased afterload, decreased systemic blood pressure, and increased coronary vascular dilatation. The effect is primarily on arterial smooth muscle and thus does not affect venous capacitance and preload.

The selectivity of the various calcium channel antagonists for cardiac versus peripheral vascular effects has long been recognized. The mechanism of this selectivity is not entirely clear. Charged drugs (e.g., verapamil) appear to block calcium channels preferentially in the open state, whereas nonpolar drugs block the channel in both open and closed states. This has been invoked to explain the selectivity of verapamil and other charged compounds for rhythmically depolarizing cardiac cells and why the effects may be more pronounced on pacemaker cells, which have a relatively depolarized diastolic membrane potential.²⁴ Additionally, as stated above, there is a degree of variability in the molecular structures of the α_1 subunit and the other subunits.^{18,19} Consequently, calcium channel antagonists act at the particular L-type channel with the α_1 subunit that has the greatest affinity for the particular drug.²¹

PHARMACOKINETICS

The pharmacokinetics of calcium channel antagonists is summarized in Table 59-1. The calcium channel antagonists are rapidly and nearly completely absorbed from the gastrointestinal tract but have extensive first pass metabolism. Times to peak serum levels are typically

rapid. Several have been formulated as extended-release preparations. Time to peak plasma concentration with extended-release preparations is 3 to 7 hours.

Several conditions as well as xenobiotics may affect the pharmacokinetics of the calcium channel antagonists. CYP3A3/4 isoenzymes and CYP1A2 isoenzyme are involved in phase one metabolism of all calcium channel antagonists.²⁵ Diltiazem and verapamil inhibit P glycoprotein-mediated drug transportation in the gut and peripheral tissues.²⁵ Consequently, interactions with other xenobiotics are extensive (Table 59-2).

Certain examples are notable. Verapamil and diltiazem both decrease digoxin clearance and reduce its distribution to peripheral tissues. Cyclosporin and carbamazepine bioavailability are also increased.²⁶ Lithium toxicity has been reported during verapamil therapy, but the mechanism is not known.²⁷ Cimetidine increases diltiazem, felodipine, nifedipine, and nisoldipine bioavailability as a result of interactions with CYP3A3/4.²⁶ Importantly, grapefruit juice contains spiro ortho esters that are powerful inhibitors of the intestinal CYP3A enzymes, leading to increased bioavailability of felodipine, nifedipine, and verapamil.^{25,28}

Given the extensive hepatic metabolism of calcium channel antagonists, it is not surprising that disease states of the liver affect the pharmacokinetics of calcium channel antagonists. Verapamil has an increased half-life with both concomitant hepatic disease and reductions in hepatic blood flow.^{29,30} Furthermore, nifedipine clearance is linearly related to hepatic blood flow in animals.³¹

TOXICOLOGY

Acute Toxicity

Acute effects following calcium channel antagonist overdose are both exaggerations of the therapeutic effects due to action at the therapeutically targeted L-type channels of the vascular system as well as other pathophysiologic effects due to cross-reactivity with lower affinity L-type channels in other tissues.

TABLE 59-1 Pharmacokinetics of Calcium Channel Blockers

	ABSORPTION (%)	BIOAVAILABILITY (%)	VOLUME OF DISTRIBUTION (L/kg)	PROTEIN BINDING (%)	TERMINAL HALF-LIFE (hr)
Verapamil	>90	10–22	4.7	90	3–7
Diltiazem	>90	30–60	5.3	80–90	4
Nifedipine	>90	65–70	0.8–1.4	90	5

**TABLE 59-2** Drug Interactions Involving Calcium Channel Blockers

DRUG	INTERACTING DRUG	EFFECT	PROBABLE MECHANISM	COMMENT
Verapamil Bepridil (other calcium channel blockers possible, but less likely)	β blockers	Heart block, cardiac failure, asystole (after IV verapamil)	Additive depression of AV conduction, myocardial contractility	Primarily seen with verapamil; use with caution in patients taking β blockers
	Digitalis	Aggravates heart block; asystole	Additive depression of cardiac conduction	Avoid use of calcium channel blockers in patients with digitalis toxicity
Verapamil Diltiazem	Propranolol	Reduced oral clearance with increased levels of propranolol	Inhibition of first pass metabolism	Propranolol dose may need to be reduced
Verapamil Diltiazem Bepridil (possibly)	Digoxin	Reduced digoxin clearance, increased digoxin levels	Inhibition of metabolism and renal excretion of digoxin	Reduce digoxin dose after starting verapamil or diltiazem; monitor serum digoxin concentration
Verapamil Diltiazem	Cyclosporine	Increased cyclosporine levels	Uncertain	Reduce cyclosporine dose after starting verapamil or diltiazem; monitor cyclosporine level
Verapamil	Quinidine	Hypotension (after IV verapamil)	Additive α -adrenergic blockade	Use IV verapamil cautiously in patients taking quinidine or other drugs with α -blocking activity
Verapamil	Prazosin	Increased prazosin levels; greater hypotensive effect	Reduced clearance; additive α -blocking effect	Use combination cautiously; may need to decrease prazosin dose
Verapamil	Halothane	Bradycardia Hypotension	Additive depression of sinus node function and myocardial contractility	Avoid coadministration
Verapamil Diltiazem	Disopyramide Flecainide	Cardiac failure	Additive depression of myocardial contractility	Avoid use if possible, particularly in patients with impaired myocardial function
Bepridil	Quinidine Disopyramide Procainamide Sotalol	Ventricular arrhythmias Torsades de pointes	Additive prolongation of QT interval	Avoid coadministration
Verapamil Diltiazem	Amiodarone Flecainide	Sinus arrest Heart block	Additive depression of sinus node function and AV nodal conduction	Use combination with extreme caution
All calcium channel blockers	Oral hypoglycemic agents	Hyperglycemia	Inhibition of insulin release usually stimulated by sulfonylurea drugs	May need to increase oral hypoglycemic doses or use insulin to maintain glucose control; beware of hypoglycemia when calcium channel blockers are discontinued
All calcium channel blockers	Cimetidine	Increased oral bioavailability of calcium channel blockers	Inhibition of metabolism; reduced presystemic metabolism	Reduce calcium channel blocker dose by 30% to 40%
Verapamil	Rifampin Sulfinpyrazone	Reduced oral bioavailability of verapamil	Accelerated metabolism; increased presystemic metabolism	Increase verapamil dose; use alternative calcium channel blocker with less presystemic metabolism

The pharmacokinetics is affected by the overdose state. All calcium channel antagonists undergo some degree of first pass metabolism. Several reports describe increased drug half-lives following overdose of verapamil, nifedipine, and diltiazem.³²⁻³⁵ The mechanism is thought to be saturation of the microsomal CYP system enzymes. Sustained-release products may have delayed absorption that results in altered pharmacokinetics. Case reports describing overdose of sustained-release preparations describe a delay in symptoms by as long as 15 to 24 hours.³⁶⁻³⁸

In overdose, cardiac versus vascular selectivity is decreased but not abolished.^{39,40} Vasodilatation, particularly associated with agents preferentially affecting vascular smooth muscle, results in decreased systemic vascular resistance, hypotension, and shock. The patient may appear warm and well perfused owing to a lack of vasomotor tone. Negative inotropic and chronotropic effects lead to decreased cardiac output contributing to the shock state. Cardiac ejection fractions as low as 10% have been reported in poisoned patients.^{40,41} Depression

of myocardial conduction may cause depression of the sinus rate and any degree of atrioventricular block. Increased ventricular rate has been reported following overdose as a result of increased conduction across the accessory pathway in Wolff-Parkinson-White syndrome.⁴² Mortality is high and is preceded by worsening shock and acidosis, culminating in cardiac arrest.

Effects not directly attributable to antagonism of L-type channels of the cardiovascular system are frequently noted. Some are due to effects on calcium channels in other tissues, while others may be attributable to the shock state.

Pulmonary edema not consistent with the degree of myocardial depression has been reported following overdose with verapamil and amlodipine.⁴³⁻⁴⁹ Precapillary vasodilatation resulting in increase in transcapillary pressure is thought to be the mechanism.⁵⁰⁻⁵² Other proposed mechanisms include change in endothelial permeability due to a direct effect of calcium antagonism, prostaglandin effects, and effects secondary to the sympathetic discharge associated with toxicity.⁵³⁻⁵⁶

Delirium, agitation, seizures, and depressed level of consciousness have been described with calcium channel antagonist overdose.⁵⁷⁻⁵⁹ Bowel infarction and ileus have been reported; however, they may be due entirely to the shock state.^{41,60-64}

Hyperglycemia has been well documented with calcium channel antagonist toxicity.^{43,65,66} Calcium influx into pancreatic islet cells via L-type channels stimulates insulin release. Nonselective blockade following calcium channel antagonist overdose with resulting hypoinsulinemia is the cause of hyperglycemia.^{65,67,68} The decrease in insulin production produces ketoacidosis in addition to the lactic acidosis due to shock.⁶⁹

Chronic Toxicity

Calcium channel antagonists are essentially free of chronic toxicity.

Adverse Effects

Prolongation of the QT interval, first-degree atrioventricular block, transient elevation of transaminases, and near syncope are reported. Most calcium channel antagonists are excreted in breast milk.⁷⁰ Levels in breast milk may approach plasma levels; however, there are no reports of neonatal toxicity.⁷⁰ Inhibition of sperm acrosomal activity resulting in reversible infertility in males taking calcium channel antagonists therapeutically has been reported.⁷¹

DIAGNOSIS

Diagnosis of calcium channel antagonist overdose includes the patient's history. If the patient is not cooperative, medication lists should be reviewed to determine if the patient has had access to calcium channel antagonists. Prehospital care providers may have seen medication containers or prescriptions. If the patient's pharmacy can be identified, the pharmacist

may provide information. Family members should be questioned regarding medications available to the patient. Many reports of calcium channel antagonist toxicity describe co-ingestants with additive or synergistic effects. Consequently, a careful search for co-ingestants via history and laboratory analysis should be conducted as well. The physical examination may be notable for a warm, peripherally dilated patient who is hypotensive and bradycardic.

Serum levels of calcium channel antagonists are rarely available to the clinician treating the overdosed patient. An elevated serum glucose level may be present and support the diagnosis. The presence of ketoacidosis should be determined, since it also supports the diagnosis.

An electrocardiogram should be obtained to diagnose the presence of bradyarrhythmia that may be amenable to therapy. In cases of severe shock, invasive hemodynamic monitoring may confirm the decreased systemic resistance and provide evidence of response to therapy.

The differential diagnosis includes anything that may cause peripheral vasodilatation or bradyarrhythmia including myocardial infarction, insult to the cardiac conduction system, and ingestion of other vasoactive xenobiotic (e.g., β -adrenergic antagonists, clinidine, guanfacine, and digoxin).

MANAGEMENT

Supportive Measures

Initial supportive care should be aggressive owing to the high mortality associated with calcium channel antagonist overdose and the potential for rapid progression of symptoms. Large-bore intravenous access must be obtained. Continuous cardiac monitoring should be initiated. Airway and ventilatory support should be provided early because of the difficulties associated with intubation in the profoundly hypotensive patient.

No clear consensus exists regarding the optimal regimen for supportive care of the patient. Nearly every form of cardiovascular support has been tried, all with some reported success. Intravenous fluid therapy is typically initiated early following calcium channel antagonist overdose. Care should be exercised, however, given the aforementioned propensity of patients to develop pulmonary edema. Furthermore, these patients are not necessarily volume depleted; consequently, administration of large volumes of fluid should be avoided in favor of early administration of pharmacologic support or an antidote to avoid the complications of fluid overload.

The choice of pharmacologic supportive agents is best guided by the hemodynamic picture, since no single agent is clearly more beneficial than the others. Adrenergic agents such as dopamine, norepinephrine, or epinephrine should be initiated in the setting of significant toxicity. The choice of agent should be determined by the clinician's comfort with the agent administered and the clinical picture, with α -adrenergic agents administered to treat peripheral toxicity and

β -adrenergic agents administered to treat cardiac manifestations of toxicity. Atropine may be given to treat bradycardia likely to be responsive. Obtaining adequate hemodynamic data may require invasive hemodynamic monitoring, including the placement of arterial lines, central venous catheters, or pulmonary artery catheters.

Amrinone deserves special mention in the treatment of calcium channel antagonist toxicity. Amrinone inhibits phosphodiesterase III (found in cardiac and vascular tissues), resulting in decreased cyclic adenosine monophosphate (cAMP) breakdown. The increase in cAMP results in greater phosphorylation of L-type calcium channels, which increases their permeability to calcium ions. Amrinone does not increase myocardial oxygen demand as the catecholamines do. Data supporting the use of amrinone are limited, however. Amrinone has been shown to reverse myocardial depression in rats and dogs with verapamil toxicity.⁷²⁻⁷⁴ Human case reports describing beneficial effect of amrinone also have been published.^{75,76} Caution should be exercised, since amrinone can induce relaxation of vascular smooth muscle, potentially worsening the peripheral effects of calcium channel antagonists. Phosphodiesterase inhibitors thus have attractive properties for use in the management of calcium channel antagonist toxicity.

Mechanical inotropic supportive measures may be necessary if pharmacologic measures fail. Transvenous pacing has been reported in several cases with varying results.^{59,77-84} Balloon pump and bypass have been successful therapies.^{41,69,81,83,85} Given the limited data, these therapies should be reserved for cases in which pharmacologic measures have failed.

Decontamination

Following performance of initial supportive measures (airway control, intravenous access), appropriate decontamination measures should be instituted. Activated charcoal is generally the best option, since it likely will absorb the greatest amount of ingested drug, is less invasive, and has fewer complications than gastric emptying procedures. Emesis induction should not be attempted given the risk for rapid deterioration in hemodynamic status, the difficulty of airway control and other therapeutic measures, and risk of aspiration in the patient with uncontrollable emesis. Gastric lavage with a No. 36 to 40 French tube (24 to 28 for children) should be considered with caution. Lavage should be considered only after life-threatening ingestions within 1 hour of the ingestion. Importantly, gastric lavage may cause vagal stimulation, leading to death in patients with heart block or other bradyarrhythmias. Patients with a bradyarrhythmia should not undergo lavage. Whole-bowel irrigation with polyethylene glycol solution is recommended following overdose of sustained-release preparations.⁸⁶⁻⁸⁸ Many calcium channel antagonists are formulated as sustained-release preparations, and these are frequently implicated in toxicity.² Whole-bowel irrigation should not be performed when the patient has ileus. Furthermore, nursing care is made more difficult when the unstable patient is producing a large amount of liquid stool. Vomiting is a risk, and airway control to

protect from aspiration should be strongly considered. If whole-bowel irrigation is not feasible, multiple doses of activated charcoal may be considered although evidence of the clinical value of this intervention is lacking.

Laboratory Monitoring

As mentioned above, levels of calcium channel antagonists are generally not available in time to be useful. Several laboratory studies may be helpful, however. Serum electrolytes should be monitored to prevent arrhythmogenic abnormalities that may occur during therapy. Serum calcium concentrations are imperative when therapy with calcium salts is performed. Arterial blood gases may be used to monitor acidosis. Serum digoxin concentrations should be obtained in anticipation of administration of calcium salts. Calcium channel blocker overdose has no effect on total or ionized serum calcium concentrations.

Antidotes

Several antidotes have been used for the treatment of calcium channel antagonist toxicity.

4-AMINOPYRIDINE

4-Aminopyridine is a potassium channel antagonist that causes an increase in intracellular calcium concentration by increasing calcium inflow across the L-type channel and an increase in calcium release from intracellular stores in the sarcoplasmic reticulum.⁸⁸ 4-Aminopyridine has improved hemodynamic parameters in cats and dogs.^{89,90} Human use has been reported, but safety and efficacy remain in question.⁹¹

CALCIUM SALTS

Calcium salts are frequently employed in the management of calcium channel antagonist overdose.^{38,92} Calcium salts are a reasonable first agent, since they are readily available and easily administered. Reports of this use of calcium salts date to the mid-1970s, and thus calcium is the first antidote reported in the English literature.⁹³

The use of calcium salts is controversial, however. Animal data generally have been positive. Rats and rabbits given 5 to 15 mg/kg/min calcium chloride or gluconate with concurrent administration of nifedipine showed increased survival time, blood pressure, stroke volume, and cardiac output over controls; however, conduction disturbances were not affected.⁹⁴ Furthermore, serum calcium concentrations correlated with increases in blood pressure and cardiac output following calcium chloride administration to verapamil-poisoned dogs.⁹⁵

Human case reports show conflicting results. Several authors report minimal or no response to the administration of calcium salts to treat severe calcium channel antagonist toxicity.^{48,66,96-98} Proponents of the use of calcium argue that most of the reports of failed therapy are due to underdosing and that high doses of calcium are effective as antidote and without adverse effects.⁴⁵

Several recommendations have been published for the administration of calcium salts. Calcium chloride has

been administered in bolus doses of 1 g every 15 to 20 minutes for a total of four doses or more aggressively as 1 g every 2 to 3 minutes until clinical effect is achieved.⁴⁵ Continuous infusion of 0.2 to 0.4 mg/kg/hr calcium chloride (0.6 to 1.2 mg/kg/hr calcium gluconate) has been recommended.^{40,99} Buckley and colleagues reported giving 30 g calcium chloride over 12 hours resulting in a plasma calcium level of 23.8 mg/dL with hemodynamic improvement and no adverse clinical effects.⁴⁵ Lam and colleagues advocate titrating calcium infusion to maintain a serum calcium level of 8 mg/dL.¹⁰⁰ Howarth and associates recommend continuous infusion titrated to improvement in hemodynamic parameters.⁴⁸

Initial bolus administration of calcium salts followed by measurement of serum calcium at a minimum of every 12 hours is reasonable practice. Serum calcium levels should be maintained in the normal range because of the lack of evidence for efficacy of above-normal concentrations. Other modes of therapy should be added if calcium therapy does not rapidly improve hemodynamic parameters.

Several precautions should be taken during calcium therapy. Careful maintenance of intravenous sites is essential to prevent tissue damage due to extravasation of calcium chloride. Continuous cardiac monitoring and at least daily electrocardiograms should be performed to prevent arrhythmias.¹⁰⁰ Calcium should not be administered if there is an elevated digoxin level or if the clinician has reason to believe that digoxin ingestion may have occurred, because of the concern for resulting life-threatening arrhythmias.¹⁰¹⁻¹⁰³ The effect of administering exogenous calcium to patients with therapeutic digoxin serum concentrations and calcium channel antagonist toxicity is unknown. It is prudent to obtain the digoxin concentration before initiation of calcium therapy and to withhold calcium therapy if a measurable digoxin concentration is present, because of the potential for concurrent overdose of digoxin, the unclear interaction between calcium and therapeutic digoxin concentrations, and the availability of other therapies.

INSULIN

Insulin as an antidote for calcium channel antagonist poisoning is based on several observations.¹⁰⁴ Hyperglycemia in calcium channel antagonist toxicity is due to blockade of pancreatic L-type channels that results in decreased insulin production.⁶⁶ Furthermore, calcium channel antagonist toxicity results in decrease in uptake of insulin or free fatty acids by the myocardium as well as a shift from oxidation of fatty acids to carbohydrates for the production of energy.⁶⁹

Insulin increases cellular uptake of glucose and lactate and improves hemodynamic parameters in verapamil-poisoned dogs.¹⁰⁴ Furthermore, measurement of the myocardial respiratory quotient and the ratio of myocardial oxygen delivery to myocardial work indicates that insulin therapy of verapamil-poisoned dogs causes an increase in energy efficiency of myocardial metabolism.¹⁰⁴ Insulin improves survival in critically ill patients owing to a variety of causes regardless of degree of hyperglycemia or insulin resistance.¹⁰⁵

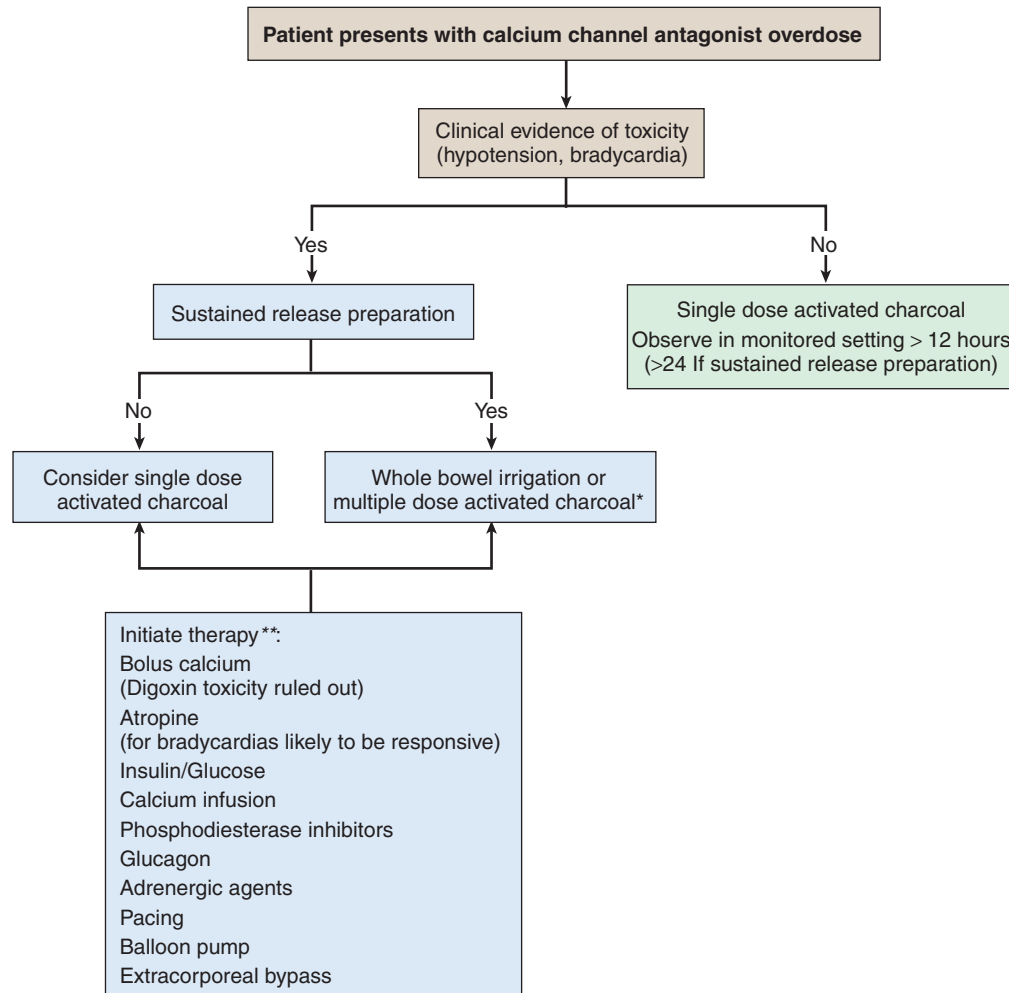

Human data support the use of insulin as an antidote for calcium channel antagonist toxicity. Yuan and associates reported on three patients with verapamil toxicity and one with amlodipine and atenolol toxicity refractory to calcium salts, fluids, and vasopressors. Patients received bolus doses of 10 to 20 IU of regular insulin followed by a continuous insulin infusion of 0.1 to 1.0 IU/kg/hr. All patients showed improvement in hemodynamic parameters temporally associated with insulin administration.⁶⁹ Serum verapamil concentrations obtained from two of these patients were markedly elevated, yet all patients survived without sequelae.⁶⁹ Boyer and Shannon reported on two patients who failed to respond to calcium or glucagon and aggressive supportive care, yet responded rapidly to insulin administration at 0.5 IU/kg/hr.¹⁰⁶ Supplemental glucose was required for only one of the patients. Insulin therapy with supplemental glucose as needed should therefore be initiated early in the treatment of calcium channel antagonist toxicity.

The preferred regimen at the author's institution for insulin therapy is as follows. Adult patients with serum glucose levels greater than 200 mg/dL receive one ampule (50 mL of 50% solution) of D-glucose (0.25 g/kg D-glucose for children). A serum potassium concentration of less than 2.5 mEq/dL is treated with 40 mEq orally or 20 mEq of potassium intravenously. A bolus dose of insulin, 1.0 U/kg, is given followed by an infusion at 0.5 to 1.0 IU/kg/hr titrated to clinical response. Therapeutic targets include a systolic blood pressure greater than 100 mm Hg and a sinus rhythm of greater than 50 beats per minute. Capillary glucose is checked every 20 minutes for 1 hour and then hourly thereafter. Serum potassium is checked hourly. Fluid therapy is half-normal saline with 10% dextrose at an infusion rate equal to 80% of maintenance. Insulin infusion is weaned as toxicity resolves. *k* Hyperinsulinemia, euglycemia (HIE) is the term applied to the use of insulin as an antidote given the large doses of insulin administered.

GLUCAGON

Glucagon has been recommended as an antidote for calcium channel antagonist therapy in prior editions of this and in other standard texts. Glucagon has a specific receptor on the surface of the myocyte.¹⁰⁷ Binding results in the stimulation of adenyl cyclase via G proteins followed by increased intracellular cyclic AMP, phosphorylation of L-type calcium channels, and influx of calcium.¹⁰⁸ In addition, the C-terminal portion of glucagon is cleaved to miniglucagon, which releases calcium from the sarcoplasmic reticulum.¹⁰⁹ Miniglucagon increases inotropy in embryonic chick ventricular myocytes. In vitro administration of both glucagon and miniglucagon produced a synergistic positive inotropic effect, thought to be due to effects on the L-type channel and the sarcoplasmic reticulum.¹⁰⁹

Multiple studies show increased inotropy, chronotropy, and dromotropy following glucagon administration to animals poisoned by calcium channel antagonists.¹¹⁰⁻¹¹⁴ Human case reports are less conclusive, since they are confounded by multiple treatment regimens and uncontrolled conditions. The majority, however, describe

*Efficacy not proven but potential benefits exceed risks in most circumstances

**Therapy may need to be started prior to decontamination if patient is unstable

FIGURE 59-3 Algorithmic approach to the management of the patient with calcium channel antagonist toxicity.

beneficial effects on hemodynamic parameters following glucagon administration.^{76,115,116}

The effects of glucagon begin within 1 to 3 minutes, peak at 5 to 7 minutes, and decline by 15 minutes.¹¹⁷ Doses between 0.5 and 14 mg intravenously have been reported, but typical dosing is 1 to 10 mg as an intravenous bolus followed by infusions of 3 to 6 mg/hr.^{115,116,118} The maintenance dose is determined by the initial effective dose, with the initial dose required to obtain response given as continuous infusion over 1 hour. The initial recommended pediatric dose is 50 to 150 $\mu\text{g}/\text{kg}$.¹¹⁹ Adverse effects of glucagon include nausea, vomiting, flushing, hyperglycemia, smooth muscle relaxation, and intestinal ileus.

Elimination

No methods are known to enhance the elimination or metabolism of calcium channel antagonists. The high degree of protein binding and volumes of distribution generally larger than 1 L/kg make dialysis unlikely to be beneficial, and no benefit has ever been reported.

Significant enterohepatic circulation has not been demonstrated. Furthermore, gut dialysis with multiple-dose charcoal is not known to occur.

Disposition

Given the severity of calcium channel antagonist toxicity and the potential for delayed toxicity, patients with a history of ingestion should be observed in a monitored setting for a minimum of 12 hours. If there is a question whether a sustained-release preparation is involved, the period of observation should be extended to 24 hours. Patients exhibiting signs of toxicity should be treated in an intensive care unit. Following resolution of toxicity, a careful search should be conducted for sequelae of prolonged hypotension including bowel infarction, stroke, and subendocardial myocardial infarction and those issues treated accordingly. An algorithmic approach to the care of the patient suffering calcium channel antagonist toxicity is shown in Figure 59-3. As always, psychiatric evaluation is prudent following intentional ingestion. The causes of therapeutic mis-

adventure should be investigated as well. Finally, a nonjudgmental evaluation of home safety should occur in cases of pediatric ingestion.

STEVEN B. BIRD, MD

At a Glance...

- The classic presentation of overdose is bradycardia, hypotension, hypoglycemia, and decreased mental status.
- Some agents may produce tachycardia and hypertension.
- Glucagon is the treatment of choice for bradycardia and hypotension.
- Combined pharmacologic therapy is often needed in moderate-to-severe poisoning.
- Invasive measures such as transvenous pacing, intra-aortic balloon counterpulsation, and cardiopulmonary bypass should be considered if pharmacotherapy is ineffective.

INTRODUCTION AND RELEVANT HISTORY

Since the first use of β-adrenergic antagonists (“β blockers”) for angina and hypertension in the early 1960s, the clinical indications for their use and number of prescriptions filled per year have increased dramatically. Currently, β-adrenergic antagonists are indicated for cardiac dysrhythmias, angina pectoris, hypertension, idiopathic hypertrophic subaortic stenosis, after myocardial infarction, for management of stable congestive heart failure, aortic dissection, thyroid storm, essential tremors, glaucoma, migraine prophylaxis, anxiety states, withdrawal states, and pheochromocytoma.^{1,2}

EPIDEMIOLOGY

Not unexpectedly, increased use of these agents has led to increased incidence of toxicity. Frishman and colleagues³ published the first review of β-adrenergic toxicity in 1979. The American Association of Poison Control Centers (AAPCC) reported a nearly sixfold increase in β-adrenergic exposures from 1984 to 2002, and an increase in mortality from 6 to 39 during the same time period.^{4,5}

It has been estimated that by the year 2030, more than 20% of the U.S. population will be aged 65 years or older⁶ and that the number of people with congestive heart failure will increase to nearly 6 million.⁷ One may expect with an aging population, combined with ever-increasing indications for β-adrenergic antagonists, that the number of poisonings (as well as the severity of the poisonings) will continue to increase. Therefore, an understanding of the pharmacology, toxicology, and clinical presentation of patients after β-adrenergic antagonist poisoning is essential.

PHARMACOLOGY

β Blockers are generally classified on the basis of their cardioselectivity or the type of β-adrenergic receptor that is antagonized. These agents may also be classified according to the degree to which they possess partial agonist properties and also their membrane stabilization and antidysrhythmic effects (Table 60-1). As with many pharmaceutical agents, receptor selectivity is largely lost upon overdose.

A thorough understanding of β-adrenergic receptor antagonist toxicity requires a brief review of these receptors. The distinction between α and β receptors was elucidated and published in 1948 by Ahlquist.⁸ Binding of epinephrine and norepinephrine to β receptors results in the phosphorylation of a G-protein complex on the cytoplasmic side of the cell membrane. Conformational changes in the G protein allow adenylate cyclase to catalyze the formation of cyclic adenosine monophosphate (cAMP) in the cytoplasm. In the myocyte, cAMP stimulates various protein kinases that phosphorylate calcium channels, thereby resulting in calcium entry into the cell and calcium-dependent calcium release from the sarcoplasmic reticulum. This calcium is responsible for the excitation-contraction coupling of myocytes.⁹ Non-specific phosphodiesterases then hydrolyze cAMP and prevent further downstream effects.¹⁰

Further characterization of the β₁ and β₂ receptors was published in 1967 by Lands and associates.¹¹ It was not until 1989 that a third β-adrenergic receptor was characterized,¹² although this β₃ receptor is primarily located on adipose cells and has no significant cardiovascular effects. A fourth type of β receptor that is responsible for partial agonist activity, termed the *cardiac putative β₄ adrenoreceptor*, has been proposed.¹³

β₁-Adrenergic specific receptors are found primarily in the myocardium, kidneys, and eyes, and they demonstrate roughly equal binding affinities for epinephrine and norepinephrine.¹¹ β₁-Receptor stimulation leads to increases in myocardial contractile force (inotropy) and rate (chronotropy) as a result of increased sinoatrial node firing as well as action potential conduction velocity.¹⁴ β₁-Receptor activation also increases renin secretion by the kidney and aqueous humor production in the anterior chamber of the eye. β₂ Receptors are found predominantly in vascular smooth and skeletal muscle, the pancreas, the liver, and adipose tissue. Agonism of β₂ receptors leads to relaxation of smooth muscle in the lungs, blood vessels, uterus, and intestines. Metabolic effects of β₂-receptor stimulation include lipolysis, glycogenolysis, and increased insulin secretion (Table 60-2).

TABLE 60-1 Classification of β Blockers

NAME	ADRENERGIC RECEPTOR ANTAGONISM	PARTIAL AGONIST	MEMBRANE STABILIZATION	LIPID SOLUBILITY	ORAL BIOAVAILABILITY (%)	PROTEIN BINDING (%)	VD (L/kg)	ELIMINATION	HALF-LIFE (hr)
Acebutolol	β_1	Yes	Yes	Moderate	40	25	2.3	Renal	3-6
Atenolol	β_1	No	No	Low	50	15	0.7	Renal	6-9
Betaxolol	β_1	No	Yes	Low	90	50	6.0	Hepatic	14-22
Bisoprolol	β_1	No	No	Low	80	30-50	2.7-3.1	Hepatic	9-12
Carteolol	β_1, β_2	No	No	Low	85	23-30	4.0	Renal	6
Carvedilol	$\beta_1, \beta_2, \alpha_1$	Yes	No	High	25-35	95	1.6	Hepatic	6-10
Esmolol	β_1	No	No	Low	N/A	55	3.4	Esterase	0.15
Labetalol	β_1, β_2	Yes	No	Low	30-40	50	10	Hepatic	3-6
Metoprolol	β_1	No	No	Moderate-high	40-50	12	5.5	Hepatic	3-4
Nadolol	β_1, β_2	No	No	Low	30-50	30	2.1	Renal	14-24
Penbutolol	β_1, β_2	Yes	No	High	100	90-98	>30	Hepatic	20
Pindolol	β_1, β_2	Yes	Yes	Moderate	99	40-60	2.0	Renal	3-12
Propranolol	β_1, β_2	No	Yes	High	30	90	3.6	Hepatic	3-5
Sotalol	β_1, β_2	No	No	Low	90-100	0	0.2	Renal	5-12
Timolol	β_1, β_2	No	No	Low	75	10	1.5	Renal	4

**TABLE 60-2** β -Receptor Effects

β_1 -RECEPTOR EFFECTS		β_2 -RECEPTOR EFFECTS	
ORGAN	EFFECT	ORGAN/SYSTEM	EFFECT
Eye	Increased aqueous humor production	Lung	Bronchial dilation
Kidney	Increase renin production	Vascular system	Arteriole dilation
Heart	Increased inotropy and chronotropy		Increased insulin secretion
			Increased lipolysis
			Increased glycogenolysis
		Metabolic system	Increased lactic acid production
		Other	Intracellular potassium shift

PATHOPHYSIOLOGY

The antagonism of β receptors and subsequent derangements in catecholamine physiologic effects cannot account for all the observed toxicity following β -receptor antagonist overdose. That is, if β -receptor antagonism alone were responsible for the observed clinical effects, then β -receptor agonism should provide adequate means to overcome the receptor blockade. However, experimental evidence and clinical experience suggest other mechanisms are at work. For instance, in isolated rat hearts depleted of catecholamines, the addition of β blockers produces toxicity. Additionally, in a canine model of acute β -blocker toxicity, Kerns and associates demonstrated no improvement in survival with the addition of high-dose epinephrine.¹⁵

PHARMACOKINETICS

β Blockers are generally rapidly absorbed after ingestion, with peak effects occurring after 1 to 4 hours.¹⁶ Sustained-release formulations, however, produce prolonged absorption. It is prudent to keep in mind that pharmacokinetics may be altered greatly in the setting of overdose.¹⁷ The volume of distribution for β blockers varies widely: only atenolol and sotalol have volumes of distribution of less than one (see Table 60-1). Half-lives of these agents are generally brief (approximately 6 hours) but vary from a low of 10 minutes for esmolol, to 24 hours for nadolol. Low cardiac output states, hepatic dysfunction, and inducers of hepatic enzymes may alter the duration of action for those β blockers, which are metabolized by the liver. Similarly, renal dysfunction and low cardiac output may increase the duration of action for agents that are excreted unchanged in the urine (see Table 60-1).

After acute oral overdose of immediate-release preparations, signs of toxicity usually begin within 30 minutes and peak by 2 hours. Toxicity after ingestion of sustained-release preparations or sotalol may be delayed until 20 hours after ingestion.¹⁸⁻²¹ Toxicity after β -blocker overdose may persist as long as several days.²²

The lipid solubility of β blockers can significantly influence the degree of clinical toxicity observed after overdose owing to penetration of the blood-brain barrier. The agents with the highest degree of lipophilicity include metoprolol, penbutolol, propranolol, and carvedilol. The

concentration of propranolol in the central nervous system (CNS) may exceed that seen in plasma by as much as 20-fold.²³

Acebutolol, carteolol, penbutolol, pindolol, and timolol uniquely possess partial β -adrenergic agonist properties (also known as intrinsic sympathomimetic activity, or ISA), leading to a normal heart rate or even tachycardia. Therefore, bradycardia should not be viewed as invariably present after β -blocker poisoning.

The decreased cAMP formation following β -blocker administration also leads to inhibition of sodium and calcium influx currents during phase 0 of the cardiac action potential, thereby classifying β blockers as Vaughn Williams class II antidysrhythmics.²⁴ This effect is termed *membrane stabilization*.

Special Populations

Clinical effects observed with β -blocker toxicity may differ according to the age of the patient. Symptomatic hypoglycemia may be more common in children than in adults. The baseline cardiovascular disease present in many elderly patients may make overdoses or unintentional poisonings more severe in this age group.

Drug Interactions

Drugs that induce hepatic mixed-function oxygenases may increase metabolism of betaxolol, bisoprolol, carvedilol, labetalol, metoprolol, penbutolol, and propranolol. Notable examples include phenytoin, phenobarbital, isoniazid, and rifampin. Other drugs (e.g., erythromycin, clarithromycin, cimetidine) may inhibit hepatic metabolism of these agents and therefore produce toxicity at unexpected doses. The other β blockers listed in Table 60-1 (except esmolol) undergo primarily renal elimination and can therefore be affected by agents that decrease renal clearance (e.g., nonsteroidal anti-inflammatory drugs). It is unknown whether the new cyclooxygenase II inhibitors sufficiently perturb β -blocker elimination.

Owing to their significant effects on myocardial physiology, the principal drugs that interact with β blockers are other antihypertensive and antidysrhythmic agents. In both therapeutic doses and overdoses, the combination of a β blocker and a calcium channel blocker may lead to hypotension, bradycardia, and death.²⁵⁻²⁷ Combination treatment with peripheral

vasodilators such as hydralazine may lead to significant hypotension as a result of β -blocker inhibition of the usual reflex tachycardia. Administration of exogenous catecholamines, or the presence of any drug that leads to release or accumulation of catecholamines (e.g., cocaine, amphetamines, monoamine oxidase inhibitors), may lead to “unopposed α -adrenergic” stimulation and resultant hypertension, cardiac ischemia, or stroke.²⁸⁻³⁰

TOXICOLOGY

Clinical Manifestations

Cardiac conduction abnormalities are common. First-degree atrioventricular (AV) block, intraventricular conduction abnormalities, high-grade AV block, non-specific ST segment and T wave changes, QT prolongation, and asystole have all been recorded. Varying degrees of ventricular depolarization and repolarization abnormalities may occur, particularly with membrane stabilizing agents and sotalol.³¹⁻³³ Most patients with overdose present with hypotension and bradycardia.²¹ Ingestion of agents with ISA, however, may lead to tachycardia and hypertension.^{34,35} Sotalol is particularly toxic, with frequent reporting of ventricular tachycardia, torsades de pointes, and ventricular fibrillation^{19,36} owing to its effect on action potential duration and subsequent QT prolongation.^{37,38}

CNS depression, ranging from drowsiness to coma, is a relatively common effect of β -blocker toxicity³² and generally reflects the severity of the poisoning.^{17,20} CNS toxicity may occur in the absence of bradycardia, hypotension, or hypoglycemia,²¹ particularly with the lipid-soluble agents.^{3,39,40} CNS depression also is exacerbated by β blocker–associated cerebral hypoperfusion, acidemia, and hypoxia.³²

While bronchospasm has been traditionally been a concern following therapeutic use or overdose of β blockers, it remains an unusual complication of β -blocker toxicity. When it does occur, bronchospasm is more likely to occur in patients with preexisting pulmonary disease. More common is respiratory depression, usually due to CNS toxicity.⁴¹ Central cyanosis may be present. Peripheral cyanosis due to antagonism of vascular β_2 receptors with the accompanying “unopposed α_1 ” effects may be evident^{21,32,42} and has led to mesenteric ischemia.⁴³

Frank hypoglycemia is infrequently seen with β -blocker toxicity, but normal serum glucose in the setting of significant β -blocker poisoning may in fact be relative hypoglycemia. Hypoglycemia is more common in children, persons with diabetes, and patients with uremia. The typical tachycardia seen during hypoglycemia may be diminished after β -blocker ingestion although other symptoms of hypoglycemia are relatively unchanged. Hyperkalemia is variably present and may be a clue to β -blocker poisoning.

Renal effects after β -blocker poisoning are unusual, although oliguric renal failure has been reported rarely.⁴⁴

TABLE 60-3 Adverse Effects of β -Adrenergic Antagonists

SYSTEM	EFFECTS
Cardiovascular	Hypotension Hypertension (partial agonists) Bradycardia, atrioventricular block, asystole Tachycardia (partial agonists) Prolonged PR interval Prolonged QT interval (sotalol) Prolonged QRS complex (membrane-stabilizing agents) Ventricular dysrhythmias (membrane-stabilizing agents, sotalol)
CNS (lipid-soluble and membrane-stabilizing agents)	Decreased level of consciousness Seizures Depression Insomnia
Respiratory	Bronchospasm Respiratory depression
Gastrointestinal	Esophageal spasm Mesenteric ischemia
Metabolic Other	Hypoglycemia Renal failure

The adverse effects observed after therapeutic doses of β blockers are listed in Table 60-3. Chronic therapeutic use of β blockers leads to an increase in adrenergic receptor expression and a resultant increase in catecholamine sensitivity upon withdrawal of β blockers. This may in part explain the degree to which high doses of β blockers are tolerated, so long as the dose is increased slowly, and why acute ingestion of a similar dose may produce toxicity in patients not accustomed to β -blocker use.⁴⁵

DIAGNOSIS

Laboratory Testing

β Blockers are not detected by current enzyme immunoassays. Routine serum or urine β -blocker concentrations are not available. Additionally, owing to inter-individual variations in metabolism and protein binding and variations in dosing, determination of serum concentrations in the acute setting generally are not helpful²² but can be used as a confirmatory test when overdose is suspected.

Other Diagnostic Testing

All patients with confirmed or suspected β -blocker overdose or symptoms consistent with β -blocker toxicity should be placed on continuous cardiac monitoring and have a 12-lead electrocardiogram (ECG) interpreted. Frequent recording of vital signs should be routine. Symptomatic patients should have determination of electrolytes, blood urea nitrogen (BUN), creatinine, glucose, and complete blood count. Determination of serum drug concentrations as indicated (e.g., digoxin)

should be performed. For patients with abnormal vital signs, a chest radiograph and arterial blood gas measurement should be assessed.

Differential Diagnosis

Other causes of cardiovascular collapse with hypotension and bradycardia (except with the possibility of tachycardia after poisoning with β blockers that possess partial agonist activity) include shock of anaphylactic, cardiogenic (including pulmonary embolism), septic, and hypovolemic etiologies. Additionally, other toxicologic sources must be considered, particularly poisoning with calcium channel blockers, organophosphorus or carbamate agents, antidysrhythmics, centrally acting anti-hypertensives, cardiac glycosides, cyanide, hydrogen sulfide, narcotics, chloroquine, sedative-hypnotics, and tricyclic antidepressants. β -Blocker poisoning should be suspected in any patient with hypotension, bradycardia, and seizures. Differentiation between β -blocker and calcium channel blocker toxicity may be aided by measurement of the serum glucose: hypoglycemia may be present with β -blocker poisoning, whereas hyperglycemia is often seen after poisoning by calcium channel blockers. The presence of hyperkalemia may also be a clue to β -blocker toxicity.

MANAGEMENT

Supportive Measures

When possible, historical data regarding the time of ingestion, agents involved, quantity ingested, other medications, and a medical history should be obtained. One should also pay particular attention to the vital signs and examination of the cardiopulmonary and neurologic systems

As for any patient, priority should be given to establishment of adequate airway, breathing, and circulation. In at least two animal studies, the primary determinant of β -blocker toxicity and death was respiratory arrest.^{46,47} Therefore, early establishment of adequate ventilation is essential.

All patients should have continuous cardiac monitoring, continuous pulse oximetry, an ECG, and frequent assessment of vital signs. Determination of the complete blood count, bedside finger-stick glucose, serum electrolytes, BUN, and serum creatinine should be performed. A chest radiograph and arterial blood gas measurement should be obtained in all symptomatic patients. If the diagnosis is uncertain, a comprehensive toxicologic screen may be of benefit.

Decontamination

Gastrointestinal decontamination with activated charcoal 1 g/kg (maximum, 50 to 60 g) should be done as soon as possible after initiation of supportive care. The use of syrup of ipecac to induce emesis cannot be advocated because of the risk of vomiting and aspiration,

particularly if respiratory or CNS depression follow. At least one author has suggested that prophylactic atropine may be beneficial to inhibit vagally mediated bradycardia during endotracheal or gastric intubation.²⁴

In an effort to decrease any enterohepatic circulation, repeated doses of activated charcoal are recommended for symptomatic patients. Additionally, in patients poisoned with sustained-release formulations, placement of a nasogastric or orogastric tube and whole-bowel irrigation with a polyethylene glycol solution (20 to 30 mL/kg/hr in adults and 10 to 20 mL/kg/hr in children) should be considered.

Laboratory Monitoring

Continuous cardiac monitoring and frequent ECGs are indicated for all patients. Serial determinations of serum potassium and glucose also are prudent, as is the determination of serum magnesium, particularly for agents known to cause torsades de pointes.

Antidotes

GLUCAGON

Glucagon is the most consistently effective agent for β -blocker poisoning in both laboratory studies and in humans^{21,32} and is the therapeutic drug of choice. Glucagon is a pancreatic polypeptide whose inotropic and chronotropic effects were first discovered in 1960.³⁰ Glucagon is thought to activate adenylate cyclase independently of the β -adrenergic receptor, thereby increasing cAMP synthesis with the resultant increase in myocardial heart rate and contractility.⁴⁸⁻⁵⁴ It increases mean arterial pressure, cardiac index, and contractility without altering the left ventricular end-diastolic pressure.⁵⁵⁻⁵⁷ Glucagon is more effective in reversing hypotension than either epinephrine or isoproterenol.³² However, therapy with several agents simultaneously may be required.

Glucagon has a half-life of roughly 20 minutes. After an initial IV bolus dose of 5 to 10 mg for adults (50 to 150 μ g/kg in children), a continuous infusion of 1 to 5 mg/hr (10 to 50 μ g/kg/hr in children) should be used, if effective. Continuous IV infusion of glucagon is preferred to intermittent bolus dosing owing to the more sustained increase in blood pressure observed after the former.⁵⁸ Clinical effects begin in as few as 1 to 3 minutes, with peak effects seen at 5 to 7 minutes.⁴⁸ It is recommended that glucagon be reconstituted in normal saline or 5% dextrose, because the diluent provided by the manufacturer contains 2 mg of phenol per 1 mg of glucagon, which may be toxic in doses of 25 mg or more.^{59,60}

Nausea and vomiting (occurring in nearly one third of patients) are the most common side effects after glucagon therapy.^{61,62} Hyperglycemia may occur and is the basis for administration of glucagon for hypoglycemia; however, the stimulation of pancreatic insulin secretion by glucagon may also lead to hypoglycemia. As a result of insulin-mediated intracellular ion shifts, hypokalemia may occur. Rare but more significant

adverse effects after glucagon therapy include Stevens-Johnson syndrome, erythema multiforme minor, and acute allergic reaction.⁶³ The few contraindications to glucagon therapy that exist are the presence of insulinoma, pheochromocytoma, or glucagon hypersensitivity.³⁰ Because of limited hospital pharmacy stocking of glucagon, additional sources should be sought soon after initiation of continuous IV therapy.^{64,65}

CALCIUM

Presumably owing to the derangements in calcium-mediated myocardial contraction and vascular tone, IV calcium is variably effective in reducing hypotension.⁶⁶⁻⁶⁹ Calcium chloride 1 to 2 g intravenously every 5 to 10 minutes as necessary is commonly used, but it must be administered cautiously because of its highly irritating effects. One must give serious consideration to delivery via central venous access. Calcium gluconate may also be used but contains only one third the calcium of calcium chloride on a gram-for-gram basis. Hypercalcemia may be a theoretical concern. However, severely poisoned patients who receive several doses of calcium chloride should be intubated, thereby mitigating concerns about hypercalcemia-induced CNS and respiratory depression.⁷⁰

CATECHOLAMINE AGENTS

Because β blockers bind to the adrenergic receptors in a competitive fashion, one might expect that β agonists and vasopressors alone would reverse toxicity. Unfortunately, therapeutic response to these agents alone is limited and variable. Doses of catecholamines needed to achieve a significant response may be four or more times greater than doses generally used.^{20,21,71} The pro-dysrhythmic potential of these agents when used in high doses, particularly isoproterenol, mitigates some of the enthusiasm for their use. Nevertheless, catecholamines remain a vital part of the multitherapy strategy for severely poisoned patients.

PHOSPHODIESTERASE INHIBITORS

Inamrinone (formerly named amrinone) may produce an increase in contractility independently of the β receptor by inhibiting phosphodiesterase and thus slowing the breakdown of cAMP. Inamrinone increased inotropy in a canine model of β -blocker poisoning,⁷² but was of no additional benefit (and may have been detrimental) when added to glucagon therapy.⁷³ The recommended dose of inamrinone for congestive heart failure is a 0.75 mg/kg IV bolus over 2 to 3 minutes, followed by a continuous infusion of 5 to 10 μ g/kg/min. If needed, a repeat bolus dose may be given 30 minutes after the initiation of therapy.

ATROPINE

Although frequently ineffective, patients with bradycardia and hypotension warrant a trial of atropine therapy and may receive modest benefit.

TREATMENT OF SEIZURES

Seizures that are not responsive to glucose should be managed with benzodiazepines, barbiturates, and possibly phenytoin.

Treatment of Bronchospasm

Bronchospasm may be induced by β -blocker toxicity, particularly in patients with a history of reactive airway disease. Treatment should proceed much as for other nontoxicologic causes of asthma, including inhaled β_2 agonists and anticholinergic agents and subcutaneous epinephrine as needed.

Nonpharmacologic Therapies

External or transvenous cardiac pacing should be considered after failure of pharmacotherapy alone.^{74,75} However, electrical capture is not always possible after severe poisoning, and while the heart rate may respond to pacing, a consistent increase in blood pressure is not always achieved.^{21,76} Transvenous cardiac pacing may be most useful in treating refractory torsades de pointes due to sotalol poisoning.^{19,36}

Other invasive measures that have been used with varying degrees of success in severe poisoning include intra-aortic balloon counterpulsion, cardiopulmonary bypass, and extracorporeal membrane oxygenation.^{18,76,77}

Sotalol Intoxication

The unique pharmacology and pharmacokinetics of sotalol warrant special attention. Patients may have significant tachycardia and hypertension due to sotalol toxicity. If no end-organ dysfunction is present, however, close monitoring in the hospital setting may be all that is required. If end-organ toxicity exists, then short-acting agents such as nitroprusside and esmolol should be used. As mentioned above, ventricular dysrhythmias, QT prolongation, and subsequent torsades de pointes may be more frequent with sotalol poisoning. Treatment of sotalol-induced ventricular tachydysrhythmias includes magnesium, lidocaine, phenytoin, and "overdrive" pacing with either transvenous electrical pacing or isoproterenol.⁷⁸⁻⁸¹

Elimination

Although the use of charcoal hemoperfusion after β -blocker poisoning has been reported,⁷⁴ the pharmacokinetic properties of most β blockers would appear to limit the usefulness of extracorporeal elimination. Owing to their low degree of protein binding and low volumes of distribution, atenolol and sotalol would be expected to be most responsive to extracorporeal elimination.^{20,82}

Disposition

All symptomatic patients after β -adrenergic antagonist ingestion or overdose, and patients with a history of

sotalol ingestion should be admitted to the hospital. Patients with significant signs or symptoms of toxicity (including but not limited to altered mental status, bradycardia, hypotension, and dysrhythmias) should be managed in an intensive care unit. While no prospective studies exist, patients who do not ingest a sustained-release formulation and who remain asymptomatic with a normal ECG and normal vital signs should be observed for at least 6 hours. Ingestion of a sustained-release formulation necessitates admission or observation for at least 24 hours.

From 30% to 40% of β -adrenergic receptor antagonist overdose patients remain asymptomatic.⁸³ However, other authors have reported a mortality rate as high as 26%.⁸⁴ In one review of the literature, 75% of deaths due to propranolol occurred at home.⁸³ Therefore, it would appear that if a patient arrives in the emergency department alive and appropriate treatment is initiated early, the prognosis is good. Attempts at prolonged resuscitation after β -blocker overdose are warranted, since survival without neurologic sequelae has been reported.⁸⁵

Nitroprusside, ACE Inhibitors, and Other Cardiovascular Agents

WILLIAM H. RICHARDSON, MD ■ DAVID P. BETTEN, MD ■ SARALYN R. WILLIAMS, MD ■ RICHARD F. CLARK, MD

At a Glance...

- Early cyanide poisoning from nitroprusside may manifest with central nervous system effects and tachyphylaxis.
- Thiocyanate poisoning, in contrast to cyanide poisoning, occurs most frequently in the setting of renal insufficiency and does not cause a metabolic acidosis.
- Supportive care including intravenous fluids and inotropic agents are the mainstay of treatment in hydralazine and minoxidil poisoning.
- Nonspecific T-wave and ST-segment ECG abnormalities are commonly described in overdose and with therapeutic use of hydralazine and minoxidil.
- Nitrates/nitrites are contraindicated in the setting of sildenafil use even in the setting of acute coronary syndrome.
- The presence of angioedema is classically described with ACE inhibitors but can also occur with angiotensin receptor blockers.
- The use of alpha-1 antagonists may result in symptomatic hypotension in the absence of tachycardia due to isolated effects on the alpha-1 adrenergic receptor.
- In diuretic abuse and overdose, care should be directed toward identification and correction of fluid and electrolyte abnormalities.

NITROPRUSSIDE

Sodium nitroprusside (SNP) is a potent vasodilator widely used due to its rapid onset of action, short half-life, and ease of titration. It is approved for reduction of blood pressure in hypertensive emergencies and for controlled hypotension during surgical procedures to reduce the risk for hemorrhage.¹ The first human use of nitroprusside was reported in 1928,² but its regular use in humans was not established until 1955 when a short-term infusion was used to treat severe hypertension.³ Approval for clinical use in the United States occurred in 1974 after a lyophilized preparation became available. In 1991 the Food and Drug Administration (FDA) approved new labeling for SNP to highlight the risk for cyanide toxicity associated with prolonged infusion at rates that exceed 2 µg/kg/min.¹

Structure

Each SNP molecule is composed of an iron center that is complexed with five cyanide molecules and one nitrosyl group. Cyanide comprises about 44% of the molecular weight of the compound. After infusion, the compound undergoes degradation and the cyanide molecules and the nitric oxide are released. Nitric oxide acts as an endothelium-relaxing factor that results in the desired vasodilatory effects of SNP (Fig. 61-1).⁴

SNP is soluble in water but is unstable when exposed to sunlight. Photodegradation may result in release of up to 40% of the cyanide into solution and reduced efficacy of the vasodilatory effect. Exposure to laboratory fluorescent light does not result in the same degree of photodegradation.⁵ Even after mild to moderate photodegradation, SNP remains biologically active and is able to reduce blood pressure.⁶ Nitroprusside solutions that are protected from the sunlight are quite stable. Prevention of this photochemical reaction involves covering the infusion bag with aluminum foil or other opaque material to minimize the exposure to ultraviolet light.

Pharmacokinetics and Pathophysiology

Nitroprusside is a nonselective vasodilator of both arteriolar and capacitance vasculature. Regional distribution of blood flow is not affected, and there is preservation of flow to all organs as long as hypotension is avoided. Renal blood flow is maintained, and pulmonary vasoconstriction due to hypoxia is reduced.⁴

After infusion of SNP solution, spontaneous dissociation of the compound occurs. The breakdown of the molecule is triggered by contact between nitroprusside and sulfhydryl groups that are found along vessel walls.⁷ Nitric oxide is released and is the active mediator of vasodilatory effects. Nitric oxide activates soluble guanylate cyclase resulting in increased intracellular concentrations of cyclic guanosine monophosphate (cGMP). Increased cGMP induces protein phosphorylation that reduces calcium influx into the cell. With less calcium movement, the smooth muscles are less likely to contract, resulting in relaxation. Vasodilation occurs with the reduced tone of the smooth muscles of blood vessels.⁸

Along with the release of nitric oxide, cyanide molecules are liberated into tissues or serum and can later be absorbed into erythrocytes.⁶ Cyanogenesis most likely occurs in the extracellular space⁹ rather than in the erythrocytes as previously thought.^{10,11} Cyanide is cleared via transsulfuration within the liver. The primary sulfur donor is thiosulfate, which is the rate-limiting step. Healthy adults usually have adequate thiosulfate to clear the cyanide released from about 50 mg of SNP.¹² Poor nutrition, recent surgery, and diuretic medications are considered risk factors for reduced thiosulfate stores.

FIGURE 61-1 Nitroprusside.

Children, and especially neonates, can have lower thiosulfate stores and may be more susceptible to elevated levels of cyanide.¹²

Cyanide acts as a nucleophilic acceptor for the transfer of sulfur from thiosulfate. Once thiocyanate is formed, the reaction is irreversible. The mechanism by which thiocyanate is formed is not entirely clear. Kinetic studies would suggest that cyanide detoxification occurs in a volume of distribution that is similar to the blood volume. A commonly accepted enzyme in the detoxification of cyanide is rhodanese; however, rhodanese may be restricted to the mitochondria in various tissues, including liver, kidney, and skeletal muscle. Thiosulfate may not be able to penetrate into the inner mitochondrial membrane. One theory suggests that sulfurtransferases including rhodanese may actually form sulfane sulfur that complexes with albumin. The sulfane-sulfur albumin complex reacts with cyanide to form thiosulfate.¹³ In contrast to this theory, an experiment in bloodless rats demonstrated that available thiosulfate reduces cyanide in the absence of blood proteins.¹⁴

Because thiocyanate is produced from thiosulfate, there is no further degradation of the thiocyanate. It is eliminated from the body primarily through renal excretion. The half-life of thiocyanate in an adult with normal renal function is about 2.7 days. The half-life in patients with renal insufficiency may be prolonged to 9 days.⁷ The elimination constants for thiocyanate were inversely proportional to the renal creatinine clearances when measured in patients with renal failure.¹⁵

In the first few minutes after infusion, SNP is found primarily in the serum compartment with minimal amounts in blood cells. The volume of distribution is the same as the extracellular space. The nonenzymatic breakdown of SNP occurs in minutes with the release of cyanide molecules and nitric oxide.⁷ The rapid breakdown of SNP correlates with the short half-life and clinical effect. Onset of action is within 30 seconds of the infusion, with peak hypotensive effects within 2 minutes. The effect on blood pressure dissipates within 3 minutes after discontinuation of the infusion.

Toxicology

The amount of SNP that results in cyanide toxicity is variable, depending on the rate infused, amount infused, and thiocyanate stores of the individual. Cyanide clearance is a first order process when adequate thiosulfate is available; however, since thiocyanate stores are limited, the kinetics of detoxification are saturable. There is also interindividual variation in the ability to transulfurate the cyanide molecule into thiocyanate.¹⁶ In the average adult patient, erythrocyte cyanide levels rise rapidly when the infusion of SNP exceeds 1 to 2 $\mu\text{g}/\text{kg}/\text{min}$.

Red blood cell cyanide levels from SNP tend to be higher than symptom equivalent levels from direct cyanide poisoning. There is a higher erythrocyte-plasma cyanide ratio during SNP-induced cyanogenesis.^{17,18} Those individuals with less reserves or low thiosulfate stores will accumulate the cyanide more quickly and may manifest signs and symptoms at lower doses.

As cyanide accumulates during an SNP infusion, it distributes into tissues and plasma and will concentrate in erythrocytes. Cyanide binds and inhibits a number of enzymes in the body. The metalloenzyme most sensitive to the binding of cyanide is probably cytochrome aa_3 , the last enzyme in the cytochrome system of oxidative phosphorylation. Cyanide has an affinity for the ferric iron that composes cytochrome aa_3 . As a result of cyanide binding, electron transport via the cytochromes is halted, causing cessation of oxidative phosphorylation. Adenosine triphosphate (ATP) can no longer be produced by this route. Electrons are not able to associate with oxygen as the final electron acceptor, so oxygen consumption diminishes as well. As cells shift to anaerobic metabolism, accumulation of lactate occurs, and a lactate-dependent acidosis develops.¹⁹

Cyanide inhibits other enzymes, including xanthine oxidase, succinate dehydrogenase, and Schiff base intermediates. The central nervous system (CNS) appears to be the most sensitive organ to the cytotoxicity of cyanide.¹⁹ Cyanide also inhibits glutamate decarboxylase, resulting in reduced production of γ -aminobutyric acid. This may cause an increased risk for convulsions.²⁰

Thiocyanate toxicity rarely occurs during SNP infusion in the setting of normal renal function since it is cleared primarily through renal elimination. When thiocyanate was used as an antihypertensive in the early 1900s, cases of toxicity were described. Older literature reports mild toxicity characterized by abdominal pain, vomiting, tinnitus, weakness, and agitation. These early symptoms may progress to more profound CNS effects, including encephalopathy, delusions, lethargy, coma, and, rarely, death.²¹⁻²³ The pathophysiology of CNS effects is not delineated.

Thiocyanate does not affect the function of metalloenzymes such as cytochrome oxidases. Oxygen utilization is also not affected. As a result, thiocyanate toxicity does not result in a metabolic acidosis. When thiocyanate was used as an oral antihypertensive, cases of hypothyroidism were reported. The mechanism proposed for this observation was that thiocyanate interfered with thyroidal uptake of iodine.

Diagnosis

In the setting of SNP infusions, close monitoring of patients for clinical evidence of cyanide toxicity must occur. The organ systems usually first affected are the ones most sensitive to histotoxic anoxia: the central nervous and cardiovascular systems.

Early cyanide-induced CNS effects include agitation and restlessness. As cyanide poisoning progresses, encephalopathy may develop and may be misinterpreted as worsening hypertensive encephalopathy. This can progress to coma, and convulsions may occur. Cerebral death may occur simultaneously with terminal cardiovascular effects.

The initial cardiovascular effects are tachycardia and worsening hypertension. Tachyphylaxis to SNP develops and may not be recognized initially as a manifestation of cyanide toxicity. Late findings include hypotension,

shock, and bradycardias. Tachypnea may be seen early in the poisoning and can be followed by apnea.

Since cyanide reduces oxygen utilization by the tissues, the mixed venous oxygen content will rise with a decline in the arteriovenous oxygen difference provided cardiac output has not diminished. Elevated venous oxygen concentrations may result in reddish skin coloration; however, cyanosis has also been reported in the setting of cyanide poisonings due to low cardiac output and intrapulmonary shunting.²⁴

Due to disruption of oxidative phosphorylation and inability to produce ATP, an anion-gap metabolic acidosis ensues. A worsening metabolic acidosis is a sensitive marker for the presence of cyanide poisoning, although it is not specific for cyanide. Absence of a metabolic acidosis would infer that despite the body burden of cyanide from SNP, the cyanide is being effectively detoxified and is exerting minimal effects on the capacity of oxidative phosphorylation to manufacture ATP.

Blood cyanide levels are usually not available in an expedient manner to assist in the diagnosis of cyanide poisoning. Plasma cyanide concentrations are a better reflection of tissue cyanide levels because cyanide in the plasma is in equilibrium with tissue levels²⁵; however, erythrocyte cyanide levels are more commonly measured. In the setting of SNP infusion, cyanide accumulates in erythrocytes, so the red blood cell to plasma cyanide concentrations will be higher than after acute poisoning from inorganic cyanide.^{18,26}

Thiocyanate levels do not correlate with the degree of cyanide poisoning.²⁷ Likewise, an elevated thiocyanate level does not infer that the patient has high levels of cyanide. Thiocyanate levels correlate only with thiocyanate toxicity. Toxicity does not occur until thiocyanate levels have exceeded 100 mg/L. Thiocyanate levels will increase when thiosulfate is concurrently infused with the SNP.²⁸

Management

If cyanide toxicity is suspected in a patient receiving an SNP infusion, the infusion must be discontinued while the patient is administered maximal oxygen therapy. Patients with evidence of severe poisoning may require induction of methemoglobinemia with intravenous infusion of sodium nitrite. The dose may need to be adjusted to accommodate a patient with anemia. Sodium thiosulfate should be administered to provide substrate for the production of thiocyanate. In those patients who may not tolerate a reduction in oxygen carrying capacity from methemoglobinemia, sodium thiosulfate should be administered alone. In an animal model, simultaneous infusion of thiosulfate during SNP infusion provided protection against cyanide toxicity.²⁹ Recommendations have included the mixing of thiosulfate into the SNP solution at a 10 to 1 ratio. This would require 1 g of thiosulfate for each 100 mg of SNP.²⁵ The coadministration of thiosulfate with SNP reduces the rise in cyanide concentrations in circulation.^{7,17}

Hydroxycobalamin is another treatment for cyanide poisoning since it binds to cyanide to form cyanocobal-

amin, a nontoxic compound. Hydroxycobalamin has been used to prevent accumulation of cyanide after SNP administration. Concurrent infusion of hydroxycobalamin resulted in lower erythrocyte and plasma cyanide levels in patients receiving SNP compared with controls who received a similar rate of nitroprusside infusion.³⁰ One animal model compared infusion of thiosulfate to infusion of hydroxycobalamin during administration of SNP and measured the red blood cell and plasma cyanide levels. Thiosulfate appeared to be more effective in lowering cyanide levels; however, the amount of hydroxycobalamin that could be infused was a limiting factor, so smaller doses were used.³¹ Side effects from the use of hydroxycobalamin may include a transient reddish discoloration of the skin and mucous membranes. Anaphylaxis has rarely been reported. The use of hydroxycobalamin may be limited by availability and cost of the product.³²

Thiocyanate toxicity due to accumulation of thiocyanate from renal failure may be easily removed with hemodialysis. Rapid decline in levels correlates with improvement in the CNS effects.³³

NITRATES

As a class, organic nitrates are commonly used for treatment of ischemic heart disease. Their effect of dilating coronary arteries and improving coronary blood flow in addition to reducing myocardial oxygen demand led to their use as a cornerstone of therapy in patients with ischemic heart disease.

Nitroglycerin was first synthesized in 1846 by Sobrero and was developed 1 year later into a formulation for sublingual administration. In the 1850s, amyl nitrite was found to relieve angina when given inhalationally; however, its clinical effects had a short duration.³⁴ In the 1870s, Murrell described the successful use of 1% nitroglycerin solutions in three patients who had symptoms consistent with angina pectoris. The patients would administer the solution orally via drops on a scheduled basis and if the symptoms occurred. Murrell also described the side effect of a severe headache that was associated with the administration of nitroglycerin, both from his patient's experiences and his own self-administration.³⁵ Subsequent use of nitrates became widespread as a treatment modality for angina pectoris.

Pharmacokinetics and Pharmacology

Nitroglycerin is a polyol ester of nitric acid and is known as glyceryl trinitrate. Organic nitrates of low molecular weight such as nitroglycerin tend to be volatile oily liquids. Organic nitrates such as isosorbide dinitrate are high-molecular-weight esters and are found in solid form.

Organic nitrates are biotransformed in the liver via reductive hydrolysis. The reduction of nitrates results in the formation of water-soluble metabolites that have less vasodilatory activity than the parent compound. Nitro-

glycerin given sublingually reaches peak concentrations within 4 minutes after administration. The half-life of the parent compound is about 1 to 3 minutes. The dinitrate metabolites have a half-life of 40 minutes and have 10 times less potency as vasodilators.³⁴ Isosorbide dinitrate also undergoes denitration after reacting with glutathione. The parent compound has a half-life of about 45 minutes but the metabolites have half-lives of 3 to 6 hours. Isosorbide-5-mononitrate has a longer half-life than the dinitrate formulation and has increased bioavailability since it does not undergo first pass metabolism.³⁴

Organic nitrates release nitric oxide via denitration when exposed to vascular smooth muscle. The release of nitric oxide stimulates soluble guanylate cyclase, causing increased cGMP. Increased cGMP activates cGMP-dependent protein kinase, culminating in dephosphorylation of the myosin light chain and subsequent vascular smooth muscle relaxation vasodilation.³⁶

The mechanism for release of nitric oxide is not well elucidated. Nitroglycerin requires a three-electron reduction to release nitric oxide from its third carbon. This release occurs when nitroglycerin is exposed to mammalian vascular smooth muscle. Initial theories suggested that cellular thiols were needed to accomplish this biotransformation. Nonenzymatic release of nitric oxide may occur in the presence of large concentrations of thiol-containing compounds such as cysteine; however, the most abundant source of thiols, glutathione, does not release nitric oxide from nitroglycerin via this nonenzymatic process. Additional evidence in an experiment with bovine coronary smooth muscle cells suggests that nitroglycerin releases nitric oxide via an enzymatic process that is attached to cellular surface membrane. Glutathione may be required for this reaction as a cofactor, rather than a substrate.^{37,38}

Nitroglycerin is also processed via enzymatic pathways that utilize glutathione *S*-transferases. Instead of releasing nitric oxide, this reaction releases inorganic nitrite (NO₂⁻).³⁸ The inorganic nitrite is not vasoactive unless at very high concentrations; however, it may oxidize ferrous iron in hemoglobin to ferric iron, resulting in methemoglobinemia.

Tolerance to the antianginal effects may occur with continued use of organic nitrates. It is not a uniform phenomenon, since some individuals may develop only partial tolerance. The mechanisms of tolerance are not well understood and may be multifactorial. Tolerance may involve the reduced efficiency of the vascular wall to biotransform nitrates to nitric oxide. In addition, there has been a link between nitroglycerin tolerance and superoxide production from the endothelium. The superoxide may react with the nitric oxide to produce peroxynitrite. Peroxynitrite has a shorter half-life than nitric oxide and is less effective in activating guanylate cyclase.³⁹ Removal of endothelium of the aorta in animal models markedly reduces the development of tolerance to nitroglycerin. The role of endothelium in promoting tolerance has been confirmed in another animal model and was associated with the activation of nitric oxide synthase and protein kinase C as well as the production of superoxide and peroxynitrite free radicals.⁴⁰

Toxicology

Since organic nitrates affect all smooth muscle beds, their effects extend beyond the coronary arteries. Low concentrations of nitroglycerin may result in venodilation that precedes the arteriodilation. Higher doses result in venous pooling and may reduce arteriolar resistance. A resulting decrease in systolic and diastolic blood pressure may result in dizziness, weakness, and postural hypotension. Syncope has even been described from the transgingival absorption of nitroglycerin paste that was inadvertently used as toothpaste.⁴¹ Dilation of meningeal vessels is thought to result in the commonly reported side effect of headache.

Although rare, induction of methemoglobin has been reported in the setting of organic nitrate use. Nitrite is formed from the breakdown of the nitroglycerin and acts as the oxidizer of ferrous iron to the ferric state. One case of methemoglobinemia was reported after an oral overdose of nitroglycerin tablets, although the methemoglobin level was only 7% with a hemoglobin of 14 g/dL.⁴² Intravenous nitroglycerin has been reported to result in methemoglobinemia, but the dose required is not clear. Higher infusions of nitroglycerin may be more likely to produce higher levels of methemoglobin than lower infusion rates.⁴³

Cerebral vessel vasodilation from nitroglycerin infusion has been associated with a rise in intracranial pressure. Intracranial hypertension from therapeutic doses of nitroglycerin has been associated with oculomotor palsies, headache, vomiting, and coma. Reversal of these abnormalities occurred upon discontinuation of the nitroglycerin.^{44,45}

Most preparations of nitroglycerin include propylene glycol as a diluent. Toxicity may occur in patients who accumulate propylene glycol. Since a large portion of propylene glycol is excreted by the kidneys, patients with renal insufficiency may be at greater risk for diminished clearance. Manifestations of toxicity may include hyperosmolality from the propylene glycol and a metabolic acidosis from its metabolism to lactate. Coma, stupor, and dysconjugate eye movements may occur. Hemolysis with subsequent hemoglobinuria has also been reported.⁴⁶

Another potential interaction with nitroglycerin infusion is an interference with the efficacy of heparin infusion. Col and colleagues noticed a resistance to anticoagulation with heparin when nitroglycerin was concomitantly infused, and they performed *in vitro* and *in vivo* studies that supported their observation. These investigators found that the propylene glycol diluent alone could reduce the activated partial thromboplastin time (aPTT) prolongation induced by heparin. Infusion of nitroglycerin prepared with propylene glycol reduced the aPTT even more dramatically than just the propylene glycol.⁴⁷ Another study suggested that patients on nitroglycerin infusions require more heparin to maintain their anticoagulation. In addition, two patients in this study were administered nitroglycerin infusion prepared without propylene glycol. Heparin resistance still occurred comparably with those patients who received the standard nitroglycerin preparation with propylene

glycol.⁴⁸ In another study in patients with acute coronary syndromes, only nitroglycerin infusions that exceeded 350 $\mu\text{g}/\text{min}$ had an effect on the aPTT and heparin requirements.⁴⁹ The mechanism of this potential drug interaction is not clear.

Drug interactions with medications that inhibit the cGMP phosphodiesterase-5 enzyme such as sildenafil may occur. In the presence of these inhibitors, nitrates cause a profound increase in cGMP. As a result, increased vasodilatory effects and hypotension results. Nitrates should be used with great caution in patients who have used sildenafil or one of its analogs in the previous 24 hours.⁵⁰

Diagnosis

The diagnosis of nitroglycerin-induced hypotension requires the association of abnormal vital signs with a recent exposure. Medications that are orally administered may have longer half-lives as opposed to the intravenous formulations of organic nitrates.

The diagnosis of methemoglobinemia is suggested by the presence of cyanosis and reduced pulse oximetry in the setting of a relatively normal partial pressure of oxygen on arterial blood gas. Methemoglobin levels are measured using co-oximeter readings on heparinized blood samples. Levels that exceed 1.5 g/dL may induce cyanosis; however, levels below this threshold may still impact the oxygen-carrying capacity of critically ill patients, particularly if they are anemic.

During a rapid nitroglycerin infusion, the presence of a persistent metabolic acidosis that may also be associated with hyperosmolality would suggest propylene glycol toxicity. A patient with significant renal insufficiency may be at high risk for propylene glycol toxicity due to diminished renal elimination. Many other medications that utilize propylene glycol, such as lorazepam, phenytoin, diazepam, and intravenous formulations of sulfamethoxazole and trimethoprim, may be associated with formation of a lactate-dependent acidosis.⁵¹

Management

Cardiovascular effects and side effects from organic nitrates will resolve with discontinuation of the infusion. Hypotension may require fluid boluses of crystalloid or additional inotropic support given the clinical scenario.

Methemoglobinemia that is symptomatic may be treated with the infusion of a 1% methylene blue solution. The infusion rate is usually a 1- to 2-mg/kg bolus with a repeat dose if no response occurs in 30 minutes. If the patient has underlying glucose 6-phosphate dehydrogenase deficiency, then the administration of methylene blue will not be efficacious and could potentially be deleterious. These patients may benefit from a transfusion of packed red blood cells to provide additional oxygen-carrying capacity.

If a patient develops a severe metabolic acidosis from the accumulation of propylene glycol, hemodialysis will effectively remove the diluent. Reduction in the

half-life of propylene glycol has been reported with hemodialysis.⁴⁶

HYDRALAZINE

Hydralazine was introduced to the United States in the 1950s as an oral antihypertensive medication and has subsequently been approved for intramuscular and intravenous administration. Although labeled a class C medication during pregnancy, it is commonly used to treat hypertensive crisis in late gestation. Hydralazine is seldom the primary treatment for chronic hypertension because of tachyphylaxis and sympathetic discharge effects.

Despite its use as an oral treatment agent for hypertension, reports of acute severe poisoning with hydralazine are rare. The American Association of Poison Control Centers (AAPCC) reported 212 exposures to the Toxic Exposure Surveillance System (TESS) in 2002. No deaths were reported of the 103 hydralazine exposures subsequently treated in a health care facility.⁵²

Structure

1-Hydrazinophthalazine, or hydralazine (Apresoline, [Ciba Pharmaceuticals Summit, NJ]), has a hydrazine moiety in the 1-position of the hydrazine ring that is believed to produce the vasodilatory effects of the drug.⁵³ The structure of hydralazine is shown in Figure 61-2.

Pharmacology and Pharmacokinetics

Hydralazine directly relaxes arteriolar smooth muscle through its effects on cGMP. Venous smooth muscle is not affected. Hydralazine-induced vasodilation frequently stimulates an increase in heart rate and myocardial contractility. This sympathetic surge is primarily a baroreceptor-mediated reflex, but hydralazine may directly stimulate the release of norepinephrine from sympathetic neurons.⁵⁴

Absorption of hydralazine from the gastrointestinal tract is rapid, with peak plasma levels occurring between 30 and 120 minutes. The volume of distribution (Vd) is 1.6 L/kg with approximately 90% protein binding. Hydralazine is primarily metabolized by *N*-acetylation in the liver. With therapeutic dosing, the half-life is approximately 1 hour, although the duration of clinical effects usually lasts longer. The rate of elimination is dependent on genetically established *N*-acetyl-transferase activity. Approximately 50% of patients in the United States are fast acetylators. Fast acetylators produce an inactive metabolite more rapidly; therefore, slow

Hydralazine

FIGURE 61-2 Hydralazine.

acetylators may have a greater or longer antihypertensive effect. Slow acetylators are also more likely to develop a hydralazine-induced lupus erythematosus–like syndrome and antinuclear antibodies.

Toxicology

Common side effects related to therapeutic use of hydralazine include tachycardia, hypotension, palpitations, headache, flushing, nausea, and dizziness. Many of these side effects may be minimized by administering a β -adrenergic receptor blocker and diuretic in conjunction with hydralazine. Chest pain and myocardial injury may occur with hydralazine administration, especially in patients with significant coronary artery disease or angina. Electrocardiogram (ECG) abnormalities, including reversible ST-segment depression, have been reported in a young female intentionally overdosing on hydralazine.⁵⁵ Caution should be used when considering hydralazine use in elderly patients and those with coronary artery disease. A coronary artery blood flow steal phenomenon, increased myocardial oxygen demand from greater sympathetic output, and lack of epicardial coronary artery vasodilation may precipitate myocardial ischemia.

The second type of hydralazine-related side effects appears to be immunologically mediated through production of autoantibodies. The exact mechanism of this reaction is uncertain. Most commonly described is a drug-induced lupus-like syndrome manifesting as fever, myalgias, arthralgias, and rash. This reaction usually resolves after discontinuation of the medication but may require corticosteroids for refractory symptoms. Less commonly reported are pleuritis, pericarditis, vasculitis, hemolytic anemia, and nephritis. Patients can also rarely develop a pyridoxine-responsive polyneuropathy from hydrazone formation when hydralazine binds to pyridoxine.⁵⁶

Diagnosis and Management

Treatment of hydralazine poisoning is primarily supportive. Because no antidote exists, care should be directed toward improving hemodynamic status. Intravenous fluids are the initial management for hypotension. Additional vasopressor support with direct-acting α -adrenergic receptor agonists such as norepinephrine and phenylephrine should be considered for refractory hypotension. Administration of inotropic agents should be cautiously titrated because hydralazine-induced sympathetic discharge may already contribute to tachycardia. For recent oral ingestions where the airway is stable, consideration may be given to the administration of a single dose of activated charcoal. No additional gastrointestinal decontamination is indicated. Due to the rarity of overdose and lack of significant morbidity, few data exist regarding the benefit of enhanced elimination. Presently, there is no indication for hemodialysis or other methods of enhanced elimination in the management of hydralazine toxicity.

Cardiac telemetry for symptomatic patients is warranted until supportive care measures are no longer required,

and clinical recovery has occurred. ECG and complete cardiac evaluation for myocardial injury may be necessary in the setting of chest pain from hypotension-induced cardiac ischemia in certain patient populations.

MINOXIDIL

The hypotensive effects of minoxidil were discovered in 1965, and the oral tablet formulation became available as Loniten (Pharmacia and Upjohn, Peapack, NJ) in October 1979.⁵⁷ It is primarily used to treat hypertension refractory to multiple other regimens. In 1988, a 2% Rogaine (Pharmacia and Upjohn, Peapack, NJ) formulation (topical minoxidil preparation) became available by prescription to enhance hair growth in male-pattern baldness. Hypertrichosis with minoxidil therapy was first described in 1980.⁵⁸ In November 1997, the FDA approved the over-the-counter (OTC) sale of 5% Rogaine Extra Strength for Men. This topical formulation contains minoxidil 50 mg/mL in excipients of 30% ethanol vol/vol, 50% propylene glycol vol/vol, and purified water.⁵⁷ Minoxidil overdose is uncommon today, and this is likely a reflection of its diminished use in the treatment of hypertension. However, the topical minoxidil preparations are frequently purchased OTC and provide an easy source of exposure for pediatric and intentional ingestions.^{57,59,60}

Structure

6-Amino-1,2-dihydro-1-hydroxy-2-imino-4-piperidinopyrimidine, or minoxidil, must be metabolized to minoxidil N-O sulfate by hepatic sulfotransferase to manifest vasodilatory properties.⁶¹ The parent compound is not active, and the active metabolite produced from sulfate conjugation may explain the prolonged effects of the drug. The structure of minoxidil is shown in Figure 61-3.

Pharmacology and Pharmacokinetics

Minoxidil is rapidly and completely absorbed from the gastrointestinal tract, with peak plasma concentrations within 1 hour postingestion. The Vd is 2.8 to 3.3 L/kg, minimal plasma protein binding occurs, and the drug does not cross the blood-brain barrier. The large Vd is hypothesized to reflect an accumulation of the active drug in the vascular smooth muscle.⁶² While the half-life of minoxidil is 3 to 4 hours, the duration of action is

Minoxidil

FIGURE 61-3 Minoxidil.

typically 24 hours and may extend to 3 days. The pharmacokinetics of minoxidil N-O sulfate are less clear but may explain the longer duration of action.

The primary route of elimination is hepatic glucuronide conjugation at the N-oxide position in the pyrimidine ring. The production of the active metabolite, minoxidil N-O sulfate, is a minor pathway. Twenty percent of the drug is excreted unchanged in the urine. Although minoxidil and its glucuronidation products are hemodialyzable, this does not reverse clinical effects from tissue sequestration of the active metabolite in the vascular smooth muscle.

Minoxidil sulfate activates ATP-sensitive potassium channels, enhancing channel opening and subsequent potassium efflux. This causes hyperpolarization and subsequent vascular smooth muscle relaxation.⁶³ While arteriolar vasodilation causes decreased peripheral vascular resistance and blood pressure, there is little effect on capacitance vessels. Hypertrichosis is also probably a consequence of potassium channel augmentation.

A baroreceptor-mediated sympathetic response can sometimes occur even with therapeutic dosing of minoxidil.⁶⁴ Sympathomimetic medications should be avoided due to excess cardiac stimulation with reflex tachycardia and baroreceptor activation from minoxidil therapy. Although renin and aldosterone secretion are increased during minoxidil therapy, it is thought that fluid retention occurs primarily from increased proximal renal tubular reabsorption secondary to reduced renal perfusion. Some side effects of minoxidil therapy, specifically fluid retention and reflex tachycardia, can be minimized by administering a diuretic and β -receptor antagonist in conjunction.

Toxicology

Typical adult therapeutic dosing is 10 to 40 mg orally once a day up to a maximum of 100 mg per day. Pediatric dosing is 0.25 to 1.0 mg/kg to a maximum of 50 mg per day. The manufacturer package insert states it is difficult to establish an exact minoxidil serum toxic level due to patient variation, but levels above 2000 ng/mL are likely representative of an overdose.⁶⁵ An average adult consumption of 30 mg orally would produce a serum minoxidil level of 40 ng/mL 3 hours postingestion⁵⁹; however, a 2-year-old was reported to consume 100 mg of minoxidil and developed significant tachycardia with a 3-hour postingestion serum minoxidil level of 150 ng/mL.⁶⁶

The highest reported serum minoxidil concentration was 3140 ng/mL in a 20-year-old woman who developed tachycardia, labile hypotension, ST-segment depression, and T-wave inversion after an unknown quantity of minoxidil was ingested in a suicide attempt. She was stabilized with intravenous fluids and supportive care and eventually discharged from the hospital.⁶⁷

Common pharmacologic side effects related to therapeutic administration of minoxidil include tachycardia, hypotension, and hypertrichosis. Because heart rate, myocardial contractility, and myocardial oxygen consumption are increased, chest pain and myocardial injury may develop in patients with significant coronary

artery disease or angina. Worsening left ventricular systolic and diastolic dysfunction can develop in patients with congestive heart failure and pulmonary hypertension. While ECG abnormalities such as flattened and inverted T waves are commonly reported in therapeutic dosing or overdose of minoxidil from potassium channel activation,⁶⁷ myocardial infarction has also been reported.⁶⁰

In addition to sodium and fluid retention, pericardial effusions and pericarditis have been reported with minoxidil use, primarily in hemodialysis patients.⁶⁸ Other rarely described complications include rashes, thrombocytopenia, nausea, headache, gynecomastia, polymenorrhea, and breast tenderness. Increased hair growth occurs on the scalp, face, back, arms, and legs. There are no reports of hypertrichosis occurring from a single ingestion or overdose.

Diagnosis and Management

Cardiac and hemodynamic monitoring is warranted in the symptomatic patient. Additional cardiac evaluation and serial ECGs may be indicated if chest pain or other symptoms of cardiac ischemia develop. A serum radioimmunoassay is available through the manufacturer, but serum concentrations generally do not correlate with therapeutic response and are often delayed and unlikely to assist in management.

Treatment of minoxidil poisoning is primarily supportive. No antidote exists, and a single dose of activated charcoal is only indicated in recent ingestions when airway reflexes are intact. Intravenous fluids are the initial management for hypotension. Additional vasopressor support with norepinephrine and phenylephrine should be considered for refractory hypotension. Cautious administration of inotropic support is necessary to avoid excessive tachycardia and cardiac stimulation. Although intravenous fluids should be used judiciously in the setting of hypotension, congestive heart failure in patients with reduced left ventricular function can develop. Enhanced elimination is not indicated.

Cardiac telemetry and hemodynamic monitoring is necessary in these cases until clinical recovery has occurred. Serial ECGs and evaluation of cardiac markers for myocardial injury may be necessary in the setting of hypotension-induced cardiac ischemia, especially in the elderly or patients with coronary artery disease ingesting minoxidil. T wave changes from minoxidil-induced potassium channel activation usually resolve once the metabolites are eliminated.

SILDENAFIL

Sildenafil (Viagra [Pfizer, New York, NY]) is the first oral drug approved by the FDA, in March 1998, for the treatment of male erectile dysfunction.⁶⁹ This condition affects more than 30 million men in the United States alone. While the development of this agent has significantly improved the lifestyle of many patients, concerns for medication interaction and drug abuse have arisen. Over 6 million outpatient prescriptions were

including blurred vision, light perception abnormalities, and color perception distortions can also develop with therapeutic dosing. Higher doses of sildenafil can increase the frequency of visual disturbances, but these symptoms are usually transient, lasting less than a few hours. Although rarely reported, myocardial infarction has occurred in close temporal proximity to sildenafil usage,⁷⁶ although this is likely a result of a transient decrease in blood pressure culminating in decreased coronary blood flow. These effects can be more significant in the setting of concomitant nitrate use. While a decrease in systemic vascular resistance may develop, sildenafil use is not thought to directly cause tachycardia.⁶⁹ Effective treatment of erectile dysfunction might intuitively increase the risk for priapism, but no cases of priapism were reported in the initial clinical trials.⁶⁹ More recently, a patient with sickle cell trait was reported to develop priapism while using sildenafil.⁷⁷ Another case of priapism, successfully treated with aspiration and intracorporal injection of α -receptor agonists, was described in a 28-year-old man taking a 100-mg dose of sildenafil-citrate for prior penile trauma-induced mild erectile dysfunction.⁷⁸

Diagnosis and Management

In the setting of isolated sildenafil overdose, supportive care including intravenous fluids, cardiac monitoring, and direct-acting α agonists for refractory hypotension are indicated. Obtaining serum concentration results via the manufacturer are not likely to assist in clinical management of overdose. Although few gastrointestinal decontamination data exist, a single dose of activated charcoal is appropriate in the setting of recent ingestion and adequate airway protection.

The American College of Cardiology and the American Heart Association have several management recommendations for sildenafil-induced hypotension due to nitrate interaction. Discontinuing nitrate use, Trendelenberg positioning, intravenous fluid resuscitation, direct-acting α -agonist vasopressors, and intra-aortic balloon pump have all been advocated depending on the severity of hypotension.⁵⁰ In the setting of acute coronary syndrome in a patient using sildenafil, recommendations include avoiding nitrates if sildenafil has been used in the past 24 hours. Administering other non-nitrate antianginal agents like β -receptor antagonists is more appropriate under those circumstances. Otherwise, standard therapy for acute coronary syndrome is indicated.

ACE INHIBITORS

With the introduction of captopril in 1981, angiotensin-converting enzyme (ACE) inhibitors have gained widespread popularity due to their proven effectiveness in the treatment of hypertension and congestive heart failure.⁷⁹ Those populations that appear to derive benefit are diabetics and patients with recent myocardial infarctions.^{80,81} With increasing use and various clinical indications, the

potential for increased frequency of both intentional and unintentional poisonings exists. Despite their widespread use, however, the number of reported cases of toxicity related to overdose with ACE inhibitors remains relatively small. As a class, the ACE inhibitors have proven to be relatively safe with a high therapeutic index and infrequently reported poor outcomes secondary to overdose.

Pharmacology and Pharmacokinetics

There are currently 11 available ACE inhibitors approved for use by the FDA, including captopril, benazepril, enalapril, enalaprilat, fosinopril, lisinopril, moexipril, perinodpril, quinapril, ramipril, andtrandolapril. While all contain a similar 2-methyl propanolol-L-proline moiety, the pharmacokinetic profiles differ considerably based on variations in this common core structure (Fig. 61-5).⁸²

ACE inhibitors are generally well absorbed, reaching peak serum concentrations in the first 1 to 4 hours. The level of protein binding is low (25% to 60%), with the exception of benazepril (98%).⁸³ Drug half-lives of these agents range from 2 to 12 hours. With the exception of lisinopril and captopril, ACE inhibitors are administered as prodrugs with good bioavailability. In the liver, each of the prodrugs are converted to active metabolites following the cleavage of an ester moiety. These active metabolites may demonstrate effects for several days due to slow dissociation from the ACE. With the exception of fosinopril, which is eliminated both renally and hepatically, ACE inhibitors are cleared predominantly via the kidneys. Dosage adjustments should be considered in those with impaired renal function.⁸³

The effectiveness of ACE inhibitors lies in their ability to directly bind to the active site of the ACE and inhibit the production of angiotensin II (see Fig. 61-6). In the lung and vascular endothelium, ACE is responsible for converting inactive angiotensin I to the highly active compound angiotensin II. Angiotensin II is a potent vasoconstrictor having direct effects on vascular smooth muscle. In addition, angiotensin II stimulates aldosterone release that acts at the distal and collecting tubules of the kidney by increasing sodium retention while excreting potassium and hydrogen ions. By inhibiting the production of angiotensin II, ACE inhibitors are able to decrease peripheral vascular resistance, lower sodium and water retention, and decrease blood pressure.

Other effects of ACE inhibitors include inhibiting bradykinin inactivation. Kininase II is responsible for the inactivation of bradykinin and is identical in structure to ACE. By inhibiting kininase II, ACE inhibitors allow bradykinin to accumulate, leading to a further decrease

FIGURE 61-5 Captopril.

in blood pressure through direct vasodilation and stimulation of prostaglandin biosynthesis.⁸⁴ This accumulation of bradykinin also contributes to side effects of cough and angioedema commonly described with therapeutic ACE inhibitor usage.⁸⁵ The renin-angiotensin system plays a vital role in regulating perfusion to the kidney in states of reduced renal flow. In the setting of bilateral renal artery stenosis, the ability of angiotensin II to maintain adequate post-glomerular efferent arteriolar tone by way of its vasoconstrictive properties ensures adequate glomerular perfusion. By inhibiting the production of angiotensin II, ACE inhibitors are capable of decreasing glomerular perfusion leading to prerenal azotemia. While bilateral renal artery stenosis may primarily cause a small percentage of hypertension, acute renal decompensation following the administration of an ACE inhibitor should raise suspicion for this particular etiology.⁸⁶

Toxicity

Hypotension is the most pronounced toxic effect of ACE inhibitor action. A “first dose phenomenon” similar to that described with α_1 -antagonists following initiation of treatment can result in lightheadedness, dizziness, and syncope. One study described a systolic blood pressure decrease of greater than 50 mm Hg in 10% of healthy volunteers after initiation of captopril therapy.⁸⁷ Hypotension can be most pronounced in therapeutic and excessive dosing in patients with fluid depletion, renovascular disease, and congestive heart failure. Tachycardia is rarely reported in ACE inhibitor toxicity, and more frequently a relative bradycardia develops.

Noncardiovascular effects in overdose include drowsiness, lethargy, and confusion. Renal and electrolyte abnormalities may occur as a result of renal insufficiency related to profound hypotension.⁸⁸ In addition, decreased production of aldosterone may cause worsening hyperkalemia and hyponatremia. Hyperkalemia is more commonly seen in individuals with prior renal impairment or those taking potassium supplements or potassium-sparing diuretics such as spironolactone.⁸⁹ The presence of oliguria and electrolyte abnormalities are generally short lived and improve with discontinuation of the inciting agent. Cases of ACE inhibitor overdose are frequently complicated by the presence of co-ingestants that may contribute to the clinical presentation.⁹⁰ Death as a result of isolated ingestion of ACE inhibitors is exceedingly rare.^{91,92} Interestingly, children seem to be particularly resistant to the effects of ACE inhibitors, remaining asymptomatic in most cases despite large accidental ingestions.⁹³

Angioedema is a frequently reported side effect of ACE inhibitor therapy with the potential for significant morbidity and mortality. The overall incidence is estimated to be approximately 0.1% to 0.2%. African Americans have a 4.5 times greater risk of ACE inhibitor-induced angioedema compared with those of European descent.^{94,95} Angioedema occurs as a result of increased perfusion in the capillary beds located in subcutaneous tissue and dermis with leakage of fluid into

the interstitium. With fluid accumulation comes swelling, most prominently in the periorbital, perioral, and oropharyngeal tissue, that can rapidly progress to airway obstruction. The mechanism behind angioedema in the setting of ACE inhibitor administration is thought to involve increased levels of bradykinin, substance P, and other inflammatory intermediates such as histamines, prostaglandin D, and leukotrienes.⁸⁵

The onset of angioedema resulting from ACE inhibitor therapy is classically described to occur in two thirds of patients within the first week of therapy, with the remaining one third developing this potentially life-threatening side effect weeks to years after initiation of the drug.⁹⁶ ACE inhibitors should not be prescribed to patients who have a history of hereditary or acquired angioedema.⁹⁷ Accumulation of bradykinin is felt to also be responsible for the persistent and often debilitating cough described in 5% to 10% of patients taking ACE inhibitors.

Management

Initial management of ACE inhibitor poisoning should focus on aggressive supportive care with cardiac monitoring and ensuring adequate urine output. Hypotension is often responsive to intravenous fluid administration alone. Vasopressors have been used with success in cases of refractory hypotension.⁹⁸ The presence of hyperkalemia should prompt urgent potassium-lowering intervention. Activated charcoal should be administered after recent ingestions in compliant and awake patients. Orogastric lavage, with its inherent risks, should not be routinely recommended due to the relatively low rates of morbidity and mortality associated with ACE inhibitors and the effectiveness of supportive care alone.

Reports of asymptomatic patients following large ingestions of ACE inhibitors are relatively common.^{89,99} A study by Spiller and colleagues evaluated 48 children with ingestions not greater than adult therapeutic dosages of captopril and enalapril and found no adverse outcomes with close home monitoring and telephone follow-up.¹⁰⁰ Maximum hemodynamic effects following ingestion should occur within the first 1 to 6 hours, depending on the particular ACE inhibitor ingested.¹⁰¹ Individuals manifesting hypotension at the time of evaluation should be monitored closely for at least 24 hours given the prolonged effects of many of these agents and their active metabolites.

Other treatment options that have found limited yet sometimes dramatic effects in reversing hypotension seen with ACE inhibitor overdose include naloxone and angiotensin II administration. Naloxone is felt to work through inhibition of the naturally occurring endorphins that can inhibit angiotensin II activity. Success has been demonstrated in both animal models and in limited case reports.^{102,103} Angiotensin II administration has been effective in treating refractory hypotension from ACE inhibitor poisoning, but its lack of availability makes this intervention an unlikely treatment option.¹⁰⁴ Particular ACE inhibitors such as captopril, enalapril, and lisinopril may be amenable to dialysis; however, it would be rarely

FIGURE 61-6 Sites of action of ACE inhibitors in the metabolism of angiotensin II and bradykinin and the site of action of the angiotensin II receptor antagonists.

necessary given the effectiveness of other treatment options and the lack of clinical symptoms in most cases.

Figure 61-6 shows the sites of action of ACE inhibitors in the metabolism of angiotensin II and bradykinin.

ANGIOTENSIN II RECEPTOR ANTAGONISTS

Currently, seven angiotensin II receptor antagonists are available in the United States: losartan, valsartan, irbesartan, telmisartan, olmesartan, candesartan, and eprosartan. This new class of antihypertensive agent was introduced in 1995 and has gained popularity due to its outstanding side effect profile and effectiveness in treating hypertension and heart failure.^{105,106} These drugs are rapidly absorbed in the gastrointestinal tract and reach peak serum levels in 1 to 4 hours. Protein binding is greater than 90%, while bioavailability is generally low (less than 50%). Many of these drugs have active metabolites with effects lasting longer than their parent drug half-life, ranging from 6 to 24 hours. As a class, the angiotensin receptor antagonists and their metabolites are eliminated predominantly through biliary and fecal excretion and to a lesser degree by the kidneys.

The angiotensin II receptor antagonists are similar to ACE inhibitors in their ability to reduce the effects of angiotensin II. Rather than decreasing the production of angiotensin II through inhibition of the ACE, angiotensin receptor blockers competitively antagonize angiotensin II at the type I angiotensin receptors. These receptors are located in the adrenal gland and peripheral vasculature. Inhibition results in a loss of the vasoconstrictive properties and aldosterone-promoting effects of angiotensin II. Type II angiotensin receptors are not affected by angiotensin II receptor antagonists. In contrast to stimulation of type I angiotensin receptors, stimulation of uninhibited type II angiotensin receptors by angiotensin II results in a vasodilatory response, further contributing to blood pressure reduction.¹⁰⁷

This high specificity that angiotensin II antagonists have for the renin-angiotensin system is felt to be responsible for their favorable side effect profile. Angiotensin receptor antagonists block the effects of angiotensin II; however, they do not interfere with the metabolism of bradykinin. Due to a lack of bradykinin accumulation, cough, a side effect frequently reported with ACE inhibitors, is less likely to occur.¹⁰⁸ Decreased accumulation of bradykinin would also be expected to decrease the incidence of angioedema; however, numerous cases of angioedema in the setting of angiotensin receptor antagonists have been reported.^{109,110} This challenges the previously held belief that bradykinin excess is responsible for angioedema. While the incidence of angioedema in patients taking angiotensin receptor antagonists is lower than that seen with ACE inhibitors, the use of these agents in patients with previous angioedema should be undertaken with caution. Patients with previous episodes of angioedema related to ACE inhibitors have had similar reactions when later given an angiotensin receptor antagonist.^{109,110}

In individuals with severe renal artery stenosis or diffuse intrarenal vascular sclerosis, angiotensin receptor antagonists should be avoided because they can cause deleterious effects to renal function similar to that seen with ACE inhibitors.¹¹¹ In addition, given their effect on aldosterone production, hyperkalemia can occur in individuals with normal renal function. Recent case reports have also noted a relationship between angiotensin receptor blockers and pancreatitis.^{112,113} Similar to ACE inhibitors, angiotensin receptor antagonists should be avoided in pregnancy because of teratogenic potential.¹¹⁴

There are no published reports of overdose involving this relatively new class of antihypertensive medication. Given the mechanism of action, hypotension and reflexive tachycardia would be anticipated to occur. Treatment with activated charcoal in individuals with recent ingestions is appropriate. Hypotension should be addressed with aggressive administration of intravenous fluid as well as vasopressors in cases of persistent hypotension.

α_1 -ADRENERGIC ANTAGONISTS

With the introduction of prazosin in the early 1970s, the selective α_1 -adrenergic antagonists have gained acceptance as effective agents in the treatment of essential hypertension. Their ability to improve urinary retention in men with benign prostatic hypertrophy has more recently increased their popularity.¹¹⁵ Despite their increased use, overdose with these quinazoline-derived α_1 -receptor antagonists, including prazosin, doxazosin, and terazosin, is infrequently reported. Only 1555 cases of exposure were reported to the AAPCC's TESS in 2002, with major effects requiring hospitalization reported in only 26 patients.⁵² The structure of prazosin is shown in Figure 61-7.

The α_1 -antagonist nonspecific predecessors, such as phentolamine and phenoxybenzamine, inhibit both α_1 and α_2 receptors and continue to be used in limited circumstances. These nonspecific antagonists are attractive agents for the treatment of high catecholamine states such as pheochromocytomas, extravasation of vasopressors, and MAO inhibitor toxicity. Given their limited in-hospital administration, toxicity with these drugs is exceedingly rare.

Pharmacology and Pharmacokinetics

Located on the smooth muscle of arterioles and veins in the peripheral circulation, α_1 receptors respond to circulating catecholamines with vascular constriction leading to increased vascular tone and a resultant increase in blood pressure. Alpha-1 antagonists competitively inhibit these postsynaptically located adrenergic receptors. Unlike α_2 receptors, which are located both in the periphery and centrally, α_1 receptors appear to be present solely in the peripheral vascular system. α_2 Receptors lie presynaptically and inhibit the release of norepinephrine when stimulated. In a similar fashion, stimulation of central α_2 receptors will cause a decrease in sympathetic outflow. Phentolamine, capable of causing peripheral vasodilation via α_1 -antagonistic effects, acts antagonistically at α_2 receptors as well producing an increase in sympathetic tone and a resultant tachycardia.

The selectivity that agents such as prazosin, doxazosin, and terazosin have for the α_1 receptor site is evident in the fact that tachycardia rarely occurs. In addition, α_1 -antagonists have demonstrated the ability to depress sinus node sensitivity, further inhibiting a reflexive tachycardic response from the heart.¹¹⁶ However, like many agents in the setting of overdose, the selectivity that α_1 -antagonists have for particular receptors may be lost.¹¹⁷

The α_1 -adrenergic antagonists are rapidly absorbed with peak plasma levels reached in the first 1 to 3 hours.

FIGURE 61-7 Prazosin.

Bioavailability ranges from 43% to 69% with prazosin and doxazosin to greater than 90% with terazosin.^{118,119} Prazosin is highly metabolized in the liver, with its demethylated metabolite possessing a slower rate of excretion and the ability to cause prolonged hypotension.¹¹⁹ The half-life of prazosin is 3 hours, but in the setting of congestive heart failure may be prolonged up to 6 to 7 hours.¹²⁰ The duration of action following therapeutic doses of prazosin is typically 7 to 10 hours due to active metabolites and tissue binding. Doxazosin and terazosin both possess half-lives of 9 to 12 hours allowing for once daily dosage and the potential for prolonged symptoms following overdose when compared to prazosin.

Toxicology

Not surprisingly, hypotension is the most commonly seen side effect in therapeutic dosing as well as with overdose. Postural hypotension can be seen following treatment initiation, an increase in dose, or with the addition of other antihypertensive medications. Frequently referred to as the “first dose phenomenon,” lightheadedness, dizziness, palpitations, diaphoresis, and syncope may occur within 30 to 90 minutes of the initial dose. This symptomatic hypotension is felt to be secondary to selective antagonism of α_1 receptors, causing peripheral vasodilation without a compensatory sympathetic response. To avoid this effect and potential complications, current recommendations include administration of medication prior to sleeping, low starting doses, and slow upward titration of the dose.¹²¹

Transient hypotension responsive to intravenous fluid is the most common presentation of symptomatic α_1 -antagonist overdose.¹²²⁻¹²⁵ One elderly man who ingested 120 mg of prazosin had a prolonged course of hypotension, CNS depression, and respiratory failure secondary to pulmonary edema requiring vasopressor support and mechanical ventilation for 48 hours prior to recovery.¹²³ Hypotension was accompanied by tachycardia in a 19-year-old male who ingested approximately 10 times the maximum therapeutic dose of prazosin, with symptoms resolving after several hours of observation and hydration.¹²² While tachycardia in overdose has been described, hypotension will more frequently be present with normocardia or mild bradycardia, consistent with isolated α_1 receptor antagonism.¹²³⁻¹²⁵

Priapism has been reported with both therapeutic administration and overdose and is likely related to the sympatholytic effects from α_1 -adrenergic blockade. By inhibiting α_1 receptors, a parasympathetically mediated erection can occur while inhibiting ejaculation and detumescence.¹²⁶ Other symptoms described in overdose include headache, vertigo, paresthesias, and weakness.¹²³ In one small series of patients with chronic renal insufficiency taking prazosin, neuropsychiatric effects were reported and felt to be secondary to poor drug clearance. These symptoms included delusions of grandeur, visual hallucinations, confusion, as well as electroencephalography findings consistent with metabolic encephalopathy. These symptoms resolved within 2 months of medication cessation.¹²⁷

Management

Supportive care and observation following overdose with α -adrenergic agents should include blood pressure and urine output monitoring to ensure adequate perfusion of vital organs. Aggressive intravenous hydration should be administered to hypotensive patients. Placement of a symptomatic patient in a supine or Trendelenburg position may be effective in correcting mild hypotension. The administration of a single dose of activated charcoal in a timely fashion is appropriate in patients with preserved mental status. Given the benign nature of most overdoses of α_1 -antagonists, the risks associated with orogastric lavage in nearly all cases outweigh the potential benefit.

If vasopressor support is required, direct-acting α agents such as norepinephrine and vasopressin would be preferred over nonspecific α - and β -agonists such as epinephrine. Stimulation of vascular β_2 receptors by epinephrine could theoretically lead to worsened hypotension and tachycardia given the isolated α_1 receptor blockade. Drug levels can be obtained; however, it is unlikely that these levels would be useful in the acute management of overdose.^{123,125} The occurrence of priapism warrants emergent urology consultation and the need for possible surgical intervention. Hemodialysis has not been reported after α_1 -antagonist overdose and would likely be of little benefit given the high rate of protein binding and large volume of distribution.

DIURETICS

Diuretics make up the most commonly prescribed class of medications in the United States. One study found that 28% of individuals older than 70 years were taking diuretics at the time of hospital admission.¹²⁸ Despite their widespread use, the frequency of intentional or accidental overdose remains relatively small. With overdose and therapeutic use, potential complications related to volume depletion and electrolyte abnormalities may occur. Those most susceptible appear to be the elderly and the malnourished, and patients with renal failure. Intentional overuse of diuretics has also been described in individuals with anorexia and bulimia, with up to one third of bulimic patients reporting diuretic abuse in an attempt to decrease body weight.¹²⁹

Diuretics used for the treatment of hypertension can be divided into three major classes: thiazide diuretics, loop diuretics, and potassium-sparing diuretics.

THIAZIDE DIURETICS

The thiazides were the first class of diuretics to be introduced in the 1950s when chlorothiazide was noted to be effective in decreasing blood pressure by reducing extracellular fluid volume and sodium in hypertensive patients. Other commonly used thiazide diuretics today include metolazone, chlorothalidone, indapamide, and hydrochlorothiazide. Thiazides act on the proximal

Hydrochlorothiazide

FIGURE 61-8 Hydrochlorothiazide.

portion of the distal tubule and the distal portion of the ascending loops of Henle by inhibiting the sodium/chloride symporter. The result is a decrease in renal sodium absorption and increase of sodium excretion into the urine. With less sodium uptake, the distal tubule is exposed to high sodium concentrations resulting in potassium excretion via the Na^+/K^+ pump. The structure of hydrochlorothiazide is shown in Figure 61-8.

The most serious effects of thiazide diuretics at therapeutic dosing, chronic overuse, and intentional overdose are related to fluid and electrolyte imbalance. With the loss of large amounts of sodium comes a decreased uptake of free water from distal tubules, leading to the potential for volume depletion and hypotension. Symptomatic dehydration appears most commonly in the elderly, who possess limited physiologic reserve.¹²⁸ Other evidence of decreased end-organ perfusion secondary to volume depletion includes cerebrovascular incidents and renal failure, often when used in conjunction with an ACE inhibitor or nonsteroidal anti-inflammatory drugs.¹³⁰⁻¹³² The presence of hyponatremia (less than 135 mmol/L) has been seen in one fifth of elderly patients taking thiazide diuretics.¹³³ The level of hypokalemia that may be induced appears to be dose dependent and more significant with thiazide diuretics when compared with loop diuretics.¹³⁴ In addition to hyponatremia and hypokalemia, other electrolyte abnormalities such as hypochloremia, hypomagnesemia, hypercalcemia, hyperuricemia, and metabolic alkalosis can be seen.

Thiazide-induced hypokalemia, while often mild at therapeutic dosing, becomes more concerning with diuretic abuse and in the setting of concomitant use of other potassium-wasting agents. The presence of significant hypokalemia and the potential for cardiac dysrhythmias warrants aggressive electrolyte replacement. The presence of hypokalemia in the setting of digoxin use is especially problematic because hypokalemia appears to enhance the effects of digoxin on the myocardium and predisposes the heart to additional dysrhythmias.

Other symptoms, including nausea, vomiting, diarrhea, anorexia, and abdominal pain, have been described with thiazide diuretic overdose. CNS depression ranging from mild transient lethargy to coma has been reported in the setting of overdose and after therapeutic administration. CNS depressant effects have also occurred in the absence of significant hypotension, suggesting a direct-acting CNS depressant effect. Grand mal seizures have been reported with the use of high-dose thiazide-type diuretics in the pediatric and adult population.^{135,136} Other effects associated with thiazide use include pancreatitis,

FIGURE 61-9 Furosemide.

cholecystitis, erectile dysfunction, thrombocytopenia, and hemolytic anemia.^{130,137-140}

LOOP DIURETICS

Four loop diuretics are currently approved for use in the United States: furosemide, bumetanide, ethacrynic acid, and torsemide. Their effectiveness lies in their ability to inhibit the $\text{Na}^+\text{-K}^+\text{-Cl}^-$ symporter found on the thick ascending limb of the loop of Henle, resulting in loss of sodium, chloride, and potassium ions in the urine. Loop diuretics also act as direct vasodilators that can reduce left ventricular filling pressures via increased systemic venous capacitance.¹⁴¹ The structure of furosemide is shown in Figure 61-9.

Toxicity related to loop diuretic abuse in many ways is similar to that observed with thiazide diuretics, with the potential for developing hyponatremia, hypokalemia, hypocalcemia, hypomagnesemia, and fluid depletion. In addition to the potential risk for cardiac dysrhythmias, hypokalemia in the setting of furosemide overuse has led to significant muscular weakness and rhabdomyolysis. Hyponatremia can also be severe, resulting in seizures, lethargy, and coma. Rapid correction of hyponatremia following furosemide abuse resulted in central pontine myelinolysis in one report.¹⁴² Symptoms such as tetany and peripheral sensory and motor dysfunction resulting from loop diuretic abuse improve rapidly following electrolyte correction.^{136,143}

The use of loop diuretics has also been associated with auditory nerve damage. This dose-dependent phenomenon is reported with furosemide and bumetanide use but is more frequently described with the use of ethacrynic acid. The intravenous administration of high doses of loop diuretics concomitantly with other potentially ototoxic drugs such as aminoglycosides is associated with the highest risks of ototoxicity.^{144,145} With discontinuation of treatment, hearing loss and tinnitus frequently improve.

POTASSIUM-SPARING DIURETICS

While relatively weak in diuretic activity, potassium-sparing diuretics such as triamterene and amiloride are frequently administered in combination with loop and thiazide diuretics to decrease the amount of potassium excreted into the urine. These agents, in addition to spironolactone and eplerenone, act on the distal renal tubule to decrease sodium reabsorption and limit

excretion of potassium. While reports of toxicity related to overdose are exceedingly rare with potassium-sparing diuretics, the development of life-threatening hyperkalemia can occur with therapeutic dosing, frequently in patients with renal insufficiency or with coadministration of other potassium-elevating medications. One report found that 8.6% of patients treated with spironolactone developed hyperkalemia.¹⁴⁶

The coadministration of a potassium-sparing diuretic with a loop or thiazide diuretic often obviates the need for supplemental potassium administration.¹⁴⁷ Two cases of life-threatening hyperkalemia were reported in individuals who were taking potassium-containing salt substitutes while concurrently taking spironolactone.¹⁴⁸ In overdose of these agents, gastrointestinal irritation and central nervous depression have also been reported. Spironolactone has other unique side effects related to its steroid structure, including development of gynecomastia, impotence, hirsutism, and menstrual irregularities. Use of triamterene is unique in its association with interstitial nephritis and nephrolithiasis.¹⁴⁹

Management

Treatment of diuretic toxicity is supportive with close monitoring and correction of electrolyte abnormalities and hypovolemia. The administration of activated charcoal should take place shortly after drug ingestion in order to limit absorption. Aggressive fluid administration is indicated in cases of diuretic-induced hypotension and shock. The possibility of co-ingestion with potassium supplements must be considered. Large potassium tablets may be visible on radiography, and although poorly adsorbed by activated charcoal, whole bowel irrigation may be an appropriate intervention to decrease absorption. An initial ECG should be performed in patients with diuretic overdose followed by continuous cardiac monitoring when electrolyte abnormalities are suspected. Significant hyperkalemia in the presence of ECG abnormalities should be corrected with insulin and dextrose, calcium, sodium bicarbonate, and cation-exchange resins.

JAMES F. WILEY II, MD, MPH

At a Glance...

- Clonidine and related imidazolines act at central and peripheral α_2 -adrenergic receptors and at imidazoline receptors.
- In overdose, imidazolines produce central nervous system depression, bradycardia, hypotension, and respiratory depression.
- As little as 0.1 mg or 1 clonidine tablet may cause major poisoning effects in young children.
- Pediatric clonidine exposure is increasing and reflects greater use of this drug for behavioral problems in children.
- Management of clonidine poisoning should focus on respiratory support and maintenance of hemodynamic stability.
- No antidote exists for clonidine toxicity, although reports of clinical improvement after naloxone or yohimbine administration have been described.

INTRODUCTION AND RELEVANT HISTORY

Clonidine and related drugs, including apraclonidine, brimonidine, dexmedetomidine, guanabenz, guanfacine, methyl dopa, naphazoline, oxymetazoline, tetrahydrozoline, tizanidine, and xylometazoline, share similar toxicity. Clonidine, guanabenz, guanfacine, and methyl dopa have been used primarily as antihypertensive medications, although new indications have been developed for clonidine and guanfacine. Tetrahydrozoline, oxymetazoline, naphazoline, and xylometazoline are over-the-counter topical vasoconstrictors. Apraclonidine and brimonidine are prescribed for ocular hypertension and open-angle glaucoma. Tizanidine is a new muscle relaxant used for the spasticity associated with cerebral and spinal disorders. Dexmedetomidine is a new imidazole used for intravenous sedation and analgesia.¹ Most examples of severe toxicity attributable to this class of drugs have occurred with clonidine.

Clonidine was initially developed as a topical nasal decongestant in 1962. Subsequently, it was found to be a potent antihypertensive agent with sympatholytic effects not attributable to ganglionic blocking.² Clonidine is synergistic in antihypertensive effect with diuretics and has been employed as a second or third agent in the treatment of essential hypertension. The advent of converting enzyme inhibitors has decreased the use of clonidine as an antihypertensive agent. Alternative off-label indications in adults include anesthetic premedication, induction of spinal anesthesia, ultrashort opiate detoxification, alcohol withdrawal, smoking cessation, and alleviation of postmenopausal hot flashes.³⁻⁸ In children, treatment of attention-deficit hyperactivity disorder (ADHD) accounts for the greatest off-label use.⁹ Refractory conduct disorder, Tourette's syndrome, and

diagnosis of growth hormone deficiency make up other potential uses in children.^{10,11} Guanfacine has been evaluated for the treatment of children with both ADHD and Tourette's syndrome¹² and has been shown to induce growth hormone secretion without the concomitant hypotension or sedation common with clonidine.¹³

EPIDEMIOLOGY

Clonidine exposure occurs in about 1 in 1000 poisonings and is notable for serious signs and symptoms after many ingestions.¹⁴⁻¹⁶ In 2004, there were 5802 clonidine and 1579 tetrahydrozoline exposures reported to U.S. poison centers. Major toxicity and death occurred in only 3.6% and 0.2% of clonidine exposures and in 0.1% and 0% of tetrahydrozoline exposures, respectively.¹⁷ Moderate toxicity, however, was observed in 22.8% of all clonidine exposures. Total clonidine exposures in children younger than 19 years have almost doubled in recent years.¹⁴ Many pediatric exposures involve the child's own medication or that of another child in the household. This pattern contrasts with the previously reported situation of young toddlers ingesting a grandparent's clonidine.^{16,18} Exposure to over-the-counter nose drops and eye drops is another important cause of imidazoline poisoning but tends to be uneventful.¹⁹ Guanabenz, guanfacine, and methyl dopa are rarely prescribed or ingested and appear to cause similar but lesser effects than clonidine.²⁰⁻²²

STRUCTURE AND STRUCTURE–ACTIVITY RELATIONSHIPS

Clonidine and some related imidazolines are depicted in Figure 62-1.

PHARMACOLOGY

Clonidine, guanabenz, guanfacine, oxymetazoline, tetrahydrozoline, naphazoline, xylometazoline, tizanidine, and dexmedetomidine are related imidazolines with central and peripheral α_2 -adrenergic agonist effects. In addition, some of the central antihypertensive effects may be attributable to binding of specific imidazoline receptors. As sympathomimetic agents, imidazolines have little to no β -adrenergic effect and have peripheral vasoconstrictive properties similar to specific α_1 -adrenergic agonists. However, imidazolines differ markedly from most sympathomimetics in their central inhibition of sympathetic outflow.²³ Developed as an analog of 3,4-dihydroxyphenylalanine (DOPA), methyl dopa is chemically

FIGURE 62-1 Structure of clonidine and some other imidazolines.

unrelated to the imidazolines but stimulates α_2 -adrenergic receptors centrally through its metabolite, α -methyl norepinephrine.²⁴

The imidazolines produce effects by a complex interaction with central α_2 -adrenergic receptors, peripheral α_2 -adrenergic receptors, and central imidazoline receptors. The α_2 -adrenergic receptors have subtypes A, B, and C, which are structurally distinct and have varying affinity for α_2 -adrenergic receptor agonists and antagonists. α_{2A} -Adrenergic receptors are found predominantly in the brainstem, whereas α_{2B} -adrenergic receptors are found on vascular smooth muscle cells.²⁵ Central α_{2A} -adrenergic receptors have a higher affinity for agonists (e.g., clonidine) than do peripheral α_{2B} -adrenergic receptors.²⁵ Binding at each of these receptors reduces the intracellular activity of adenylyl cyclase through a pertussis toxin-sensitive G protein.²⁶ Elucidation of the receptor-binding properties for the drugs under discussion have involved radioligand studies using [³H]clonidine. Clonidine strongly binds to central α_{2A} -adrenergic receptors located in the brainstem (nucleus tractus solitarii). This binding has an inhibitory effect on norepinephrine release centrally, resulting in decreased sympathetic outflow.²⁷⁻²⁹ Therapeutically, this action causes reduced blood pressure, bradycardia, and sedation. The hypotensive changes are not seen in quadriplegic patients who receive clonidine.²⁶ Clonidine also inhibits acetylcholine release. Clinically, this effect is manifest as dry mouth in therapeutic doses. In the hypothalamus, clonidine stimulates the release of growth hormone and has varying effects on sympathetic tone and blood pressure. In the spinal cord, clonidine decreases sympathetic tone and blood pressure and has analgesic properties that are similar to those of narcotic medications.^{26,30}

The similarity in effects found upon stimulation of central α_2 -adrenergic receptors and opiate receptors has prompted much investigation into a possible molecular link between these sites. Clinical evidence supporting such a link includes the use of clonidine for ultrashort opiate detoxification,^{4,5} the successful use of clonidine for spinal analgesia,³⁰ the likeness of toxicity found after overdose with narcotics and clonidine, the reversal of clonidine toxicity with naloxone in some patients,¹⁶ and the decreased density of central α_2 -adrenergic receptors in heroin addicts.³¹ Both opiate and central α_2 -adrenergic receptors act through G proteins. The possibility of "cross-talk" between these receptors through the G-protein complex has been raised, although initial studies in a neuroblastoma-glioma cell line were not supportive.³²

Other proposed mechanisms for α_2 -agonist inhibitory effects, such as hyperpolarization of neuronal cells by activation of potassium channels, inhibition of N-type voltage-gated calcium channels, and increased Na^+/H^+ exchange, may hold the answer regarding the relationship between imidazolines and opiates.²⁴ Improved understanding concerning the relationship of central α_2 -adrenergic and opiate receptors must await further study.

Specific imidazoline (I) receptors of multiple types exist and have been identified in a variety of tissues and animal species. Current nomenclature delineates I_1 and I_2 receptors, with a further breakdown of I_2 receptors into I_{2a} (amiloride-sensitive) and I_{2b} (amiloride-insensitive) receptors.³³ These receptors do not act through G proteins.³⁴ Clonidine has strong affinity at I_1 receptors, which are located in the ventrolateral medulla in humans. Binding at these sites leads to decrease in blood pressure independent of central α_2 -adrenergic effects.³⁵ An endogenous substance with imidazoline receptor affinity called *clonidine-displacing substance* has also been discovered, but its physiologic role has yet to be elucidated. Guanabenz is an agonist at I_2 imidazoline receptors, which are strongly linked to monoamine oxidase A and B expression, but the mechanism of action and function of I_2 receptors is uncertain and requires further study.³⁶

Peripheral imidazoline effects are varied, relate to agonist effects at α_{2B} -adrenergic receptors, and are usually overshadowed by central α_{2A} -adrenergic receptor effects. Agonist activity at peripheral α_{2B} -adrenergic receptors located on vascular smooth muscle cells causes vasoconstriction. Effects at these receptors typically require a higher serum concentration of agonist, as occurs after overdose and intravenous administration of agonist.²⁵ Thus, intravenous administration of clonidine and suprathreshold levels of clonidine are associated with hypertension and pallor in some patients. Stimulation of presynaptic peripheral α_2 -adrenergic receptors, however, reduces vasomotor tone in other blood vessel sites and inhibits renin release, which would lead to synergism with central effects.³⁵ The net effect is a reduction of blood pressure and sympathetic outflow in both hypertensive and normotensive patients who receive clonidine. By reducing sympathetic outflow, imidazolines lower arterial pressure through reduction in both cardiac output and peripheral vascular resistance. Reduced cardiac output is from a decrease in heart rate and myocardial contractility.

PATHOPHYSIOLOGY

In overdose, the sympatholytic effects of imidazolines predominate. The organs most commonly affected are the brain and the heart. Decreased norepinephrine release in the central nervous system (CNS) causes lethargy, coma, miosis, hypotonia, respiratory depression, apnea, and hypothermia.¹⁴⁻¹⁸ Cardiac consequences of imidazoline toxicity include bradycardia (sinus or first-degree atrioventricular [AV] block) and hypotension related to central α_2 -adrenergic and imidazoline receptor stimulation.¹⁴⁻¹⁸ Peripheral α_2 -adrenergic effects may cause vasoconstriction with hypertension. Rarely, malignant hypertension and seizures occur, particularly in patients with renal insufficiency who ingest large doses of clonidine.³⁷ Children are particularly sensitive to the toxic effects of the imidazolines. As little as 0.1 mg of clonidine and 2.5 mL ($\frac{1}{2}$ teaspoon) of 0.05% tetrahydrozoline eye drops have caused significant toxicity.^{14,38,39}

PHARMACOKINETICS

Rapid absorption follows oral clonidine administration, with drug bioavailability of 75% to 96% after a single dose.⁴⁰ Bioavailability falls with chronic administration to 65%.⁴¹ Maximal hypotensive effect coincides with peak plasma concentration 1 to 3 hours after ingestion. Therapeutic clonidine levels range from 0.5 to 2 ng/mL, with a close relationship between plasma concentration and clinical effects.²³ Clonidine is 20% to 40% protein bound and has a volume of distribution of 2.9 to 5.3 L/kg.⁴⁰ Clonidine undergoes hepatic metabolism to inactive compounds, but about half of a single oral dose is excreted unchanged in the urine. The elimination half-life is 12 to 16 hours and is prolonged in patients with renal insufficiency, often necessitating decreased dosing.⁴¹ In preoperative patients, clonidine may be given sublingually or rectally, with pharmacokinetics similar to oral administration.^{43,44}

Clonidine patch formulations range from 2.5 to 7.5 mg of drug within a timed matrix delivery system. These systems provide a constant rate of transdermal clonidine administration over 7 days. Maximum plasma concentration occurs 2 to 3 days after application and peaks at 0.1 to 0.5 ng/mL. Elimination half-life ranges from 26 to 55 hours while the patch is applied. Drug

delivery varies by application site, with highest absorption from the left arm and lowest from the thigh.⁴⁵ Twenty to 75% of residual clonidine may remain in the patch after 7 days of use.⁴⁶

Pharmacokinetic comparisons of certain imidazolines are shown in Table 62-1. α -Clonidine, brimonidine, naphazoline, tetrahydrozoline, oxymetazoline, and xylometazoline are approved and intended only for topical use; pharmacokinetic data based on ingestion are not available for these agents.

Special Populations

PEDIATRIC

Despite the frequent use of imidazolines (clonidine and guanfacine) in children, no controlled pharmacokinetic data exist.

HEPATIC AND RENAL IMPAIRMENT

Hepatic disease necessitates careful monitoring and possible dose reduction in patients receiving dexmedetomidine and guanabenz. Patients with renal disease should have a proportionate reduction in clonidine dose. Methyldopa is contraindicated in patients with active hepatic disease and in those who have experienced liver disorders attributable to prior methyldopa administration.⁴⁷

PREGNANCY AND LACTATION

Methyldopa and guanfacine have category B designation for use in pregnancy. However, a great deal of human experience with methyldopa suggests that the chance of fetal harm is very low and that the benefit of controlling hypertension in pregnancy using methyldopa far outweighs potential teratogenic risks. No human reproductive data exist for guanfacine. Clonidine, guanabenz, and dexmedetomidine all have category C designation in pregnancy, with some evidence of adverse fetal effects in animals. Clonidine is also excreted in breast milk; its safety for use while breast-feeding is unknown.⁴⁷

Pharmacologic Agents

Table 62-2 lists the most common imidazoline formulations available.

TABLE 62-1 Pharmacokinetics of Clonidine, Guanfacine, and Guanabenz

DRUG	BIOAVAILABILITY (%)	T _{max} (hr)	t _{1/2} (hr)	Vd (L/kg)	PROTEIN BINDING (%)	ELIMINATION
Clonidine	75-96	1-3	12-16	3-5	20-40	Renal
Clonidine patch	25-80*	40-80	26-55	3-5	20-40	Renal
Guanfacine ^{67,68}	95-100	1-3	17-24	4-6	20-30	Renal
Guanabenz ⁶⁹	75	2-5	7-14	7-17	90	Hepatic
Dexmedetomidine	100	0.1	2-3	1.3	94	Hepatic
Tizanidine	20-40	1-2	2-4	8-16	30	Hepatic

*Twenty percent to 75% of drug remains in the patch after 7 days.²⁶

T_{max}, maximum plasma concentration; t_{1/2}, half-life of drug; Vd, volume of distribution.

TABLE 62-2 Imidazoline Formulations

DRUG	FORM	DOSE/CONCENTRATION	BRAND NAME
Clonidine	Tablet	0.25 mg 0.1, 0.2, or 0.3 mg 0.1, 0.2, or 0.3 mg with 15 mg chlorthalidone	Dixarit Catapres Combipres
	Patch	2.5 (3 cm ²) 5.0 (7 cm ²) 7.5 mg (10 cm ²)	Catapres-TTS 1 Catapres-TTS 2 Catapres-TTS 3
Guanfacine	Intravenous	100 µg/mL, 500 µg/mL	Duraclon
	Tablet	1, 2 mg	Tenex
Guanabenz	Tablet	4, 8 mg	Generic
Methyldopa	Tablet	125, 250, 500 mg	Generic
	Oral solution	250 mg/5 mL	
Dexmedetomidine	IV solution	50 mg/mL	
	IV solution	100 µg/mL	Precedex
Brimonidine	Topical ophthalmic	0.15%, 0.2%, 0.5%	Alphagan-P
Naphazoline	Topical ophthalmic	0.1%	Naphcon Forte, Vasocon, and others
	Topical nasal and ophthalmic	0.05%, 0.1%	Tyzine, Visine, and others
Tizanidine	Tablet	2, 4 mg	Sirdalud, Ternelin, Zanaflex
Oxymetazoline	Topical nasal and ophthalmic	0.01%, 0.025%, 0.05%	Dristan, Afrin, Neosynephrine, Visine LR, and others
	Topical nasal	0.05%, 0.1%	Otrivin

Drug Interactions

Significant drug interactions are rare with imidazolines. They may combine with other antihypertensive medications (e.g., α_1 -adrenergic, β -adrenergic, and calcium channel antagonists) to produce hypotension or bradycardia. All forms of imidazolines may cause malignant hypertension in patients taking monoamine oxidase inhibitors. Methyldopa may alter lithium levels and has decreased bioavailability when ingested with iron formulations.⁴⁷ Three sudden deaths were reported in children taking the combination of clonidine and methylphenidate for ADHD. Circumstances in each case led the U.S. Food and Drug Administration to conclude that both clonidine and methylphenidate have potential cardiotoxicity, but there was no convincing evidence for a lethal drug interaction involving these two medications.^{48,49} Cyclic antidepressants potentially interfere with the antihypertensive effect of clonidine. Clonidine may potentiate CNS depression when combined with ethanol, barbiturates, or other sedative-hypnotic medications. Klonopin (clonazepam) and clonidine sound alike and may be inadvertently substituted for each other and result in accidental toxicity.

TOXICOLOGY

Clinical Manifestations

Clinical findings of clonidine and other imidazoline poisonings appear soon after ingestion. In one series of clonidine poisoning in children, 75% of patients had signs of toxicity within 1 hour of ingestion, and no patient had any new findings occur more than 4 hours

after poisoning.¹⁶ Topical imidazoline exposure by unintentional oral ingestion or nasal administration in infants and young children can cause lethargy and coma within 1 hour.⁵⁰ One case report describes the intentional poisoning with clonidine eye drops for criminal purposes resulting in prolonged coma, respiratory depression, and hemodynamic instability.⁵¹ The potential for rapid decompensation in patients who ingest imidazolines makes close observation of these patients imperative.

About 60% of clonidine exposures reported to poison control centers are symptomatic.¹⁴ The relative frequency of clinical findings in symptomatic children and adults who ingest clonidine are shown in Table 62-3. Lethargy and coma typically accompany serious clonidine toxicity and occur soon after ingestion. Miosis, hyporeflexia, and hypotonia are common associated findings, particularly in children. This constellation of neurologic findings closely mimics opiate toxicity. Frequently, children with clonidine intoxication and coma have transient responsiveness to a painful stimulus, such as intravenous line placement or phlebotomy, but quickly revert back to profound CNS depression. Irritability, dilated pupils, and the presence of extensor plantar responses (i.e., positive Babinski's sign) occur less frequently in children and are rarely seen in adults.

Bradycardia and hypotension follow clonidine ingestion in a significant number of children and adults. Sinus bradycardia is the most common rhythm in these patients, with first-degree AV block seen occasionally. Although complete AV block and supraventricular tachycardia complicated clonidine ingestion in a 22-year-old woman with systemic lupus erythematosus and renal insufficiency,⁵² second-degree block or complete AV dissociation should prompt the consideration of toxicity

**TABLE 62-3** Clinical Findings in Children and Adults after Clonidine Poisoning

FINDING	CHILDREN, HOSPITAL BASED* (<10 yr)	CHILDREN, POISON CONTROL CENTER (<19 yr)	ADULT, HOSPITAL BASED (>18 yr)
N (number)	180	6042	37
Central Nervous System			
Lethargy/coma	87%	82%	78%
Miosis	16%	3%	3%

*Age-specific definitions of bradycardia, hypotension, and hypertension were used for pediatric findings in the hospital-based pediatric reports. Adapted from Klein-Schwartz W: Trends and toxic effects from pediatric clonidine exposures. *Arch Pediatr Adolesc* 2002;156:392–396; Stein B, Volans GN: Dixerit overdose: the problem of attractive tablets. *BMJ* 1978;2:667–668; and Wiley JF II, Wiley CC, Torrey SB, Henretig FM: Clonidine poisoning in young children. *J Pediatr* 1980;116:654–658.

from other drugs, such as digoxin, calcium channel blockers, and β -adrenergic blockers. Hypotension may be quite profound but usually responds readily to rapid intravenous fluid administration.¹⁶ Hypertension is associated with a large ingested dose of clonidine and is usually an early transient finding.⁵³ Severe hypertension with encephalopathy or seizures attributed to clonidine exposure has been described in a patient with renal insufficiency.³⁷ Hypertension may also be precipitated by naloxone administration.^{16,53} Cardiac arrests have been described in adults with clonidine poisoning, and one pediatric death has been reported.^{14,15}

Apnea and respiratory depression occur more commonly after clonidine exposure in children but also complicate clonidine poisoning in adults. In many patients, the degree of respiratory compromise necessitates endotracheal intubation. Stimulation of the child often increases respiratory rate and effort transiently. This finding may be useful in differentiating apnea caused by clonidine poisoning from the apnea associated with opiate intoxication. Occasional findings with clonidine intoxication include dry mouth, hypothermia, and pallor. The duration of toxic manifestations after ingestion of clonidine tablets is less than 24 hours, with an averaged reported duration of 9 to 16 hours.^{15,16}

Other imidazolines could potentially cause any of the clinical findings seen with clonidine poisoning. Most

topical imidazoline exposures result in no symptoms. Guanabenz, guanfacine, and methyl dopa are rarely used or ingested. The most commonly reported adverse findings in symptomatic patients who have been exposed to imidazolines other than clonidine are variable CNS depression (i.e., lethargy to coma), miosis, bradycardia, and respiratory depression.^{19-22,38,50,54} Similar to clonidine, tizanidine overdose has been associated with first-degree and Wenckebach's type II AV block.⁵⁵ Dexmedetomidine may cause profound bradycardia or hypotension but does not cause significant respiratory depression.²⁶

Adverse Effects

Common adverse effects after oral clonidine, guanfacine, or guanabenz administration include dry mouth, lethargy, and dizziness. Methyl dopa is notable for its ability to cause Coombs' test-positive hemolytic anemia and liver disorders. Reversible granulocytopenia and thrombocytopenia may also follow methyl dopa therapy. Fever, eosinophilia, elevated serum liver transaminase levels, and jaundice may occur in the first month of treatment. Rarely, fatal hepatic necrosis may transpire. Dexmedetomidine infusion has been associated with transient hypertension, bradycardia, and hypotension. Overuse of topical nasal vasoconstrictors may result in

rebound congestion with chronic nasal redness and swelling.⁴⁷

A withdrawal syndrome can occur after sudden cessation of clonidine. This state is characterized by hypertension, tachycardia, sweating, anxiety, insomnia, abdominal pain, nausea, and palpitations. Rarely, clonidine withdrawal can cause malignant hypertension and cardiac dysrhythmias in patients with heart disease. Clonidine withdrawal occurs 1 to 3 days after the abrupt termination of chronic clonidine therapy and coincides with elevated urine and plasma catecholamine levels.^{56,57} Patients receiving concomitant β -blocker therapy at the time clonidine is stopped are at higher risk for serious effects. Reinstitution of clonidine therapy usually suffices to treat clonidine withdrawal, but occasionally patients may require nitroprusside infusion for control of hypertension.⁵⁸ β Blockers should be avoided because they could produce unopposed α -adrenergic effects that may worsen hypertension in the setting of withdrawal. Abrupt cessation of guanabenz and guanfacine may also cause mild withdrawal symptoms but to a lesser degree than clonidine.⁵⁹

DIAGNOSIS

The diagnosis of imidazoline poisoning is based on a positive history of ingestion coupled with suggestive physical findings. When the history is unknown, imidazoline exposure should be suspected in any patient who has the appearance of opiate intoxication but does not respond to high doses of naloxone. A positive clinical response to naloxone and negative workup for opioid intoxication may occasionally be consistent with imidazoline poisoning. In addition, hypertension that occurs after naloxone administration may be suggestive of imidazoline poisoning, especially clonidine. No routine laboratory or other ancillary tests (e.g., electrocardiogram) can be used to identify imidazoline toxicity, but they are helpful to exclude other disease processes or poisonings. Imidazolines are not detected on routine comprehensive toxicology screening evaluations. Quantitative and qualitative tests are available for clonidine, guanabenz, and methyldopa to confirm the diagnosis, but they usually take several days to perform and are not helpful for patient management.

Differential Diagnosis

The clinical manifestations of imidazoline poisoning are similar to many toxicologic and nontoxicologic entities. Toxicity from imidazolines may be clinically indistinguishable from that produced by opioids. The CNS and cardiovascular manifestations of imidazolines may also be similar to effects produced by alcohols, antiarrhythmics, antiepileptics, barbiturates, α - and β -adrenergic antagonists, calcium channel antagonists, cardiac glycosides, carbon monoxide, cyanide, ergot alkaloids, lithium, sedative-hypnotics, γ -hydroxybutyrate, and skeletal muscle relaxants. CNS infection, traumatic head injury, cerebrovascular accidents, and metabolic

disturbances should be considered and excluded with appropriate testing.

TREATMENT

Immediate Supportive Measures

The treatment for imidazoline overdose is primarily supportive. Patients with significant CNS or respiratory depression should have their airway protected, breathing assisted, and cardiovascular support provided as necessary. In one series, 12% of children who ingested clonidine required endotracheal intubation because of apnea, deep coma, or respiratory depression.¹⁶ Although naloxone administration may reverse symptoms of respiratory depression, it has not prevented the need for endotracheal intubation in most reported patients.^{16,60} When performing endotracheal intubation in these patients, atropine and muscle relaxant administration should precede laryngoscopy to avoid bradycardia and difficulty due to patient agitation, respectively.

All symptomatic patients suspected of imidazoline overdose should have continuous cardiac monitoring, an intravenous line established, and an electrocardiogram performed. Supplemental oxygen, continuous pulse oximetry, and parenteral thiamine, dextrose (or rapid fingerstick glucose determination), and naloxone should be considered for patients with altered mental status. Bradycardia typically responds well to administration of a routine dose of atropine (0.02 mg/kg, up to 1 mg). Hypotension should be treated with rapid infusion of 20 to 40 mL/kg of isotonic crystalloid, either normal saline or Ringer's lactate. Dopamine infusion has been used successfully in the minority of patients who do not improve after fluid administration.¹⁶ Hypertension after clonidine ingestion is usually transient and frequently requires no treatment. If treatment is instituted, a short-acting agent such as sodium nitroprusside is recommended. β -Adrenergic blockers should be avoided for imidazoline-induced hypertension to prevent unopposed effects and worsening of hypertension. A search for an adherent clonidine patch should occur during skin exposure and examination of patients in whom imidazoline poisoning is suspected.⁶¹

Suggested laboratory analysis for symptomatic patients includes a complete blood count; blood gas analysis; measurement of electrolytes, blood urea nitrogen, creatinine, and glucose concentrations; and pregnancy testing for women of child-bearing age. Serum acetaminophen and salicylate concentrations should be measured in all intentional overdose patients.

Decontamination and Prevention of Systemic Absorption

The most useful method of decontamination after imidazoline overdose varies based on the type of exposure and the drug formulation. A single dose of activated charcoal is indicated after the oral ingestion of clonidine pills or imidazoline topical preparations. Gastric

emptying with syrup of ipecac is contraindicated because of the potential for rapid onset of CNS depression. Gastric lavage before administration of activated charcoal may be useful in patients who have ingested a large amount of pills within 1 hour of hospital presentation. Toxicity after nasal or ocular administration of imidazoline drops in young children is unlikely to be significantly altered by any means of gastric decontamination.

Ingestion of a clonidine patch preparation presents a special challenge. Two reports highlight the beneficial use of cathartics in this situation. In one case, a 29-month-old girl had persistent findings of clonidine intoxication 26 hours after presumed ingestion of a patch. Administration of magnesium citrate led to passage of the patch 30 hours later.⁶² Another patient had spontaneous passage of a clonidine patch after 4 hours of whole bowel irrigation with polyethylene glycol at 500 mL/hr.⁶³ Based on this experience, administration of a single dose of activated charcoal followed by whole bowel irrigation may be an effective method for the prevention of clonidine absorption after transdermal patch ingestion.

Antidotes

There is no true antidote for imidazoline poisoning. Naloxone, however, has reversed signs of imidazoline toxicity in some patients. The mechanism by which naloxone works in imidazoline poisoning is unknown. The response rate is about 15% to 40% in patients receiving up to 0.1 mg/kg of naloxone.¹⁶ A total dose of 10 mg of naloxone may need to be administered before determining that naloxone is ineffective.⁶² Naloxone infusion after an initial response is rarely needed in patients who ingest clonidine. Given the low risk of naloxone administration in the emergency setting, it should be given to patients with significant CNS, cardiovascular, or respiratory compromise. Patients with severe imidazoline poisoning often need immediate supportive care, such as endotracheal intubation, atropine administration, and rapid crystalloid infusion despite having received naloxone.¹⁶

Yohimbine, a central α_2 -adrenergic antagonist, has reversed lethargy, miosis, and bradycardia due to clonidine ingestion. The oral dose used was 0.1 mg/kg. It has not been used to reverse respiratory depression. Furthermore, it is only available in oral form, thus limiting its efficacy as an antidote for clonidine toxicity.⁶⁴

Tolazoline, a central and peripheral α_2 -adrenergic antagonist, was initially used in the treatment of clonidine poisoning, but was frequently ineffective.⁶⁵ In addition, it has adverse effects of tachycardia, hypertension, and dysrhythmias. Given the excellent outcome in patients poisoned with imidazolines who receive supportive care alone, the risk of tolazoline outweighs the potential benefit.

Elimination Enhancement

The imidazolines are not amenable to any form of elimination enhancement.

Disposition

Small accidental dosing errors in patients already maintained on the medication may be managed outside of health care facilities with close phone follow-up.¹⁴ Children younger than 6 years with any imidazoline exposure should be referred to a health care facility, as should any patient with intentional ingestion. Those patients who ingest imidazolines but remain asymptomatic can be watched for 4 to 6 hours from the time of ingestion and medically cleared if no physical findings of imidazoline poisoning are seen. Those patients who ingest a clonidine patch, however, should be admitted and monitored for 12 to 24 hours due to the potential for delayed clinical effects. Symptomatic patients who respond to naloxone should be admitted and monitored to ensure no recrudescence of toxicity. These patients often can receive adequate treatment on a regular inpatient ward. Symptomatic patients who do not respond to naloxone require immediate supportive care and admission to an intensive care unit. In most instances, patients fully recover from imidazoline poisoning within 1 to 2 days. There is one case report of permanent neurologic sequelae in a child who was repeatedly poisoned with clonidine by his mother.⁶⁶

Class IA Antiarrhythmics: Quinidine, Procainamide, and Disopyramide

KRISTINE A. NAÑAGAS, MD ■ R. BRENT FURBEE, MD

At a Glance...

- Life-threatening effects of IA antiarrhythmic overdose are cardiac.
- Sodium channel blockade leads to QRS widening and ventricular tachycardia, which is often responsive to sodium bicarbonate.
- Potassium efflux blockade causes widened QT_c and torsades de pointes and may respond to magnesium sulfate and correction of hypokalemia.
- Torsades de pointes usually develops in patients with bradycardia.
- Anticholinergic and hypoglycemic effects are seen with disopyramide > procainamide > quinidine.
- Extracorporeal drug removal may be of some use for procainamide and *N*-acetylprocainamide but is of minimal benefit for other IA antiarrhythmics.
- Peak plasma levels for therapeutic doses occur at 1 to 3 hours but may be delayed in overdose.
- Symptomatic patients should be admitted for cardiac monitoring.

The class IA antiarrhythmics include quinidine, procainamide, and disopyramide. Although dissimilar in structure (Fig. 63-1), all three drugs suppress cardiac dysrhythmias via the same mechanisms and produce adverse effects typical of the group. In the past, these drugs were widely used for the control of both atrial and ventricular arrhythmias, but because of the high incidence of adverse effects with therapeutic use and overdose, newer, safer agents have largely replaced them.

FIGURE 63-1 Although dissimilar in structure, all class IA antiarrhythmic agents share therapeutic and toxic effects.

HISTORY

Quinidine and its optical isomer quinine are extracted from the South American cinchona tree. Centuries ago, it was noted that patients with both malaria and atrial fibrillation, when treated with cinchona for malaria, were sometimes also cured of their arrhythmia. Jean-Baptiste de Senac, of Paris, recorded using cinchona in the treatment of atrial fibrillation in 1749. In 1936, Mautz demonstrated procaine to be effective in decreasing ventricular irritability, but this compound was rapidly metabolized and was too neurotoxic to be of clinical value. Procainamide, a congener of procaine, was introduced in 1955. Disopyramide was introduced in 1978.¹

PHARMACOKINETICS

Quinidine is well absorbed after ingestion, with a bioavailability of between 70% and 80%. Quinidine sulfate levels peak at 1.5 hours. The gluconate, sulfate, and polygalacturonate salts are sustained-release preparations, and blood levels of these may not peak until 4 hours after ingestion. Peak levels may be significantly prolonged in overdose.^{2,3} Quinidine is 75% to 95% protein bound and is metabolized by the liver via hydroxylation, with a half-life of approximately 6 hours.⁴ Quinidine has two metabolites with antiarrhythmic properties: 2'-quinidinone and 3-hydroxyquinidine. Its apparent volume of distribution is 3 L/kg. Approximately 20% of quinidine is excreted unchanged in the urine.²

Oral procainamide is absorbed well from the small intestine; levels peak 1 to 2 hours after ingestion. After intravenous administration, the drug distributes to the tissue within 30 minutes. Procainamide diffuses well into tissue and has a volume of distribution of 2 L/kg. Protein binding is approximately 15% to 20%.⁵ Procainamide is hydrolyzed by the liver into several active metabolites, the most significant being 1,4,2-*N*-acetylprocainamide (NAPA).⁶ Procainamide has a half-life of 3 hours, and NAPA of 6 hours. Fifty percent of procainamide is excreted in the urine unchanged.⁷

Disopyramide is well absorbed orally, with peak levels occurring 2 to 3 hours after ingestion.⁸ Protein binding is 30%, and the volume of distribution is 0.8 L/kg. Disopyramide is partially metabolized by the liver, with 55% being excreted unchanged in the urine. The half-life of disopyramide is approximately 8 hours.⁹

PATHOPHYSIOLOGY

A summary of reported adverse effects of these agents is found in Table 63-1.

TABLE 63-1 Noncardiac Effects of Class IA Antiarrhythmics

SYSTEM	EFFECTS
Central nervous	Giddiness, depression, hallucinations* Blurred vision, sedation†
Pulmonary	Pleural fibrosis*, pneumonitis‡
Gastrointestinal	Nausea, vomiting, diarrhea Hepatitis*,‡
Genitourinary	Urinary retention
Musculoskeletal	Myopathy with muscle weakness*
Skin	Rashes Lichen planus‡
Hematologic	IgG-mediated agranulocytosis*,* thrombocytopenia*,‡ IgM-mediated hemolysis (most often in patients with G6PD)‡
Rheumatologic	SLE*,‡
Other	Hypoglycemia†

*Primarily procainamide
†Primarily disopyramide
‡Primarily quinidine

Anticholinergic Effects

Many symptoms associated with class IA antiarrhythmics are related to the anticholinergic activity of these compounds. Disopyramide is the most anticholinergic, followed by procainamide and then quinidine. Confusion, hallucinations, tachycardia, decreased gastrointestinal motility, urinary retention, and dry mucous membranes all may occur with their use.³ Because some patients may suffer from cinchonism, the clinical presentation may be a confusing combination of the two syndromes.

Immune System Effects

Hypersensitivity reactions most commonly occur with quinidine but may also occur with procainamide and disopyramide. Hypersensitivity may be manifested as fever, rash, thrombocytopenia, neutropenia, agranulocytosis, hepatitis, hemolytic anemia, or lymphadenopathy.^{3,10-12} These reactions frequently are unrelated to dose.

Procainamide is the most common cause of drug-induced lupus. Antinuclear antibodies occur in 50% to 75% of patients treated with procainamide, and 20% to 30% of those patients develop components of drug-induced lupus.⁷ Patients suffer from arthralgias, myalgias, malar rash, fever, pleuritis, pleural effusion, and pericarditis. Renal involvement is rare.¹³ The mechanism responsible for the development of drug-induced lupus remains under investigation. Metabolic products of procainamide have been found to inhibit the covalent binding of C4 to C2 in the complement cascade, which is thought to decrease the clearance of immune complexes.^{14,15}

Thrombocytopenia has been reported to occur with therapeutic use of quinidine and procainamide.^{16,17} Drug-induced thrombocytopenia is an immune-mediated reaction. The sensitizing drug induces antiplatelet antibodies, which cause the rapid destruction of platelets.

Recovery is usually complete within 5 days of removal of the drug.¹⁷

Metabolic Effects

Symptomatic hypoglycemia has been reported to occur after therapeutic doses of disopyramide. Goldberg and colleagues demonstrated hypoglycemia with administration of disopyramide. Hypoglycemia could be reproduced on readministration of the drug.¹⁸ Quinidine and disopyramide, like the sulfonylureas, have the ability to block potassium efflux from pancreatic β -cells, thus leading to increased insulin secretion resulting in hyperinsulinemia (Fig. 63-2).¹⁹ Hyperinsulinemia is well documented with use of quinine, a stereoisomer of quinidine, and with disopyramide, but its occurrence in the presence of other class IA antiarrhythmics has not been clearly documented.^{18,20,21}

Cardiac Effects

The class IA antiarrhythmics, although structurally dissimilar, produce similar effects on the heart. These agents cause numerous cardiac arrhythmias, including heart block, atrial tachycardia, premature ventricular contractions, torsades de pointes, ventricular tachycardia, and ventricular fibrillation.^{3,10,22} The drug actions responsible for these arrhythmias are sodium channel blockade, potassium efflux blockade, and inhibition of the sodium/potassium-adenosine triphosphatase (Na^+/K^+ -ATPase) pump. Other drug effects may play a role in the development of arrhythmia, but these are not as well described. Dysrhythmias can occur at therapeutic as well as toxic serum concentrations of these drugs. The cardiac effects of quinidine are the most studied, but all

FIGURE 63-2 The presence of glucose or amino acids triggers the conversion of ATP to cAMP.¹ Cyclic AMP is needed to open calcium channels in the beta cell.² Calcium ions then enter the cell³ and bind with calmodulin to activate kinases such as myosin-light chain kinase or protein kinase C⁴ to stimulate the release of insulin⁵. The initial depolarization of the beta cell triggers potassium efflux.² The IA antiarrhythmics are thought to block the potassium efflux out of beta cells in the pancreas. This would prolong “depolarization” of the cell and increase secretion of insulin. (Adapted from Gerich JE: Oral hypoglycemic agents. *New Engl J Med* 1989;321:1231-1245.)

agents in this class act in a similar manner. Procainamide has less cardiotoxicity than quinidine and disopyramide at therapeutic doses.³

Effects on Ion Channels

In a normal Purkinje cell, the rapid influx of sodium ions in phase 0 causes the interior of the cell to become more positive (Fig. 63-3 and 63-4). Phase 1 is associated with slow leakage of potassium out of the cell, causing a decrease in positive charge within the cell, which brings the cell slightly closer to its resting potential. During phase 2, voltage-dependent calcium channels open, allowing calcium ions to enter. This calcium influx, which sustains the positive charge within the cell, is reflected as the plateau of phase 2. The slow leak of potassium from the cell during phase 2 balances the inward flow of calcium, and the net result is little change

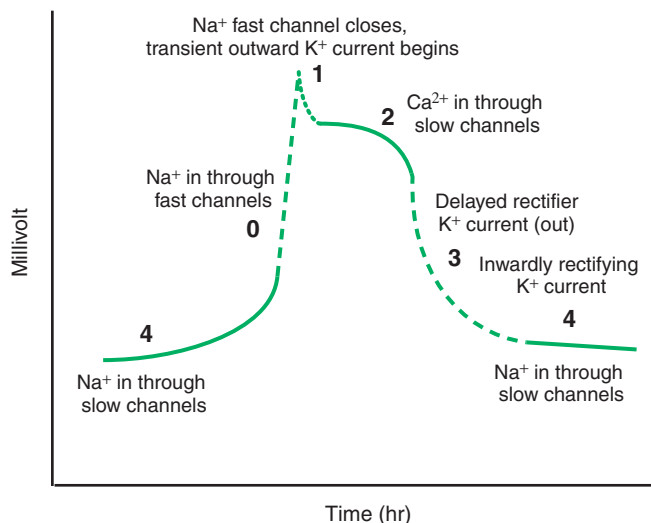

FIGURE 63-3 Ion flow during Purkinje cell action potential.

FIGURE 63-4 Normal Purkinje cell action potential and corresponding electrocardiographic pattern.

in the membrane potential. In phase 3, however, further leakage of potassium out of the cell (potassium efflux) repolarizes the cell. In phase 4, the charge within the cell has returned to its resting potential and sodium begins to enter the cell. This moves the cell membrane potential toward threshold again, and the next action potential can occur. Late phase 4 and phase 0 represent *depolarization* of the cardiac cell, whereas phases 1, 2, and 3 represent *repolarization*. Phases 0 to 3 correspond to systole, and phase 4 corresponds to diastole. Similar processes occur in other cardiac cells; however, each type of cardiac tissue has different concentrations of each kind of ion channel and thus has slightly varied patterns of depolarization and repolarization.

Sodium Channel Blockade

The IA antiarrhythmic agents can produce widening of the QRS, ventricular tachycardia, and decreased inotropy by blocking fast sodium channels in cardiac cells. Electrical conductance is dependent on the rapid influx of sodium through fast sodium channels. In terms of the action potential, this slows the rate of rise of phase 0 (V_{max}). Because phase 0 of the action potential corresponds to the QRS complex on the electrocardiogram (ECG), any toxin that slows the influx of sodium ions through the fast channels produces a widened QRS complex (Figs. 63-4 and 63-5). The class IA antiarrhythmics' ability to block Na^+ channels is dose dependent and is clinically significant only with high drug levels.^{22,23} At toxic serum concentrations, QRS widening, bundle branch block, and sinoatrial or atrioventricular block may be present.

The sodium channel blockade caused by class IA antiarrhythmics increases as the heart rate increases. Normally, as the heart rate increases, both action potential duration and effective refractory period shorten.²⁴ Studies using these agents have shown that the

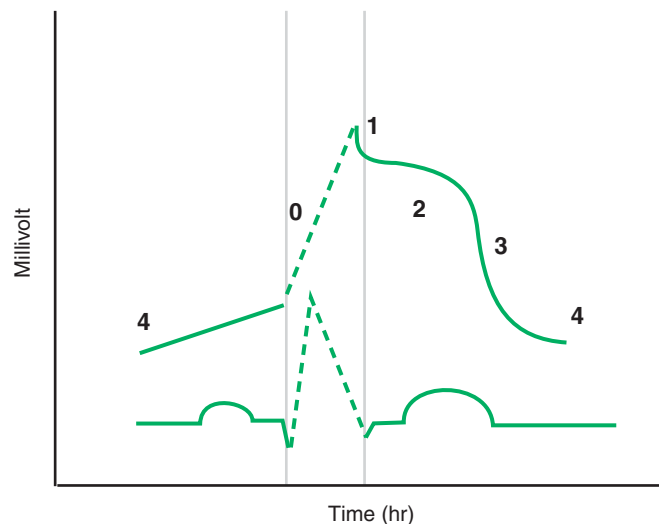

FIGURE 63-5 When sodium channels are blocked, the rate of rise of phase 0 (V_{max}) is decreased. This corresponds to a widening of the QRS complex.

action potential duration and effective refractory period have a greater relative increase at higher heart rates.²⁴⁻²⁷ Thus, they exhibit time-dependent suppression of excitability, and this effect is more pronounced at higher heart rates. This effect may be explained by the tendency of these drugs to bind to sodium channels in their open state. When heart rates are higher, there are more open sodium channels, and therefore more channels susceptible to blockade.²⁸ It may then be theorized that patients experiencing ventricular tachycardia secondary to procainamide and quinidine (and possibly disopyramide) toxicity may not respond favorably to overdrive pacing.²⁴

Potassium Channel Blockade

Repolarization in the heart is largely due to efflux of potassium out of the cells. When potassium channels are blocked, as with the class IA antiarrhythmics, repolarization is prolonged. Prolongation of repolarization is reflected by prolonged QT on the ECG. Blockade of the delayed rectifier current, I_{Kr} , is most often associated with drug-induced prolonged QT²⁹⁻³¹ (Fig. 63-6). With potassium efflux blockade, prolonged QT, premature ventricular contractions, and torsades de pointes can be seen. Development of torsades de pointes is most likely dependent on both repolarization abnormalities and triggered activity. When repolarization is disorganized, the possibility of reentrant circuits is increased, and reentrant circuits are responsible for torsades de pointes.^{28-30,32-37}

Afterdepolarization means electric oscillations of the conductive cell membrane that occur late in phase 2, throughout phase 3, or early in phase 4 of the action potential. This activity appears to occur primarily in Purkinje cells or deep subendocardial regions of the ventricular wall.³⁸ Afterdepolarization that occurs in phase 2 or 3 is known as *early afterdepolarization*. Early afterdepolarizations might be caused by calcium (L-type) current or sodium currents^{29,33,39} or might be due to

FIGURE 63-6 IA antiarrhythmics and other toxins may block the efflux of K^+ from the cardiac cell, driving the charge on the interior of the cell membrane in a less negative direction, toward threshold. This change in charge leads to early afterdepolarization (EAD) formation.

adrenergic effects.⁴⁰⁻⁴² Afterdepolarization occurring in early phase 4 is termed *delayed afterdepolarization*.³⁹ Early afterdepolarization–triggered activity tends to result in torsades de pointes. Delayed afterdepolarization activity tends to be more closely associated with premature ventricular contractions.^{26,43} The IA antiarrhythmics are capable of producing both.

Not all afterdepolarizations lead to dysrhythmias. Because they occur during the relative refractory period of cellular repolarization, some of these membrane oscillations do not cause the cell to fire again. If the cell has sufficiently repolarized, some afterdepolarizations are capable of reaching threshold and causing abnormal firing and dysrhythmias. Action potentials produced by afterdepolarizations that reach threshold are called *triggered activity* (Fig. 63-7). Triggered activity is partly responsible for the tachyarrhythmias that occur at therapeutic levels of the IA antiarrhythmics.^{28,29,36,43}

The development of torsades de pointes also revolves around heterogeneity of repolarization in the ventricles. If the triggered activity reaches area of muscle that is sufficiently repolarized, the impulse will be transmitted. As a result of different areas of cardiac muscle being in differing stages of repolarization, some areas will be refractory to depolarization from the triggered activity. The area of functional block creates the possibility for reentry, and reentrant circuits will propagate the arrhythmia.^{28,29,32,37,39,44,45}

Quinidine's potassium efflux blockade predominates at lower heart rates.^{46,47} This phenomenon is called *reverse use dependence*, meaning the duration of repolarization is greater at slower heart rates.^{28,48,49} Therefore, early afterdepolarization is more likely at slower heart rates.^{33,49} As the heart rate increases, quinidine's blockade of Na^+ channels is greater. Blockade of the movement of these positive ions into the interior of the cell keeps the blockade of potassium efflux counterbalanced.²⁷ The inside of the cell remains relatively more negative, making early afterdepolarization activity less likely and decreasing the risk of development of torsades de pointes.⁴⁶

Some patients may be at greater risk of developing torsades de pointes than others owing to a genetic

FIGURE 63-7 Blockade of potassium efflux out of the cells leads to membrane oscillations or afterdepolarizations. If they attain threshold voltage, “triggered activity” will occur.

predisposition of arrhythmia. Inherited defects of ion channels resulting in prolonged QT have variable penetrance, and not every carrier will manifest changes on a baseline ECG; however, this patient population may be at increased risk when exposed to agents that block potassium channels. This concept is termed *repolarization reserve*.^{30,50,51,52}

Na⁺/K⁺-ATPase Blockade

The premature ventricular contractions observed in overdose may be caused by inhibition of the Na⁺/K⁺-ATPase pump in cardiac cells. The Na⁺/K⁺-ATPase pump functions to repolarize the cell after contraction by transporting intracellular Na⁺ ions out of the cell in exchange for K⁺ ions transported into the cell. Class IA agents, in a fashion similar to digoxin, inhibit the Na⁺/K⁺-ATPase pump, resulting in intracellular Na⁺ accumulation.⁵³ The intracellular Na⁺ is exchanged for extracellular Ca²⁺ by the Na⁺/Ca²⁺ pump, causing an increase in intracellular Ca²⁺ (Fig. 63-8). Normally, the sarcoplasmic reticulum takes up cytoplasmic Ca²⁺ and stores it; however, excessive intracellular Ca²⁺ is thought to overload the sequestration mechanism of the sarcoplasmic reticulum. The increased intracellular Ca²⁺ then activates the Na⁺/Ca²⁺ pump, which stimulates the exchange of intracellular Ca²⁺ for extracellular Na⁺. This creates an inward current of Na⁺ ions and results in delayed afterdepolarizations^{33,39,43} (Fig. 63-9). These delayed afterdepolarizations can result in triggered activity, usually manifested by premature ventricular contractions. Afterdepolarizations reach threshold more frequently as the heart rate accelerates.

Dzimiri and Almotrefi demonstrated increasing inhibition of the Na⁺/K⁺-ATPase pump with decreasing serum potassium levels,⁵³ which may explain the exacerbation of arrhythmias caused by class IA antiarrhythmics by hypokalemia. Low serum potassium levels further inhibit the Na⁺/K⁺-ATPase pump, worsening intracellular Ca²⁺ overload and resulting in an increased frequency of delayed afterdepolarization with resultant arrhythmia

FIGURE 63-8 Inhibition of the Na⁺/K⁺-ATPase pump leads to an increase in intracellular Na⁺. This, in turn, leads to an exchange of Na⁺ for Ca²⁺ via the Na⁺/Ca²⁺ pump. The excess intracellular Ca²⁺ is sequestered in the sarcoplasmic reticulum (SR).

FIGURE 63-9 Delayed afterdepolarizations resulting in premature ventricular contraction (PVC).

FIGURE 63-10 If the inhibition of the Na⁺/K⁺-ATPase pump leads to Ca²⁺ overload of the cell, the sarcoplasmic reticulum is unable to compensate by sequestration and the internal charge begins to increase, leading to delayed afterdepolarization (DAD) formation.

(Fig. 63-10). Conditions associated with exacerbation of this process include digitalis toxicity, hypernatremia, hypokalemia, and catecholamine excess.⁵³

TOXICOLOGY

Significant ingestion of these drugs produces primarily neurologic and cardiovascular consequences.^{10,54} Ingestion of more than 1 g of quinidine by an adult has been reported to produce symptoms. As little as 7 g of procainamide or 1.5 g of disopyramide is potentially toxic. In assessing the severity of a toxic ingestion, it is important to remember that the reported history of the amount of a drug ingested is very unreliable and individual responses to these drugs vary greatly. Underlying cardiac disease may make some patients symptomatic at lower than expected doses.

Central Nervous System Toxicity

Toxicity from class IA antiarrhythmics may cause mydriasis and blurred vision. A patient's mental status

may range from lethargy and confusion to coma. Convulsions independent of hypotension secondary to quinidine have been reported.⁵⁴ Summers et al reported on a 69-year-old man who developed confusion and hallucinations while receiving quinidine during hospitalization for myocardial infarction.⁵⁵ The patient's mental status cleared after the administration of physostigmine, leading the investigators to conclude that mental status changes were due to anticholinergic toxicity.

Cardiovascular System Toxicity

The cardiotoxic effects of this class of drugs are the most threatening. Although tachycardia may be present early in serious poisoning, bradycardia secondary to conduction delays and blocks is most common. Other arrhythmias reported in overdose include atrial tachyarrhythmias, ventricular tachycardia, and fibrillation.⁵⁴ Risk factors for developing torsades de pointes include female sex, hypokalemia, bradycardia, long QT syndrome, and hypomagnesemia.^{30,33,37} Hypotension and shock associated with class IA antiarrhythmics are primarily related to depressive actions on the heart rather than to direct effects on the peripheral vasculature.^{56,57} Disopyramide exhibits the greatest negative inotropic effect of the three and has been reported to cause congestive heart failure with therapeutic use.^{3,58}

Quinidine syncope, which occurs at therapeutic and subtherapeutic levels, was initially thought to be caused by hypotension secondary to the vasodilatory effect of this drug. Ventricular tachyarrhythmias were ultimately determined to be responsible. Fifty percent of patients who develop torsades de pointes do so within the first 5 days of therapy; the remainder of the cases occurs weeks to years later, often after a dosage change.⁵⁹ Disopyramide and procainamide, although less frequently than quinidine, have also been reported to cause fatal arrhythmias in the therapeutic range.⁶⁰⁻⁶³ The arrhythmias usually are nonsustained but occasionally have been fatal. Sudden death while on quinidine therapy has been estimated at 0.5%.¹⁰ Both polymorphic ventricular tachycardia and torsades de pointes have been reported. Both rhythms can produce a rotating axis on an electrocardiogram but respond differently to various therapeutic interventions.⁶⁴ Torsades de pointes may be distinguished from polymorphic ventricular tachycardia by the following criteria: The initial complex follows a pause or sudden rate deceleration, which produces a long preceding RR interval. The initiating complex also has an accentuated U wave and occurs in the setting of a prolonged QT (Fig. 63-11).^{27,29,32,33,37,39,42-44,65,66}

There have been efforts to determine who is at risk for arrhythmia based on ECG interpretation. A QT interval greater than 500 ms^{37,39} or prolongation of the QT interval by greater than 50%⁵⁴ indicates greater risk for developing torsades de pointes. Not only does a long QT appear to have some prognostic value, but also QT dispersion may have some utility in stratifying high-risk patients who have quinidine-induced repolarization abnormalities. Several methods exist to measure QT dispersion, but in general it is calculated by measuring all QT segments, finding the shortest QT interval, and subtracting it from the longest QT segment. A value greater than 100 appears to predict arrhythmia.^{37,39,63,65}

Gastrointestinal System Toxicity

Dry mouth is a frequent complaint of patients exposed to class IA antiarrhythmics. Nausea, vomiting, and diarrhea also are common, although decreased bowel sounds, constipation, and ileus may occur secondary to the anticholinergic effects of these drugs.

Cinchonism

First described in association with quinine, the complex of symptoms called cinchonism may occur in chronic overuse or acute overdose of quinidine, although it is more common with quinine. This syndrome is characterized by abdominal pain, diarrhea, nausea, vomiting, hearing loss, tinnitus, visual disturbances, encephalopathy, coma, and seizures.¹⁰ Symptoms typically resolve after removal of the causative agent.

Genitourinary System Toxicity

Urinary retention and anuria have been reported. They are thought to be associated with the anticholinergic effects of these drugs.

Immune System Toxicity

Thrombocytopenic purpura, angioedema, exfoliative dermatitis, livedo reticularis, and photodermatitis have all been reported. Urticaria, flushing, pruritus, bullous reactions, lichen planus, psoriasis, erythroderma, and erythema multiforme have been seen.⁶⁷ Drug-induced lupus erythematosus is reported most frequently with procainamide, but is seen with other IA antiarrhythmics.

Musculoskeletal System Toxicity

Myositis, muscle weakness, and myopathy have been associated with therapeutic use. One patient has been

FIGURE 63-11 Rhythm strip of a patient with torsades de pointes suffering from chronic procainamide toxicity. Procainamide level was 27.5 $\mu\text{g/mL}$, and NAPA level was 62.4 $\mu\text{g/mL}$.

described with diaphragmatic paralysis while taking 750 mg of procainamide twice daily.⁶⁸

Pregnancy

The class IA antiarrhythmic agents clearly cross the placenta. No evidence shows that they are teratogenic. Disopyramide has been associated with premature uterine contractions, which resolved on discontinuance of the drug.⁶⁹

DRUG INTERACTIONS

A particular form of cytochrome P-450 inhibition has been described with quinidine use. Debrisoquin, an antihypertensive agent used in Europe, is metabolized by the cytochrome P-450 isozyme CYP2D6 (debrisoquin hydroxylase). A number of other drugs are metabolized by the same isozyme. Ten percent of the Western population is genetically deficient in this enzyme and metabolizes debrisoquin slowly. Quinidine, although not metabolized by this isozyme, binds to CYP2D6, interfering with its function. Commonly prescribed medications metabolized by this pathway, when taken with quinidine, are metabolized more slowly, causing higher than expected serum concentrations.⁷⁰ Drugs metabolized by CYP2D6 and potentially affected by quinidine are listed in Box 63-1.

Quinidine and Digitalis

Quinidine is thought to decrease the volume of distribution of some cardiac glycosides. This seems particularly true in the presence of digoxin. When these drugs are given concomitantly, the usual digoxin dose should be reduced by 50%.⁷¹

LABORATORY STUDIES

Serum quinidine levels of 1 to 4 $\mu\text{g}/\text{mL}$ are considered therapeutic. Toxic symptoms are expected at levels greater than 5 $\mu\text{g}/\text{mL}$. Combined serum levels of both procainamide and its active metabolite, NAPA, must be measured for evaluation of procainamide toxicity. A combined level greater than 30 $\mu\text{g}/\text{mL}$ is potentially cardiotoxic. Combined levels greater than 60 $\mu\text{g}/\text{mL}$ are likely to cause lethargy and hypotension. Disopyramide levels greater than 5 $\mu\text{g}/\text{mL}$ are considered toxic.

TREATMENT

General Management

Treatment of an overdose of a class IA antiarrhythmic should include early and aggressive management of the airway. The possibility of rapid decline in mental status and the onset of cardiac arrhythmias place these patients at very high risk of aspiration and pulmonary compromise. Once the airway is controlled, gastrointestinal

decontamination with oral activated charcoal may be considered. Repeat doses of charcoal are of minimal clinical benefit and may be harmful to patients with decreased gastrointestinal motility. Admission to an intensive care setting for cardiac monitoring is appropriate for all symptomatic patients.

Seizures secondary to use of class IA antiarrhythmics respond readily to administration of benzodiazepines. Loading with other anticonvulsants is not indicated unless the seizures are recurrent or prolonged. Phenobarbital, 15 mg/kg intravenously, should be used for persistent seizure activity. Higher doses may occasionally be required and can be associated with respiratory depression. Monitoring of creatine phosphokinase levels for evidence of rhabdomyolysis should be carried out for any patient “found down” (obtunded) for an unknown period.

Cardiac Toxicity

Class IA antiarrhythmics’ strong cardiac sodium channel blocker activity is responsible for the intraventricular conduction delays in overdose.⁵⁵ *Wide complex rhythms may respond to intravenous administration of a sodium bicarbonate bolus.*^{72,73} The exact mechanism of action of

sodium bicarbonate in the treatment of ventricular tachycardia secondary to Na⁺-blockade may be related to either the physical displacement of the drug from the Na⁺-channel by increased serum Na⁺-concentration⁷² or decreased binding to the channel by increasing the serum pH.^{73,74} Bradycardia unresponsive to atropine may require transcutaneous or transvenous pacing.⁵⁴ Hypotension should initially be treated with IV fluids. Patients with a history of cardiac dysfunction should be closely monitored for signs of fluid overload and may need placement of a Swan-Ganz catheter for continued evaluation of fluid status. Both epinephrine and dopamine are effective in treating associated hypotension.^{75,76}

Torsades de pointes is usually preceded by a relatively slow heart rate and a prolonged QT interval.^{1,3} Antiarrhythmics routinely used for ventricular tachycardia are often ineffective in its treatment. *Patients presenting with torsades de pointes of any origin should be given 2 g of intravenous magnesium sulfate followed by a 1- to 2-g/hr infusion.*^{64,77} Although the exact mechanism by which magnesium sulfate terminates torsades de pointes is not understood, research suggests it suppresses early afterdepolarization activity by shortening the plateau phase of cardiac depolarization.³ Hypokalemia also should be corrected. If these measures are ineffective, transvenous overdrive pacing may convert torsades de pointes.^{59,78-81} Isoproterenol may be considered but must be used with caution in patients with underlying cardiac disease.

Extracorporeal Drug Removal

Hemodialysis and hemoperfusion have been reported⁸²⁻⁸⁴ but are generally considered ineffective in the treatment of acute quinidine poisoning because of this drug's large volume of distribution and extensive protein binding.² The half-life of disopyramide is significantly reduced in patients undergoing hemodialysis, and this should be considered in patients not responding to supportive therapy.⁸⁵ Hemodialysis doubles the clearance of procainamide and provides a fourfold increase in elimination of NAPA, the active metabolite of procainamide.⁸⁶ Braden and associates demonstrated that hemoperfusion is superior to hemodialysis in the clearance of procainamide and NAPA.⁸⁷ Domoto et al showed that continuous arteriovenous hemofiltration provides even higher clearance than episodic hemoperfusion.⁸⁸ Dialysis equipment now capable of high flow rates may provide drug clearance that is equal if not superior to that of both hemofiltration and continuous arteriovenous hemofiltration.

Extracorporeal membrane oxygenation (ECMO) has been reported in a 16-month-old child. The ECMO course lasted 11 days with the toddler surviving neurologically intact.⁸⁹ Although ECMO is a consideration, the logistics make its use difficult and rare.

MICHAEL J. BURNS, MD ■ MICHAEL LEVINE, MD

At a Glance...

- Overdose of hypoglycemic agents (e.g., insulin, sulfonylureas, and meglitinides) is likely to produce hypoglycemia, whereas overdose of antihyperglycemic agents (e.g., α -glucosidase inhibitors, biguanides, and thiazolidinediones) is unlikely to result in hypoglycemia.
- Biguanide-associated lactic acidosis is associated with a high mortality rate and should be suspected in any critically ill patient taking metformin.
- Biguanide-associated lactic acidosis occurs most commonly in patients with renal, hepatic, or cardiac dysfunction or alcohol abuse.
- After treating hypoglycemia due to sulfonylurea ingestion with dextrose, octreotide should be given to prevent rebound hypoglycemia.
- All patients with intentional sulfonylurea overdoses, sulfonylurea exposures in children, and sulfonylurea ingestions associated with symptomatic hypoglycemia should be admitted for a 12- to 24-hour period of observation.
- Patients with inadvertent insulin reactions can usually be safely discharged after several hours of emergency department observation, whereas patients with intentional insulin overdose should be admitted for inpatient observation.

INTRODUCTION AND RELEVANT HISTORY

In recent years, the incidence of diabetes mellitus, especially type 2 diabetes, has dramatically increased in the United States and other Western countries. Currently, about 125 million people worldwide and 20 million Americans live with diabetes.¹⁻⁴ In patients with type 2 or non-insulin-dependent diabetes mellitus (NIDDM) (also known as *adult-onset diabetes*), insulin resistance is the primary abnormality, which often necessitates treatment with an oral hypoglycemic agent to achieve euglycemia. In patients with type 1 or insulin-dependent diabetes (IDDM), impaired insulin secretion is the primary abnormality, which necessitates treatment with exogenous insulin to maintain euglycemia.

Agents used to treat diabetes can be divided into two general categories: hypoglycemic agents (e.g., insulin, sulfonylureas, and meglitinides) and antihyperglycemic agents (e.g., biguanides, α -glucosidase inhibitors, and thiazolidinediones or glitazones).² Although these agents may be used alone, they are often used in combination to treat patients with both types of diabetes mellitus (see Chapter 16).

Insulin was first used to treat a patient with diabetes mellitus in 1921.³ Since that time, it has been the mainstay of treatment for type 1 diabetes patients and is some-

times part of the treatment regimen for those with type 2 diabetes.

In 1942, it was observed that certain sulfonamides were associated with hypoglycemia in animals.² Subsequently, a number of first-generation sulfonylurea compounds (i.e., tolbutamide, acetohexamide, tolazamide, and chlorpropamide) were created and marketed specifically for their hypoglycemic effect. In the 1950s, tolbutamide was the first sulfonylurea to be widely used for patients with type 2 diabetes.² In the 1980s, the second-generation agents (i.e., glyburide, gliclazide, glipizide, and glimepiride) became commercially available. These agents are significantly more potent than the first-generation agents. Currently, chlorpropamide, glyburide, and glipizide account for most prescriptions of oral hypoglycemic agents.

The biguanides, phenformin and buformin, became available for use as antihyperglycemic agents in the late 1950s.² Phenformin was subsequently withdrawn from the market in the United States and Europe in 1977 because of an association with lactic acidosis; it is still available in other areas of the world.⁵ Metformin, another biguanide less frequently associated with lactic acidosis, became available for use in Europe in 1970 and the United States in 1995.

Several other, novel classes of diabetes control agents were introduced in the late 1990s. In 1996, a new type of antihyperglycemic agent, referred to as an *α -glucosidase inhibitor*, became available for clinical use in the United States. Acarbose and miglitol are two agents in this class. In 1997, troglitazone was the first of the thiazolidinediones introduced to the U.S. market.⁶ Although troglitazone was removed from the U.S. market in 2000 because of its ability to cause a rare, idiosyncratic hepatocellular injury,⁷ other drugs in the glitazone class (i.e., rosiglitazone and pioglitazone) have become available and are frequently used.

The meglitinides, repaglinide and nateglinide, are in the latest class of antihyperglycemic agents to obtain approval for clinical use in the United States. Repaglinide became available for use in 1997, and nateglinide became available in 2000. Common diabetes control agents that are currently available for clinical use are listed in Table 64-1.

EPIDEMIOLOGY

Toxicity from diabetes control agents may be dose related, occurring after unintentional or intentional overdose, or idiosyncratic, occurring as unanticipated adverse effects during therapeutic administration. For the hypoglycemic agents, toxicity manifests largely as hypoglycemia or an overextension of the pharmacologic effects. Although

TABLE 64-1 Oral Hypoglycemic and Antihyperglycemic Agents

CLASS	GENERIC NAME	TRADE NAME	DURATION OF ACTION (hr)*
α -Glucosidase inhibitors	Acarbose	Precose	2
	Miglitol	Glyset	2
Biguanides	Metformin	Glucophage	1.5–4.9
Meglitinides	Nateglinide	Starlix	2–4
	Repaglinide	Prandin	1–3
Sulfonylureas (first generation)	Acetohexamide	Dymelor	12–18
	Chlorpropamide	Diabinese	24–72
	Tolazamide	Tolinase	16–24
	Tolbutamide	Orinase	6–12
Sulfonylureas (second generation)	Glyburide	Micronase, Glynase, DiaBeta	18–24
	Glipizide	Glucotrol, Glucotrol XL	16–24
Sulfonylureas (third generation)	Glimepiride	Amaryl	24
Thiazolidinediones	Pioglitazone	Actos	16–24
	Rosiglitazone	Avandia	12–24

In Hardman JG, Limbird LE, Gilman AG (eds): Goodman and Gilman's The Pharmacological Basis of Therapeutics, 10th ed. New York, McGraw-Hill, 2001, pp 1679–1714; Banting FG, Best CH, Collip JB, et al: Pancreatic extracts in the treatment of diabetes mellitus. Can Med Assoc J 1922;12:141–146; and Gerich JE: Oral hypoglycemic agents. N Engl J Med 1989;321:1123–1145.

agents from the antihyperglycemic class do not produce hypoglycemia when used alone, they can potentiate the hypoglycemic effect of the hypoglycemic agents when dosed with them.

The toxic effects occur commonly but are infrequently reported to U.S. poison control centers. Infrequent reporting of toxicity is likely due to the familiarity of most clinicians with the toxicity from these agents and its treatment. Most exposures are unintentional (78%) and occur in adults (68%), whereas most deaths follow acute exposure with suicidal intent.⁸ In 2003, 12,736 diabetes control agent exposures were reported to U.S. poison centers, of which 4019 (32%) were due to sulfonylureas, 3811 (30%) to biguanides, 2914 (23%) to insulin, and 1586 (12%) to thiazolidinediones. The remainder of the exposures were uncharacterized.⁸ Major toxicity and death occurred in 2.5% and 0.2% of all diabetes control agent exposures, respectively.⁸

STRUCTURE AND CLASSIFICATION

Sulfonylureas

The sulfonylureas are classified into two main groups: the first-generation agents include chlorpropamide, tolbutamide, acetohexamide, and tolazamide; the second-generation agents include glyburide (or glibenclamide), glipizide, and glimepiride. Glimepiride has sometimes been referred to as a third-generation agent. Additional agents available outside the United States include gliclazide and gliquidone. The sulfonylureas are *para*-substituted arylsulfonamides derived from sulfonic acid and urea. Sulfonylureas are closely related in structure to the sulfonamide antibiotics and thiazide diuretics. Differing side-chain substitutions on the *para* position of the benzene ring (R) and nitrogen on the urea moiety

(R₁) result in varying potency and duration of action² (Fig. 64-1). Second-generation agents are 100 to 150 times more potent than the first-generation agents owing to differing binding affinity at the sulfonylurea receptor.² Comparative characteristics of selected sulfonylureas are found in Table 64-2.

Biguanides

The biguanides contain two guanidine molecules linked together with the elimination of an amino group. Metformin is *N*-1,1-dimethylbiguanide hydrochloride and is the only biguanide currently available in the United States (see Fig. 64-1). Phenformin and buformin are still available in other countries.

α -Glucosidase Inhibitors

The α -glucosidase inhibitors are a relatively new class of drug used to treat diabetes. Acarbose, the first drug in this class approved for use in the United States, is a large, complex oligosaccharide derived from the microorganism *Actinoplanes utahensis* (see Fig. 64-1). Miglitol, which is considered a second-generation glucosidase inhibitor, has subsequently been approved. Meglitol is a small monosaccharide derivative that resembles glucose. Voglibose is currently pending U.S. Food and Drug Administration approval but is available in other countries.

Thiazolidinediones

Two thiazolidinedione derivatives are available for clinical use in the United States: rosiglitazone and pioglitazone⁹ (see Fig. 64-1). The thiazolidinediones are structurally unrelated to other diabetes control agents. These drugs are also available in a combination with other agents, such as metformin.

Meglitinides

The meglitinides are a novel class of insulin secretagogues that are structurally distinct from the sulfonylureas (see Fig. 64-1). They include repaglinide, which is a benzoic acid derivative, and nateglinide, which is a D-phenylalanine derivative.²

Insulin

Insulin is an endogenous protein hormone consisting of two polypeptide chains (A and B chains) connected by two intersubunit disulfide bonds (see Fig. 64-1 and Chapter 16). The β cells of the pancreatic islets synthesize insulin initially as the polypeptide precursor,

preproinsulin.² In the rough endoplasmic reticulum, a portion of preproinsulin is cleaved to form proinsulin. Subsequent proteolytic cleavage of proinsulin in the Golgi apparatus forms insulin and a connecting segment or C peptide. Insulin is stored in secretory granules (along with equimolar amounts of the inert C peptide) in β cells until release into the circulation.

Insulins may be classified according to their species of origin as porcine, bovine, or human and by their duration of action as short-, intermediate-, and long-acting (or regular, Lente, and Ultralente).^{2,10-12} Since 1921, insulin derived from beef or pork pancreas has been used therapeutically. During the past decade, however, human insulin has become the standard form of therapy. Human insulin is either derived enzymatically from pork insulin or produced from *Escherichia coli* using recombinant deoxyribonucleic acid techniques.² More recently, insulin analogs have also become commercially available.¹³

Insulin is prepared as an injectable solution for subcutaneous or intravenous administration. Doses and concentrations of insulin are expressed in units (U). Short-acting and rapid-acting insulins available for use include the readily soluble, regular (crystalline zinc insulin) formulation or the analogs lispro and aspart.² Intermediate-acting insulins include NPH (neutral protamine Hagedorn, an isophane suspension) and Lente (zinc suspension) formulations. Long-acting insulin preparations include Ultralente (extended insulin zinc suspension), protamine zinc suspension, and the analog glargine. The types of insulin and their pharmacokinetic properties are listed in Table 64-3.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Sulfonylureas

The major mechanism of action of the sulfonylureas is to stimulate endogenous insulin secretion by pancreatic

β cells. The sulfonylureas bind to a specific sulfonylurea receptor type 1 (SUR1) of adenosine triphosphate (ATP)-sensitive potassium channels (K_{ATP}). These potassium channels are located on the plasma membrane of β cells. Sulfonylurea binding to the receptor results in closure of the ATP-sensitive potassium channel, membrane depolarization, opening of voltage-sensitive calcium channels, and subsequent exocytic release of insulin. Second-generation agents have higher binding affinity and are, thus, more potent in their clinical effects. Other minor effects of sulfonylureas include reduced hepatic gluconeogenesis and clearance of insulin, suppressed glucagon and somatostatin secretion, and enhanced peripheral tissue sensitivity to insulin (stimulate synthesis of glucose transporters).² The extrapancreatic effects of sulfonylureas are not likely clinically significant in vivo.^{2,14,15}

Biguanides

The biguanides reduce fasting blood glucose levels and insulin concentrations by suppressing basal hepatic gluconeogenesis and improving peripheral tissue (i.e., fat, muscle) insulin sensitivity, thus enhancing peripheral insulin-mediated glucose uptake.² The biguanides potentiate insulin and are only effective in the presence of this hormone. Specifically, the biguanides increase the binding of insulin to its receptors, increase tyrosine kinase activity, and promote the synthesis and translocation of glucose transporters to the cell surface. The biguanides may also decrease blood glucose levels by impairing glucose absorption from the small intestine.¹⁶ The biguanides are not insulin secretagogues and do not cause hypoglycemia, even at large doses.² The biguanides also do not alter secretion of glucagon, cortisol, or somatostatin. Biguanides reduce blood triglycerides and free fatty acids.

The pathophysiology of lactic acidosis from biguanides is largely due to inhibition of gluconeogenesis.¹⁷⁻²² At supratherapeutic levels, biguanides inhibit pyruvate

**TABLE 64-3** Properties of Insulin Preparations Currently Available*

TYPE OF INSULIN	BRAND NAME	TIME TO ONSET (hr)	TIME TO PEAK EFFECT (hr)	DURATION OF ACTION (hr)
Rapid				
Regular (soluble crystalline zinc)	Novolin R	0.5–1	1.5–4	5–8
Lispro	Humalog	0.25	0.5–1.5	2–5
Aspart	NovoLog	0.17–0.33	1–3	3–5
Intermediate				
NPH (isophane insulin suspension)	Novolin N	1–1.5	4–12	24
Insulin zinc suspension	Lente	1–2	6–12	18–24
Slow				
Extended insulin zinc suspension	Ultralente	4–8	16–18	20–36
Glarginine	Lantus	2–5	5–24	18–24

*The pharmacokinetic data listed are for therapeutic doses with subcutaneous administration; times will vary with route of administration (intravenous versus subcutaneous administration and dose (therapeutic versus excessive doses).

carboxylase, the enzyme responsible for converting pyruvate to oxaloacetate (first step of gluconeogenesis). Elevations of pyruvate subsequently lead to lactate accumulation. Any condition that leads to elevated blood concentrations of biguanides (i.e., biguanide overdose, impaired excretion from hepatic and renal dysfunction) may precipitate lactate accumulation. Any medical condition that impairs lactate clearance (i.e., hepatic, renal, and cardiac dysfunction) will also lead to lactate accumulation and increase the risk for lactic acidosis. In addition, ethanol facilitates the accumulation of lactate; ethanol inhibits gluconeogenesis itself, and its metabolism results in an accumulation of reduced nicotinamide adenine dinucleotide (NADH), which inhibits conversion of lactate to pyruvate.

Biguanide-induced lactic acidosis is primarily type B, or that which occurs in the absence of tissue hypoxia or hypoperfusion, and results from impaired clearance of lactate. Type A lactic acidosis, or that which occurs in the presence of hypoxia or hypoperfusion, is from the increased production of lactate. Type A lactic acidosis may also be operative in the lactic acidosis induced by biguanides. Respiratory, cardiac, and renal dysfunction or polydrug overdoses that produce seizures, hypoxia, or tissue hypoperfusion lead to lactic acid accumulation. In addition, phenformin, unlike metformin, has the added ability to inhibit cellular oxidative phosphorylation directly and increase the tissue generation of lactate.^{20,22,23}

***α*-Glucosidase Inhibitors**

α-Glucosidase inhibitors have a unique mechanism of action, in that they are the only class of drug that is not directly designed to combat a specific pathophysiologic defect of type 2 diabetes.⁶ Rather, these agents competitively inhibit the activity of *α*-glucosidase, a brush-border enzyme responsible for breaking down disac-

charides (e.g., sucrose, maltose) and polysaccharides (e.g., starch) into monosaccharide. Therefore, the *α*-glucosidase inhibitors delay intestinal glucose absorption and diminish postprandial glucose elevations.²⁴ Acarbose also competitively inhibits the action of pancreatic *α*-amylase. These drugs are not insulin secretagogues and do not result in hypoglycemia.

Thiazolidinediones

The thiazolidinediones improve insulin sensitivity (largely in adipose tissue) and result in a reduction of fasting plasma glucose, insulin, and free fatty acids. These agents regulate gene expression and are associated with a delay of 4 to 12 weeks from initiation of dosing to therapeutic effects. The thiazolidinediones are selective agonists for the nuclear hormone receptor known as *peroxisome-proliferation-activated receptor-γ* (PPAR- γ).² After binding, there is activation of transcription of a variety of genes that regulate lipid and carbohydrate metabolism.^{6,25} Thus, similar to biguanides and *α*-glucosidase inhibitors, the thiazolidinediones do not stimulate the pancreatic β cells to secrete more insulin.

Meglitinides

Similar to sulfonylureas, meglitinides are insulin secretagogues that directly stimulate first-phase insulin release in pancreatic β cells. Although the meglitinides bind to a different receptor than the sulfonylureas, their mechanism of action is identical; their binding results in closure of K_{ATP} channels, membrane depolarization, opening of voltage-sensitive calcium channels, and subsequent exocytic release of insulin.^{2,26}

Unlike the sulfonylureas, however, the meglitinides do not stimulate insulin secretion in the absence of glucose. In addition, these agents (particularly nateglinide) induce a more rapid but less sustained secretion of

insulin than sulfonylureas.⁶ Although the magnitude of the glucose-lowering effects of repaglinide is similar to that of the sulfonylureas, it is associated with a significantly reduced risk for delayed hypoglycemia owing to a shorter duration of action.¹⁰ As compared with repaglinide, nateglinide has a higher binding affinity and quicker offset kinetics at the K_{ATP} channel. Thus, nateglinide has the more rapid onset and offset of insulinotropic effects of the two meglitinides.

Insulin

Insulin stimulates the uptake, utilization, and storage of glucose, amino acids, and fatty acids by peripheral tissues² (see Chapter 16). As an anabolic hormone, insulin impairs the catabolism of glycogen, proteins, and fats in all tissues. Insulin release by the pancreas is primarily regulated by and inversely correlated to blood glucose concentrations. Once released into the systemic circulation, insulin binds to specific membrane-bound receptors in peripheral tissues, which are ligand-activated protein kinases. Insulin binding stimulates tyrosine kinase activity, receptor autophosphorylation, and a cascade of phosphorylation and dephosphorylation reactions intracellularly, which serve to activate other intracellular signaling molecules.² The downstream effects of insulin binding are multiple. One such effect is the translocation of glucose transport proteins to the cell surface and subsequent enhanced glucose uptake by peripheral tissues (e.g., skeletal muscle and adipose tissue). In addition to stimulating the uptake of glucose by peripheral tissues, insulin also impairs hepatic gluconeogenesis and glycogenolysis. Insulin further promotes hypoglycemia by inhibiting protein degradation and lipolysis. The usual substrates for hepatic gluconeogenesis (e.g., alanine, glutamine, pyruvate, glycerol, nonesterified fatty acids) are reduced in the presence of insulin. In addition to its effects on carbohydrate, protein, and lipid metabolism, insulin promotes cellular uptake of potassium and magnesium.

PHARMACOKINETICS

Sulfonylureas

The sulfonylureas are available for oral administration only. These drugs are well absorbed from the gastrointestinal (GI) tract, with bioavailabilities greater than 80%.²⁷ Food and hyperglycemia reduce absorption. Once absorbed, all sulfonylureas are extensively (90% to 99%) bound to plasma proteins (predominantly albumin) and have small volumes of distribution (about 0.2 L/kg).^{2,27} With the exception of acetohexamide, all sulfonylureas are metabolized in the liver to inactive or less active metabolites; metabolites and small amounts of unchanged drug are eliminated in the urine. Acetohexamide is metabolized to hydroxyhexamide, which is more active and more slowly eliminated than the parent drug. Up to 20% of chlorpropamide is excreted unchanged in the urine.²

With therapeutic dosing, the hypoglycemic effects of these agents begin within 1 to 2 hours of oral dosing and peak by 4 to 6 hours; the first-generation agents may have a more delayed time to peak effect. Relative potencies, elimination half-lives, duration of hypoglycemic action, and therapeutic dose range are found in Table 64-2. With therapeutic dosing, the first-generation agents have variable elimination half-lives and a long duration of hypoglycemic action (12 to 24 hours), whereas the second-generation agents have short elimination half-lives and a long duration of hypoglycemic action (12 to 24 hours).^{2,27} After overdose, the duration of hypoglycemic action may last days.¹¹

Biguanides

After oral administration, metformin has a bioavailability of 30% to 60%; significant concentrations (27%) of unabsorbed drug are recovered from feces.²⁷ Peak plasma concentrations of metformin occur within 1 to 3 hours of a therapeutic dose. The antihyperglycemic effects of metformin begin in 1 hour and last about 12 hours after standard oral dosing. Metformin is not bound to plasma proteins, has a volume of distribution of 3.7 L/kg, and is largely excreted unchanged in the urine (50%) by both glomerular filtration and tubular secretion. At therapeutic doses, the plasma elimination half-life is estimated at 1.5 to 4.9 hours in subjects with normal renal function.²⁸ Geriatric patients or those with renal impairment have prolonged elimination half-lives. The recommended daily oral doses for normal adult patients range from 500 to 2500 mg, either as a single dose of the extended-release preparation or twice daily with the normal-release preparation. Metformin can be used either as a single agent or in combination with a sulfonylurea or insulin in the management of diabetes.

α -Glucosidase Inhibitors

Less than 2% of acarbose is absorbed from the GI tract, and more than 50% is excreted unchanged in the feces. Acarbose is metabolized in the GI tract by intestinal bacteria and digestive enzymes. Acarbose is mostly absorbed (34% of a dose) as metabolites of the parent drug. Elimination half-life of acarbose activity is normally about 2 hours in adults. Thus, bioaccumulation of the drug does not occur with dosing three times a day. Unlike acarbose, which has minimal absorption from the small intestine, miglitol is well absorbed from the small intestine. Both of these drugs have a small volume of distribution, and little to no protein binding at therapeutic doses. Miglitol is excreted unchanged by the kidney. The recommended oral dose for adult patients ranges from 25 to 100 mg three times daily, just before each meal.²

Thiazolidinediones

Rosiglitazone and pioglitazone are rapidly absorbed (peak blood concentrations within 1 to 2 hours), with a bioavailability of 99% and 50%, respectively. These drugs

are highly protein bound (99%) and have similar small volumes of distribution (0.2 to 1.0 L/kg) and elimination half-lives (2.7 to 7 hours). Both drugs are extensively metabolized by the liver cytochrome P-450 system. Pioglitazone is metabolized by CYP2C8 to metabolites with pharmacologic activity similar to and elimination half-lives longer than the parent drug. Rosiglitazone is metabolized by CYP3A4 to very weakly active compounds. No clinically significant drug interactions have been described with the thiazolidinediones.^{9,29} Although both thiazolidinediones are absorbed within 2 hours of oral administration, maximal clinical effect is not observed for 6 to 12 weeks. Pioglitazone is dosed from 15 to 45 mg once daily in adults, whereas rosiglitazone is administered as 4 to 8 mg daily in one or two divided doses.

Meglitinides

The meglitinides are rapidly absorbed from the GI tract, with peak blood concentrations observed within 0.5 to 1 hour of an oral therapeutic dose. The onset and duration of clinical effects are rapid, occurring within 1 and 4 hours, respectively. Bioavailability is about 60% for both agents. These drugs are highly protein bound (more than 98%) and have small volumes of distribution (0.4 L/kg). In addition, both drugs are metabolized by CYP3A4 to inactive metabolites.² Elimination half-lives are only 1 to 2 hours.²⁶ Drugs that enhance or inhibit CYP3A4 enzyme may decrease or increase the clinical effects of these drugs, respectively.^{2,30} Small amounts of each drug are excreted by the kidney unchanged (10% to 16%).² The recommended adult dose is 60 to 120 mg for nateglinide or 0.5 to 4 mg for repaglinide, three times daily, each dose administered within 10 minutes of a meal.

TOXICOLOGY: CLINICAL MANIFESTATIONS AFTER OVERDOSE

Sulfonylureas

The principal effect of overdose of any of the sulfonylurea agents, whether in a diabetic or nondiabetic individual, is hypoglycemia. Although hypoglycemia has been defined in absolute terms as a plasma glucose concentration of less than 2.78 mmol/L (50 mg/dL),³¹ it is perhaps more usefully defined in functional terms as a depressed concentration of blood or plasma glucose producing evidence of a physiologic counter-regulatory hormone response or evidence of neurologic dysfunction (neuroglycopenia). As the plasma glucose concentration decreases to about 4 mmol/L (72 mg/dL), there is an increase in the secretion of counter-regulatory hormones (e.g., glucagon, epinephrine, growth hormone, and cortisol) and activation of the autonomic nervous system. If the plasma glucose concentration reaches 3.2 mmol/L (58 mg/dL), this increase in autonomic activity is normally of a sufficient magnitude to result in symptoms. This response may be modified in

patients with diabetic autonomic neuropathy or in those who are receiving β -blocker therapy. Glucose is the principal energy substrate for the brain. The brain does not produce glucose and can only store a few minutes' supply. Therefore, the brain is extremely sensitive to hypoglycemia. Concentrations of circulating glucose below 3 mmol/L (54 mg/dL) impair cerebral function, whereas more severe and prolonged hypoglycemia can cause convulsions, permanent neurologic damage, or death.³²

The onset of hypoglycemia after acute sulfonylurea overdose occurs after a variable time interval; the latency is dependent on the size of the ingestion, the particular agent involved, and individual host factors (i.e., age, comorbid illness [hepatic or renal disease], presence of insulin resistance). It usually occurs within 6 to 8 hours of ingestion but may be delayed for 16 to 18 hours.^{33,34} In one study of sulfonylurea ingestion in children, 50% and 96% of patients developed hypoglycemia within 2 and 8 hours, respectively.³⁴ A single tablet is sufficient to produce symptomatic hypoglycemia in children.^{33,34} The duration of hypoglycemia is dose related and ranges from several hours to several days. In one case, hypoglycemia lasted for 27 days after intentional chlorpropamide overdose.¹¹

The signs and symptoms of sulfonylurea-induced hypoglycemia are identical to those associated with hypoglycemia from other causes. Signs and symptoms are manifestations of neuroglycopenia or are the consequence of the autonomic response to hypoglycemia (Box 64-1). Long-lasting or permanent neurologic dysfunction may occur if hypoglycemia is severe or prolonged before treatment.

BOX 64-1 SIGNS AND SYMPTOMS OF HYPOGLYCEMIA

Central Nervous System Effects (Neuroglycopenia)

- Lethargy to coma
- Dizziness
- Slurred speech, blurred vision, ataxia
- Irritability, anxiety, agitated delirium
- Headache
- Confusion, cognitive dysfunction, memory loss
- Seizures (single or multiple; focal or generalized)
- Focal neurologic deficits
- Hallucinations, altered personality
- Generalized weakness
- Paresthesias

Autonomic and Other Effects

- Diaphoresis
- Tachycardia, palpitations, tachyarrhythmias
- Syncope
- Hypertension
- Hunger
- Nausea, vomiting
- Tremor
- Piloerection
- Tachypnea
- Peripheral vasoconstriction, pallor
- Hypothermia

Biguanides

Acute biguanide overdose is usually well tolerated. GI effects occur most commonly and include nausea, vomiting, anorexia, hematemesis, metallic taste, abdominal pain, and diarrhea.³⁵⁻³⁷ Although hypoglycemia virtually never occurs in association with therapeutic doses of biguanides, it has rarely been described after overdose with these agents.³⁸ Biguanide-induced lactic acidosis is the most serious complication of biguanide treatment. It is most commonly associated with therapeutic dosing of biguanides (see “Adverse Effects”) but has also been described after acute, large, intentional overdose in adults.³⁹⁻⁴⁶ Lactic acidosis has not been described after accidental ingestion of 1 or 2 tablets of metformin in children.⁴⁷ Patients with biguanide-associated lactic acidosis typically present with relatively nonspecific symptoms, such as vomiting, somnolence, agitation, nausea, epigastric pain, anorexia, hyperpnea, lethargy, diarrhea, and thirst.²² Coma, hypothermia, seizures, and cardiovascular collapse may rapidly ensue.

α -Glucosidase Inhibitors

Overdose of the α -glucosidase inhibitors has not been reported in the literature. Signs and symptoms of overdose would be expected to include nausea, abdominal bloating and pain, flatulence, and diarrhea. Because these agents do not stimulate endogenous insulin release, they should not produce hypoglycemia with overdose.

Thiazolidinediones

There are no published data describing the effects of overdose with the thiazolidinediones. Supratherapeutic doses of these agents ingested over a week have not been associated with acute toxicity.³ Because this class of drugs does not stimulate insulin secretion, hypoglycemia is not expected to occur with overdose.

Meglitinides

As insulin secretagogues, meglitinides are expected to produce hypoglycemia after overdose. Unlike the sulfonylureas, however, these agents have a very short duration of action. Thus, the hypoglycemic effect should not be delayed in onset or prolonged in effect. Limited clinical overdose experience with meglitinides, however, precludes confident clinical predictions at this time. Nakayama and colleagues reported a case of a 30-year-old nondiabetic woman who presented to the emergency department 1 hour after ingesting 3420 mg of nateglinide in a suicide attempt.⁴⁸ Her initial blood glucose was 2 mmol/L (36 mg/dL) 1 hour after ingestion, which was treated with 50 mL of 50% dextrose. Four hours after ingestion, rebound hypoglycemia occurred, which necessitated further dextrose administration. The patient remained hypoglycemic for 6 hours after nateglinide ingestion. Surreptitious doses of repaglinide have been associated with severe hypoglycemia in an 18-year-old man.⁴⁹

Insulin

Insulin overdose manifests primarily as hypoglycemia (see Box 64-1). Other effects include various metabolic abnormalities, such as hypokalemia, hypomagnesemia, hypophosphatemia, and hypocalcemia. Cardiac effects are uncommon but include tachyarrhythmias (i.e., atrial fibrillation, premature atrial and ventricular contractions, and ventricular tachycardia), bradyarrhythmias (i.e., sinus bradycardia, heart block), repolarization abnormalities on the electrocardiogram (i.e., T-wave flattening, ST-T changes, and QTc prolongation), angina and myocardial infarction, congestive heart failure, and hypertension. Hypothermia may occur with prolonged hypoglycemia. As for sulfonylureas, prolonged hypoglycemia may be associated with prolonged or permanent neurologic deficits.⁵⁰

Insulin-induced hypoglycemia occurs very commonly as an unintentional adverse effect (see “Adverse Effects”) but may also occur as an intentional overdose (self-poisoning with suicidal intent, poisoning of others with homicidal intent, or as part of Munchausen syndrome or Munchausen syndrome by proxy). Although intentional insulin overdose is uncommon, it likely occurs more frequently than is recognized or reported. In 2003, 2914 insulin exposures were reported to U.S. poison control centers, of which 493 (17%) were categorized as intentional.⁸ The time of onset and duration of hypoglycemia that occur with insulin overdose depend on the type and dose of insulin preparation used, the blood glucose of the patient, the caloric intake of the patient just before and after the overdose, and the presence of insulin antibodies (insulin resistance) in the patient. The onset of hypoglycemia may be delayed after overdose with extended-release preparations (e.g., NPH and Lente).⁵¹ The duration of hypoglycemia may be prolonged and last for days after massive subcutaneous overdose of insulin.⁵²

ADVERSE EFFECTS

Sulfonylureas

Sulfonylureas are generally well tolerated; adverse effects occur in 2% to 4% of patients, with less than 2% of patients discontinuing therapy because of side effects.^{15,53}

As for sulfonylurea overdose, the most common and severe complication of sulfonylurea therapeutic dosing is hypoglycemia. Hypoglycemia is simply an extension of the therapeutic objective and effects of these agents. Hypoglycemia occurs in 2% to 4% of patients; severe hypoglycemia requiring patient hospitalization occurs in 0.4 cases per 10,000 patient-years of treatment.^{53,54} Clinically significant hypoglycemic reactions occur more commonly with agents that have a longer duration of action² (see Table 64-2). Risk factors for sulfonylurea-induced hypoglycemia include an age older than 60 years, impaired renal and hepatic function, poor nutrition, and multidrug therapy.^{55,56} The use of other diabetes control agents may result in inadvertent hypoglycemia from syn-

ergistic effects (pharmacodynamic interaction). Alternatively, hypoglycemia may occur with the coadministration of drugs that interfere with sulfonylurea protein binding, metabolism, or excretion (pharmacokinetic interaction). The concurrent use of sulfonylureas with the histamine-2 (H_2) receptor antagonists cimetidine and ranitidine, or with the antifungal azole derivatives ketoconazole and fluconazole, is associated with increased incidence of hypoglycemia.²⁹ In addition, the antibiotics doxycycline, ciprofloxacin, and gatifloxacin have been associated with increased incidence of hypoglycemia in patients taking sulfonylureas.⁵⁷⁻⁵⁹ Furthermore, clofibrate, dicumarol, sulfonamides, sulfamethoxazole, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs (e.g., phenylbutazone, salicylates), β blockers, and ethanol may potentiate the hypoglycemic activity of these agents.^{2,29,60}

Other adverse effects of sulfonylureas include hematologic (e.g., hemolytic anemia, bone marrow aplasia) and dermatologic (e.g., rashes, pruritus, erythema nodosum, erythema multiforme, and exfoliative dermatitis) complications. These effects are rare hypersensitivity reactions and usually occur during the first 6 weeks of therapy. Their incidence is less than 0.1% with all agents. GI side effects include nausea, vomiting, cholestatic jaundice, and liver function test abnormalities; they occur with a frequency of 1% to 3%. Weight gain is common in patients who achieve improved glycemic control and is probably the result of reduced caloric loss associated with the diminution in glycosuria.^{9,61} Chlorpropamide, unique among the sulfonylureas, has been associated with a disulfiram-type reaction. Some sulfonylureas (e.g., chlorpropamide, glyburide, and glipizide) may produce hyponatremia by inducing increased renal sensitivity to antidiuretic hormone (syndrome of inappropriate antidiuretic hormone, or SIADH).^{2,9,53} The sulfonylureas may be associated with an increased risk for cardiovascular mortality, but the data supporting this theory are conflicting.^{2,62} In addition, some sulfonylureas can precipitate acute porphyria in susceptible individuals.⁹

Biguanides

When used at therapeutic doses, the most common side effects associated with metformin are GI and include anorexia, nausea, abdominal discomfort, and diarrhea. These symptoms occur in up to 20% of patients shortly after initiating therapy with metformin, but only rarely persist.² Nonetheless, about 10% of patients cannot tolerate the drug at any dose.⁹ A metallic taste can also be observed in about 3% of patients taking metformin.⁶³

The most serious adverse effect of metformin is lactic acidosis, which occurs in 0.06 cases per 1000 patient-years.¹⁷ The incidence is significantly less with metformin therapy than with phenformin. Lactic acidosis is defined as a metabolic acidosis due to an accumulation of lactic acid in the blood in excess of 5 mmol/L with an accompanying blood pH of less than 7.35.^{18,19} Biguanide-associated lactic acidosis is initially a type B lactic acidosis (not associated with tissue hypoxia or hypoperfusion).

BOX 64-2

CONTRAINDICATIONS TO BIGUANIDE THERAPY

- Renal impairment (plasma creatinine > 1.5 mg/dL [132 μ mol/L] for men, > 1.4 mg/dL [124 μ mol/L] for women)
- Cardiac or respiratory failure of sufficient magnitude to cause central hypoxia or reduced peripheral perfusion
- History of lactic acidosis
- Acute or chronic metabolic acidosis
- Severe infection that could lead to decreased tissue perfusion
- Liver dysfunction (demonstrated by abnormal liver function tests)
- Alcohol abuse with binge drinking sufficient to cause acute hepatotoxicity
- Use of iodinated radiographic contrast material (within 48 hours)
- Pregnancy

Adapted from Bailey CJ, Turner RC: Metformin. *N Engl J Med* 1996;334:574-579.

Type A lactic acidosis, however, is often superimposed on type B lactic acidosis in patients who are critically ill.

Biguanide-associated lactic acidosis has a mortality rate of 12% to 50%.²² When this complication occurs at therapeutic doses, it usually is in the context of having been prescribed in patients for whom the drug was initially contraindicated (Box 64-2). It appears that a critical blood level of biguanide, as yet undefined, is required to produce the metabolic abnormalities that lead to lactic acidosis.⁶⁴ The listed contraindications, especially impaired renal function, are likely to result in impaired elimination and excessive blood levels of metformin, thus increasing the likelihood of the critical blood level and accumulation of lactic acid (see "Pharmacology and Pathophysiology"). As already stated, significant lactic acidosis may also occur after metformin overdose in the absence of established risk factors.^{39,40}

In patients with metformin-associated lactic acidosis, there are frequently additional factors that increase blood lactate concentrations, such as major illness causing tissue hypoperfusion or liver disease.^{28,65} Thus, an elevated plasma lactate concentration in someone who regularly takes metformin may primarily represent an underlying systemic process (e.g., septic shock) and not a direct complication of metformin therapy.²⁸ Iodinated contrast materials may create a predisposition to metformin-induced lactic acidosis. Current consensus recommendations are to withhold metformin for 24 to 48 hours before a planned procedure that necessitates administration of iodinated contrast. The metformin should not be reinstated until at least 48 hours after the iodinated contrast administration.⁶⁶ Finally, treatment with metformin should be withheld if plasma lactate levels exceed 3 mmol/L (more than 3 mEq/L).²

α -Glucosidase Inhibitors

Adverse effects associated with the α -glucosidase inhibitors are primarily GI and include dose-related increases in flatulence, abdominal discomfort and bloating, and diarrhea.² Adverse effects tend to diminish with continued use.⁶⁷ Thus, side effects can be minimized by

starting with low doses and titrating the dose upward at 4- to 8-week intervals.² Although approved for monotherapy, this class of drug rarely is used alone owing to its mild efficacy. More frequently, the α -glucosidase inhibitors are used in combination with sulfonylureas or insulin. This class of drugs is associated with dose-dependent hepatotoxicity (elevations of hepatic transaminases).⁶⁸ Hepatic transaminase elevations are usually asymptomatic and reversible with drug cessation.

Thiazolidinediones

The thiazolidinediones are relatively well tolerated. Side effects, when they occur, include anemia, edema, headache, myalgia, and weight gain. On average, the thiazolidinediones cause an increase of 2 to 3 pounds for every 1% decrease in glycosylated hemoglobin value.²⁵ Thus, these agents should be given cautiously, if at all, to patients with advanced heart failure or anemia. In Europe, the presence of congestive heart failure is considered a contraindication to the use of thiazolidinediones.⁹ Idiosyncratic hepatotoxicity has rarely been associated with pioglitazone or rosiglitazone therapy.^{69,70} The presence of hepatic dysfunction is considered a contraindication to treatment with thiazolidinediones. Hypoglycemia does not occur with thiazolidinedione monotherapy but has been described during combination therapy with sulfonylureas or insulin.

Meglitinides

The most common adverse effects from meglitinides include GI symptoms, weight gain, and hypoglycemia. Repaglinide has an incidence of adverse reactions similar to that observed with sulfonylureas, whereas nateglinide appears to be better tolerated.^{2,6,26,30} Nateglinide appears to have a hypoglycemic effect that is more mild.³⁰

Insulin

The primary adverse reaction from insulin is hypoglycemia.² Hypoglycemia may occur from an increase in insulin dose, change in insulin preparation, decreased food intake, increased exercise, or impaired insulin clearance (in those with renal dysfunction). The time of onset of hypoglycemia and time to peak hypoglycemic effect after therapeutic doses of insulin have been established and are listed in Table 64-3. The duration of hypoglycemia is less than that observed with insulin overdoses. Hypokalemia, hypomagnesemia, and hypophosphatemia may also occur as adverse effects of insulin, particularly if insulin is administered at high therapeutic doses.

DIAGNOSIS

The diagnosis of acute toxicity from diabetes control agents often occurs in the setting of symptomatic hypoglycemia and a positive history of exposure. Hypoglycemia should be considered in every patient who

TABLE 64-4 Dosing of Dextrose

AGE	DEXTROSE
Adults	0.5–1.0 g/kg or 1–2 mL/kg D-50 (50% dextrose)
Children	2–4 mL/kg D-25
Infants/newborns	5–10 mL/kg D-10

presents after a seizure or with an alteration in mental status. The diagnosis should be rapidly excluded or confirmed on the basis of a bedside test for blood glucose concentration. When this cannot be done rapidly, or when the result is equivocal, an intravenous bolus of 50% dextrose (0.5 to 1 g/kg or 1 to 2 mL/kg D-50-W; Table 64-4) should be administered empirically. The diagnosis of hypoglycemia typically requires symptoms and a positive response to supplemental dextrose. A lack of response, however, does not exclude the diagnosis because prolonged, severe hypoglycemia can result in permanent neurology deficits that will not respond to correction of hypoglycemia. If a diagnosis of hypoglycemia is made, a patient history may help to establish whether toxicity from a diabetes control agent (e.g., sulfonylurea, meglitinides, insulin) is the likely cause. If the history does not suggest the diagnosis, other drug-associated and medical causes of hypoglycemia should be considered and addressed (Box 64-3).

Specific drug levels are rarely necessary to make the diagnosis. When no explanation for hypoglycemia is initially apparent, however, measurements of serum insulin, C peptide, proinsulin, and sulfonylurea concentrations and a urine screen for sulfonylureas may be helpful to establish a diagnosis, particularly in the setting of accidental, surreptitious, or felonious poisoning. Standard blood and urine toxic screens should be performed to rule out the presence of other drugs associated with hypoglycemia (e.g., ethanol, salicylate). Because therapeutic doses of sulfonylureas can produce hypoglycemia, the qualitative presence of this class of agents in blood or urine of patients not regularly prescribed these drugs is sufficient to confirm the diagnosis. In the presence of exogenous insulin injection, C peptide and proinsulin levels are low. In the presence of sulfonylurea or meglitinide toxicity (insulin secretagogues) or an insulinoma, the proinsulin, insulin, and C-peptide levels should be elevated. Insulinomas can be differentiated from ingestion of insulin secretagogues by the presence of very high proinsulin levels in patients with insulinomas, with an increased ratio of proinsulin to insulin.⁷¹

The diagnosis of biguanide-induced lactic acidosis should be suspected in any patient receiving therapeutic or taking excessive doses of biguanides who becomes ill. Laboratory analysis in these patients should include measurements of blood glucose, blood urea nitrogen, creatinine, electrolytes, and lactate and urinalysis. The diagnosis is confirmed by documentation of an anion-gap metabolic acidosis and an elevated serum lactate level (more than 5 mmol/L). For patients with an elevated

anion gap or blood lactate level, an arterial blood gas should be performed. The hallmark of biguanide-associated lactic acidosis is severe acidosis without evidence of hypotension or hypoxia.

TREATMENT**Overview**

Treatment of diabetes control agent poisoning is largely directed at evaluating for and treating hypoglycemia. Although patients with significant central nervous system or respiratory depression may sometimes need airway protection, breathing assistance, and cardiovascular support, correction of hypoglycemia may be sufficient to normalize neurologic or cardiopulmonary function. In addition to fingerstick glucose determination and dextrose administration as necessary, supplemental oxygen, continuous pulse oximetry, and parenteral thiamine and naloxone should be considered in patients with altered mental status or seizures. All symptomatic patients should have an intravenous line established and continuous cardiac monitoring performed. Frequent neurologic evaluation and vital sign and fingerstick determinations should be performed in the initial several hours of evaluation. Fluid and electrolyte abnormalities should be corrected as necessary. Therapy (e.g., antidotal treatment, enhanced elimination) that is unique to each class of agents is discussed below.

After initial patient stabilization, GI decontamination is recommended for patients who present after acute oral overdose of most diabetes control agents. Single-dose administration of activated charcoal (1 g/kg orally or by nasogastric tube) is the preferred method of GI decontamination. Orogastric lavage is not routinely recommended because the risk for death after acute diabetes control agent overdose is very low. If performed, gastric lavage should be followed by the administration of activated charcoal.

Sulfonylurea Poisoning

Treatment with dextrose should be reserved for patients with symptomatic hypoglycemia and withheld from patients with low blood glucose values in the absence of symptoms. The administration of dextrose to an asymptomatic patient with numeric hypoglycemia may necessitate further treatment with dextrose and force a prolonged period of observation. Even in the absence of sulfonylurea exposure, exogenous dextrose administration can stimulate further insulin secretion, particularly when associated with transient hyperglycemia (overshoot). Rebound euglycemia or hypoglycemia often occurs and requires further treatment with dextrose. This pattern of cyclical hypoglycemia often results in a longer period of observation that would not have been necessary if dextrose had not been administered initially.

Treatment with oral dextrose may be sufficient for patients with mild hypoglycemia, whereas those with significant symptoms should receive an intravenous bolus of concentrated dextrose (see Table 64-4). It is advisable to give no more dextrose than is necessary to achieve euglycemia; overshoot may precipitate rebound hypoglycemia. Frequent fingerstick blood glucose determinations help to guide initial and continued dextrose supplementation. Once euglycemia is achieved, patients

should be given a meal if oral intake is feasible and not contraindicated. A continuous infusion of 10% to 20% dextrose in water (D-10 to D-20) may be necessary to maintain euglycemia in patients with an intentional sulfonylurea overdose. If concentrations of 20% dextrose or greater are used, the infusion should be given through a central venous catheter to avoid damage to peripheral veins.

If oral dextrose is not an option (owing to patient altered mental status) and intravenous dextrose cannot be administered because of difficulty with intravenous access, glucagon can be administered to produce a temporary elevation in blood glucose. Glucagon is particularly helpful in the preadmission setting. Glucagon is administered by intramuscular or subcutaneous injection (1 mg for adults and children greater than 20 kg; 0.5 mg for children less than 20 kg). Glucagon increases blood glucose by promoting glycogenolysis and gluconeogenesis. It is usually effective only when adequate glycogen stores exist. Glucagon stimulates insulin release and, thus, needs to be followed by the parenteral administration of glucose.⁷² Glucagon is only a bridging therapy before successful intravenous access and dextrose administration. Glucagon administration may be associated with nausea and vomiting.

In the setting of sulfonylurea toxicity, a profound rebound or recurrent hypoglycemia often occurs within 30 minutes of initial dextrose administration.⁷³ Although dextrose is the recommended initial treatment for all episodes of symptomatic hypoglycemia, a number of additional drugs can be used as adjuncts in the management of sulfonylurea-induced hypoglycemia.

The antihypertensive diazoxide effectively inhibits insulin secretion from the pancreatic β cells and has been used successfully in the management of refractory sulfonylurea-induced hypoglycemia.⁷⁴ Specifically, diazoxide may bind at the sulfonylurea binding site to prevent membrane depolarization and insulin release. Diazoxide is given by slow intravenous infusion over 30 minutes (3 mg/kg in adults; 1 to 3 mg/kg in children); the dose may be repeated every 4 hours. Diazoxide is complicated by orthostatic hypotension, tachycardia, and sodium and water retention.

Octreotide, a long-acting synthetic analog of somatostatin, is a potent inhibitor of insulin, glucagon, and growth hormone secretion. It has been reported to effectively inhibit excessive insulin secretion and significantly reduce dextrose requirements after sulfonylurea overdose. With octreotide treatment, insulin levels are reduced to baseline values, and there are fewer episodes of rebound hypoglycemia.⁷³⁻⁷⁹ It appears that octreotide is superior to diazoxide for reducing the subsequent amount of glucose needed after the initial dextrose treatment.^{73,74} The use of dextrose followed by octreotide should be considered first-line therapy in patients with sulfonylurea-induced hypoglycemia. Octreotide should be dosed in all individuals with a single episode of symptomatic hypoglycemia; it is not necessary to wait for recurrent hypoglycemia. Octreotide can be given by subcutaneous or intravenous injection (1 to 2 μ g/kg in children and 50 to 100 μ g in adults).⁷⁶ The dose can be

repeated in 6 to 12 hours, if clinically necessary. No significant side effects occur with octreotide therapy.

Activated charcoal has been demonstrated to bind effectively to chlorpropamide, tolbutamide, tolazamide, glibenclamide, and glipizide in vitro,⁸⁰ and to tolbutamide, chlorpropamide, and glipizide in vivo.⁸¹⁻⁸³ Although there has not previously been a study demonstrating clinical benefit from the administration of activated charcoal to patients who overdose on sulfonylureas, its administration is recommended in the overdose setting. The role of whole bowel irrigation is unknown after ingestion of sustained-release agents (e.g., Glucotrol XL) from this class.

Most cases of sulfonylurea overdoses are adequately managed with dextrose supplementation, and attempts at enhanced elimination are not indicated. Alkalinization of the urine has been demonstrated to enhance the excretion of chlorpropamide (a weak acid, pKa 4.8), reducing its elimination half-life from 50 to 13 hours.⁸¹ However, in their position statement on urinary alkalinization, the American Academy of Clinical Toxicology and the European Association of Poison Centers and Clinical Toxicologists state "as the administration of dextrose alone is effective treatment in the majority of patients with chlorpropamide poisoning, which is now rare, urine alkalinization is only likely to be employed very occasionally."⁸⁴ Urinary alkalinization is not expected to enhance urinary excretion of other sulfonylureas.

Charcoal hemoperfusion was demonstrated to enhance elimination of chlorpropamide after overdose by a man with chronic renal failure.⁸⁵ In general, the use of extracorporeal methods to enhance removal of sulfonylureas is not recommended; most agents are metabolized in the liver. Repeat-dose activated charcoal is ineffective in enhancing elimination of chlorpropamide, and therefore is not recommended.⁸⁶ The use of multidose activated charcoal has not been investigated for other sulfonylureas.

Metformin Poisoning

The treatment of biguanide toxicity is supportive. Initial management should focus on stabilization of the airway, breathing, and circulation. Adequate and early volume expansion is essential and may improve lactic acidosis. Hypoglycemia, although rarely present or profound, should be corrected with intravenous dextrose administration.

The administration of intravenous bicarbonate to those with biguanide-induced lactic acidosis is controversial. Sodium bicarbonate may be detrimental by resulting in paradoxical acidification of cerebrospinal and intracellular fluid; increased hemoglobin affinity for oxygen, leading to impaired oxygen delivery to the tissues; hypernatremia and volume overload; severe hypokalemia and hypocalcemia; and increased cellular membrane permeability to biguanides, resulting in further increases in cellular lactate production.^{87,88} Sodium bicarbonate therapy is not recommended because it has not been associated with clinical benefit in patients with biguanide-induced or other forms of lactic acidosis.⁸⁸⁻⁹¹

Hemodialysis with a bicarbonate dialysate has been reported to dramatically increase the survival rate of patients with metformin-induced lactic acidosis. Lalau and associates reported on five patients with severe metformin-induced lactic acidosis, whose clinical status and metabolic abnormalities rapidly responded to bicarbonate hemodialysis despite incomplete removal of metformin as determined by serum sampling. All patients had acute renal failure, and three were in cardiovascular collapse at the time of presentation.⁹² In addition, Teale and colleagues reported on two patients with intentional metformin overdose with cardiovascular collapse, who were successfully managed with continuous venovenous hemodiafiltration.³⁹ Hemodialysis is recommended as first-line treatment in patients with severe biguanide-induced lactic acidosis.

α-Glucosidase Inhibitor and Thiazolidinedione Poisoning

The initial management of toxicity associated with α -glucosidase inhibitors and thiazolidinediones is supportive. Adequate volume expansion should be commenced early, if indicated. Hypoglycemia, which should only occur when these agents are ingested in combination with insulin secretagogues, should be treated with intravenous dextrose administration. In addition to standard laboratory analysis in poisoned patients, liver function tests should be obtained in patients who overdose on α -glucosidase inhibitors.

Meglitinide Poisoning

Treatment is aimed at correcting symptomatic hypoglycemia with administration of intravenous dextrose as necessary. The risk for and duration of hypoglycemia should last only a few hours after ingestion of meglitinides. Thus, a 4-hour period of observation is sufficient for patients who ingest meglitinides, even for those who required initial treatment with dextrose for symptomatic hypoglycemia.

Insulin Toxicity

The mainstay of treatment for insulin toxicity is the administration of supplemental dextrose for symptomatic hypoglycemia and correction of coexisting metabolic abnormalities (e.g., hypokalemia) as necessary. As for sulfonylurea toxicity, patients with mild hypoglycemia may be given an oral, rapidly acting dextrose formulation followed by a small meal. Patients who develop significant symptomatic hypoglycemia should receive an intravenous bolus of concentrated dextrose (see Table 64-4) followed by a continuous infusion of 10% or 20% dextrose. As for sulfonylurea overdose, overzealous administration of dextrose may precipitate rebound hyperinsulinemia (for patients without type 1 diabetes). Thus, the dextrose infusion should be titrated to just maintain euglycemia.

Oral overdose of insulin will not produce clinical effects because of rapid breakdown in the stomach.

Prolonged hypoglycemia (lasting days) has occurred in patients who have intentionally injected large subcutaneous overdoses of insulin.⁹³ Although surgical excision of skin and subcutaneous tissue insulin depots has been described for such patients, the clinical utility of this approach is unknown and cannot be recommended.^{94,95,96}

DISPOSITION

Because of the potential for prolonged hypoglycemic effects, all patients who develop symptomatic hypoglycemia from sulfonylureas require admission for ongoing blood glucose monitoring and therapy with intravenous dextrose and octreotide, as necessary. The onset of hypoglycemia after sulfonylurea overdose may be delayed for up to 18 hours; therefore, all patients with deliberate overdose and all children with suspected ingestion must be admitted for up to 24 hours. A hospitalized patient is ready for medical discharge when euglycemia has been maintained for a period of 8 to 12 hours after the last dose of octreotide and supplemental parenteral dextrose. Appropriate psychiatric evaluation in cases of deliberate self-overdose should take place before final discharge. When the overdose was inadvertent, appropriate educational intervention should occur before discharge.

Evidence of lactic acidosis associated with biguanide therapy or after biguanide overdose mandates hospital admission. Lactic acidosis is unlikely to develop in individuals with normal renal function after relatively small ingestions of metformin, but because a dose-response relationship has not been well characterized, all patients with metformin overdose should be observed for at least 6 hours. If there is no evidence of acidosis or hypoglycemia, and the patient remains asymptomatic at that time, then the patient may be discharged after appropriate psychiatric evaluation and educational intervention.

For patients who ingest excessive doses of the thiazolidinediones, α -glucosidase inhibitors, or meglitinides, a 4- to 6-hour observation period is appropriate. The observation period may need to be extended if hypoglycemia occurs.

The duration of hospital observation necessary after insulin toxicity depends on the quantity and type of insulin injected, patient intent, and duration of symptomatic hypoglycemia. Patients who experience an unintentional hypoglycemic episode associated with therapeutic dosing (an insulin reaction) typically require only several hours emergency department observation. These patients can be safely discharged provided they have eaten a small meal, do not develop recurrent hypoglycemia during their period of observation, are at their baseline mental and health status at the time of discharge, are reliable or are discharged with reliable caretakers, and have been observed in the emergency department beyond the time of expected peak effects from the injected insulin preparation (see Table 64-3). Patients who have intentionally overdosed on insulin

should be admitted for inpatient observation (24 hours) because of the possibility for delayed and prolonged hypoglycemia. Most of these patients are symptomatic within 12 hours of overdose.⁹³ Patients who require dextrose infusion after intentional insulin overdose should be observed for recurrent hypoglycemia for 8 to 12 hours after the dextrose infusion has been stopped. Intensive care unit admission is required for patients with significant and persistent central nervous system or cardiovascular abnormalities or those requiring large supplemental dextrose infusions to maintain euglycemia.

ACKEE FRUIT

Ackee (*Blighia sapida*), the national fruit of Jamaica, was originally imported to the Caribbean from West Africa in the 18th century (see Chapter 24). The ackee tree is a tall, evergreen, fruit-producing tree and is found in various parts of the world, including the Caribbean, the Antilles, Central America, and parts of Florida.⁹⁷ The fruit is yellow and opens while still attached to the tree to reveal three glassy black seeds surrounded by a thick, oily, yellow aril.

The ackee fruit was first associated with Jamaican vomiting sickness (also called *toxic hypoglycemic syndrome*) in 1875. Risk factors associated with the development of Jamaican vomiting sickness are threefold: (1) consumption of raw or unripe ackee fruit; (2) consumption of ackee that is forcibly opened; and (3) consumption of water in which unripe ackee was cooked.⁹⁸ The unripe ackee fruit contains hypoglycin A, which is a water-soluble liver toxin that causes profound hypoglycemia by interfering with certain cofactors and enzymes necessary for hepatic gluconeogenesis.⁹⁹ Hypoglycin A, or cyclopropylaminopropionic acid, interferes with carnitine-acyl CoA transferase and β oxidation of long-chain fatty acids.¹⁰⁰ Accumulations of serum carboxylic acids results in metabolic acidosis and leads to Jamaican vomiting sickness. Jamaican vomiting sickness is characterized by the onset of epigastric pain, which begins a few hours after eating the fruit. Shortly thereafter, there is a sudden onset of profuse vomiting and hypoglycemia. Seizures, coma, and metabolic acidosis are common, as is death.⁹⁷ Death typically occurs by 12 hours after ingestion. The hypoglycemia is profound, often with blood sugars as low as 3 mg/dL.⁹⁷

The fruit is illegal in the United States, but nonetheless, there have been at least two reported cases in the United States in the 1990s. The first known case of Jamaican vomiting sickness occurred in Ohio, in a Jamaican female, after the consumption of canned Ackee.¹⁰¹ The only other known case in the United States was a 27-year-old Jamaican man, residing in Connecticut, who presented with 2 months of jaundice, intermittent diarrhea, pruritus, right upper quadrant pain, and markedly elevated bilirubins.¹⁰² This patient with cholestatic jaundice had resolution of his symptoms after he ceased consumption of the ackee fruit.

Treatment for poisoning from the ackee fruit is supportive, with correction of hypoglycemia, dehydration,

acidosis, and metabolic abnormalities provided as necessary.

Theophylline and Caffeine

MICHAEL W. SHANNON, MD, MPH

At a Glance...

- Methylxanthines are purine derivatives structurally related to adenosine.
- Methylxanthines have a narrow therapeutic index. Adverse effects can appear even at therapeutic doses and serum concentrations.
- Manifestations of theophylline intoxication vary according to mechanism of overdose (acute, chronic, or acute on therapeutic).
- The major life-threatening events of theophylline intoxication are seizures and cardiac arrhythmias.
- Metabolic consequences include hypokalemia, hyperglycemia, and metabolic acidosis.
- Management strategies for theophylline intoxication include supportive care, administration of multiple-dose activated charcoal, and, in severe cases, hemodialysis.
- Hemodialysis is preferred over hemoperfusion in the treatment of severe theophylline intoxication, because it is safer, more available, and equally effective.

Theophylline, caffeine, and theobromine are the major members of a group of pharmacologic agents known as *methylxanthines*. These drugs continue to have a ubiquitous position in society: Caffeine is used around the world for the pleasure that its mild stimulation provides. For almost a century, theophylline has been used for the treatment of respiratory ailments. Although theophylline use has fallen dramatically in recent years, it enjoys continued use as a therapeutic agent.

THEOPHYLLINE

Theophylline is used to treat various illnesses. At one time, it was the primary therapy for asthma, considered valuable both for treatment of acute exacerbations and for long-term prophylactic therapy.¹ Over the past two decades, β -adrenergic agonists have largely replaced theophylline for this indication, having a more favorable profile of safety and efficacy. However, theophylline is still used as a primary agent in areas where β -adrenergic agonists are less available and for individuals who have asthma that is resistant to β -adrenergic agonist and corticosteroid therapy.² Moreover, data that suggest that theophylline has anti-inflammatory properties have led to a slight increase in its use.^{3,4} Besides asthma, theophylline is used for other syndromes of airway obstruction including chronic obstructive pulmonary disease in adults and bronchiolitis in infants, although there remains controversy about its efficacy in these diseases.⁵⁻⁸ Theophylline is prescribed for neonates, particularly premature neonates, who have apnea and bradycardia.^{9,10} Recent data suggest benefit in cardiac resuscitation, in

renal protection after exposure to nephrotoxic agents, and in the treatment of acute mountain sickness.¹¹⁻¹⁴

Individuals develop theophylline intoxication by two general mechanisms. First, its general availability makes theophylline an agent that can be ingested by curious toddlers or suicidal adolescents or adults, producing *acute intoxication*. Second, because of its highly variable pharmacokinetics and narrow therapeutic index, theophylline is often responsible for unintentional *chronic intoxication*. By either mechanism, theophylline poisoning leads to a host of clinical and metabolic complications that often result in disastrous consequences, including death. A thorough understanding of theophylline intoxication, including rational and effective treatment algorithms (Box 65-1), is therefore necessary for management of this overdose.

BOX 65-1 TREATMENT ALGORITHM FOR ACUTE THEOPHYLLINE INTOXICATION

Supportive Care

Airway control, respiratory support, and vascular access as needed; cardiorespiratory monitoring

Treatment of Life-Threatening Events

Seizures

Give benzodiazepines. Add barbiturates if necessary. Avoid phenytoin.

Paralyze if necessary. Provide electroencephalogram monitoring.

Cardiac arrhythmias

Supraventricular—administer adenosine. Consider β blocker or calcium channel blocker.

Ventricular—treat specific rhythm disturbance according to advanced cardiac life support protocols.

Laboratory Assessment

Electrolytes, arterial blood gas

Serum theophylline concentration (obtain serial measures until plateau is documented)

Electrocardiogram

Gastrointestinal Decontamination

Administer activated charcoal.

No established role for gastric emptying, e.g., ipecac or lavage. No role for cathartic administration.

Correction of Metabolic Disturbances

Hyperglycemia does not require treatment.

Hypokalemia should not be treated unless severe.

Metabolic acidosis is typically modest and requires no treatment.

Elimination Enhancement

Administer activated charcoal every 2–4 hours.

Consider hemodialysis for severe cases.

Hemoperfusion is also efficacious.

FIGURE 65-1 Theophylline and related compounds.

Structure and Structural Relationships

As illustrated in Figure 65-1, the methylxanthines are purines that are structurally related to the nucleotides adenine and guanine. Theophylline is 1,3-dimethylxanthine. It is closely related to caffeine (1,3,7-trimethylxanthine) and theobromine (3,7-dimethylxanthine). Caffeine is found in high concentration in coffee and certain teas. Theobromine is primarily found in cocoa. A related drug, pentoxifylline, is prescribed for treatment of peripheral vascular disease. Adenosine, which is an adenine-ribose nucleoside, is closely related to theophylline in structure and appears to have an important role in theophylline's pharmacologic actions and toxic effects.

Theophylline products are available as solutions, tablets, and sustained-release capsules. Because of its poor solubility in water, theophylline has an intravenous form, aminophylline, which is about 80% theophylline by weight.¹⁵

Pharmacology

PHARMACOKINETICS

In its oral form, theophylline is most commonly prescribed as a sustained-release capsule. Sustained-release theophylline is designed to provide stable serum concentrations by having a gastrointestinal (GI) absorption rate that approximates that of drug elimination. These agents are not completely absorbed until 6 to 8 hours after ingestion. Overdoses of sustained-release theophylline can be associated with 15- to 24-hour delays to peak absorption. There is no significant presystemic clearance (first-pass effect) of the drug.

Once absorbed, theophylline is distributed throughout the body with a relatively small volume of distribution (average, 0.45 L/kg, with a range of 0.3 to 0.7 L/kg).¹⁵ Young infants and elderly people tend to have larger volumes of distribution. Plasma protein binding is 40% to 65%. The therapeutic serum concentration of theophylline is generally considered to be 10 to 20 µg/mL, although lower serum concentrations can produce the desired therapeutic effect. As a general rule, 1 mg/kg of administered theophylline raises serum theophylline concentration by 2 µg/mL. Theophylline freely crosses the placenta and enters breast milk.¹⁵

The metabolism of theophylline occurs through its biotransformation by the cytochrome P-450 system. The specific isoenzymes of this superfamily responsible for theophylline metabolism are CYP1A2, CYP2E1, and CYP3A3. The primary metabolic step is *N*-demethylation by the enzyme CYP1A2, producing the pharmacologically active agent 3-methylxanthine. The secondary metabolic pathway is hydroxylation, forming inactive 1,3-dimethyluric acid. Neonates also have the ability to metabolize theophylline by its methylation, producing caffeine. Moreover, neonates excrete about 50% of theophylline in urine unchanged (versus only 10% in children and adults).¹⁵

The rate of theophylline metabolism is variable; age is a very important influence (Table 65-1), with neonates

TABLE 65-1 Theophylline Elimination Patterns by Age

POPULATION	AGE	HALF-LIFE (hr)	CLEARANCE (mL/kg/min)
Neonates and Infants			
Premature neonates	1 wk	30	0.29
Premature neonates	41 d	20	0.64
Term infants	18 wk	6.9	0.80
Term infants	34 wk	3.7	2.0
Children and Adolescents	4–15 yr	3.0	1.55
Adults			
Asthmatic nonsmokers	31 yr	9.4	0.65
Healthy nonsmokers	22–35 yr	8.1	0.86
Healthy elderly nonsmokers	67 yr	7.4	0.59
Healthy elderly nonsmokers	>70 yr	9.8	NA

NA, not available.

and elderly people eliminating the drug relatively slowly.¹⁶ Theophylline clearance is maximal between the ages of 1 and 9 years; it decreases by about 50% in adults.¹⁵ The reason for such age-dependent elimination rates is unclear but may be related to the relative activity of cytochrome P-450 enzymes.

Theophylline also exhibits Michaelis-Menten (saturable) kinetics. As a result, across a narrow range, increments in dose are associated with corresponding increments in serum theophylline concentration. At high doses, however, increments lead to disproportionate elevations in serum concentration.¹⁷ Conversely, with severe theophylline intoxication, initial drug elimination rates are extremely slow, following zero order (dose-dependent) kinetics. With decreasing serum theophylline concentration, first order (dose-independent) kinetics eventually appear, leading to abrupt increases in elimination rate. These kinetics are often responsible for inadvertent theophylline intoxication, for example, if a clinician mistakenly assumes that a 50% increase in dose will always result in a 50% increase in serum theophylline concentration.

DRUG-DRUG INTERACTIONS

Theophylline is a drug whose metabolism is highly subject to alteration by concomitant drug use. A growing list of drugs, when prescribed with theophylline, can result in either increased or decreased clearance. Chronic theophylline intoxication is often a result of unrecognized drug interactions.

The drugs that have been associated with increased theophylline clearance are relatively few; all are known to be inducers of cytochrome P-450 enzymes. Such agents include phenobarbital, phenytoin, carbamazepine, and tobacco smoke. Patients who are taking these drugs often have difficulty maintaining therapeutic serum theophylline concentrations, requiring inordinately high doses because of their high drug clearance rate. If these patients discontinue their medications or quit smoking because they feel unwell, theophylline elimination rates can quickly revert to normal. For example, theophylline clearance falls by about 40% within 1 week of abstinence from cigarette smoking.¹⁵ Passive smoking also appears to increase theophylline clearance.¹⁸

The list of agents that decrease theophylline clearance is extensive (Box 65-2). It is also notable that among drug classes, one member may inhibit clearance while others do not; for example, cimetidine, a histamine-2 (H₂) antagonist, is a potent inhibitor of theophylline metabolism. However, the H₂ antagonists ranitidine and famotidine do not appear to have this action. Other common drugs that diminish theophylline clearance include the macrolide antibiotics (e.g., erythromycin or clarithromycin) and the quinolone antibiotics (e.g., ciprofloxacin or norfloxacin). The erythromycin-theophylline interaction has been characterized as appearing between days 3 and 7 of their concomitant use, with serum theophylline concentrations rising by an average of 30% to 35% if dosing adjustments are not made.

BOX 65-2

DRUGS COMMONLY REPORTED TO REDUCE THEOPHYLLINE METABOLISM

Allopurinol
Cimetidine
Ciprofloxacin
Clarithromycin
Diltiazem
Disulfiram
Enoxacin
Erythromycin
Fluvoxamine
Interferon (recombinant α)
Methotrexate
Mexiletine
Nifedipine
Norfloxacin
Ofloxacin
Roxithromycin
Tacrine
Thiabendazole
Troleandomycin
Verapamil

Adapted from American Academy of Pediatrics Committee on Drugs: Precautions concerning the use of theophylline. *Pediatrics* 1992;89:781; and Hendeles L, Jenkins J, Temple R: Revised FDA labeling guidelines for theophylline oral dosage forms. *Pharmacotherapy* 1995;15:409.

DRUG-DISEASE INTERACTIONS

Several medical conditions have significant impact on theophylline pharmacokinetics. In young children, febrile illness can markedly reduce theophylline elimination; it is recommended that the dose of theophylline be reduced by half in children who are febrile for more than 24 hours.¹⁰ Influenza and respiratory syncytial virus have also been reported as infectious agents that can reduce theophylline elimination.¹⁰ Cardiac disease, particularly congestive heart failure, can reduce theophylline clearance by as much as 50%, presumably through hepatic congestion and secondary alterations in pharmacokinetic profile.¹⁵ Primary hepatic disease can also reduce theophylline clearance by as much as 50%. Both cystic fibrosis and hyperthyroidism have been associated with increased theophylline clearance, resulting in larger dosing requirements. Renal disease has no important effect on theophylline pharmacokinetics.

PHARMACOLOGIC ACTIONS

Methylxanthines have a number of pharmacologic actions that give them therapeutic value. They relax smooth muscles, including those of the bronchi, esophagus, and gastroesophageal sphincter. They are central nervous system (CNS) stimulants that can reduce fatigue and improve concentration. Physiologic dependence may occur with this action: Acute abstinence from caffeine is associated with malaise, headaches, emotional lability, and depression. Other CNS actions include stimulation of the CNS respiratory center, producing

tachycardia. Cardiovascular effects include reduced peripheral vascular resistance with increased cardiac chronotropy and inotropy. Improved muscle function can enhance racing performance and improve pulmonary dynamics. Evidence indicates that theophylline is a potent inhibitor of renal erythropoietin production.¹⁹ Methylxanthines are also diuretics.

MECHANISM OF ACTION

Four major hypotheses have been advanced to explain theophylline's pharmacologic effects. First is the theory that theophylline acts as an inhibitor of phosphodiesterase, the enzyme that breaks down intracellular cyclic adenosine monophosphate (cAMP). According to current theories, cAMP is created by the membrane-bound enzyme adenylate cyclase in response to a number of receptor-linked stimuli. cAMP effects a number of actions, including regulation of gated potassium channels. These actions are terminated when cAMP is metabolized by phosphodiesterase. Theophylline was once thought to be a potent inhibitor of phosphodiesterase. However, data now suggest that phosphodiesterase inhibition is negligible at therapeutic serum concentrations of theophylline, indicating that this mechanism alone cannot account for its actions.^{20,21} The extent of phosphodiesterase inhibition has not been studied in victims of theophylline intoxication.

A second theory proposed for theophylline's actions is that of secondary sympathetic nervous system stimulation. In therapeutic doses, theophylline produces marked increases in the level of circulating catecholamines, particularly epinephrine and norepinephrine.²²⁻²⁵ Theophylline's actions of bronchodilation, cardiac and respiratory stimulation, and even metabolic changes such as depression in serum potassium may result from augmented plasma catecholamine activity. In a canine model of theophylline poisoning, hypokalemia, increased oxygen consumption, metabolic acidosis, and cardiac disturbances have been directly related to plasma catecholamine activity.^{22,23}

The third potential mechanism of theophylline's action is competitive antagonism of adenosine receptors. Adenosine, which is a bronchoconstrictor, anticonvulsant, and regulator of cardiac rhythm, interacts closely with theophylline through its competition for adenosine receptors.^{19,26} The structural similarity between these chemicals and their opposite physiologic functions supports this theory of adenosine receptor antagonism.

Finally, theophylline's actions may result directly from changes in intracellular calcium transport. For example, caffeine has been shown to inhibit the uptake and storage of calcium by the sarcoplasmic reticulum of striated muscle, thereby producing increased strength in skeletal muscle. In animal models, administration of a calcium channel blocker appears to protect against theophylline-induced toxicity and death.⁶

Clinical Toxicity

Having a narrow therapeutic index, theophylline is associated with a high rate of adverse effects. For example, as

many as 15% of patients complain of adverse effects when their serum theophylline concentration is in the therapeutic range. Once serum theophylline concentrations exceed the therapeutic range (>20 µg/mL), the prevalence of adverse effects exceeds 65% to 70%.²⁷ More than 90% of patients with serum theophylline concentrations greater than 30 µg/mL demonstrate signs of toxicity.¹⁵ It is also notable that theophylline intoxication has a high rate of iatrogenic origin; Schiff and colleagues found that in 68% of patients hospitalized with theophylline intoxication, inpatient or emergency department drug administration was responsible or contributed to toxicity.²⁸

CLINICAL MANIFESTATIONS

The signs and symptoms of theophylline intoxication can be placed into five categories: GI, musculoskeletal, cardiovascular, neurologic, and metabolic.^{15,29-31}

Gastrointestinal

The GI tract seems most sensitive to theophylline's toxicity. The most common complaints associated with theophylline use are abdominal pain, heartburn, and vomiting.³² In some cases, hemorrhagic gastritis can occur. These effects result from GI actions that include increased production of gastric acid and pepsin as well as relaxation of the lower esophageal sphincter. With moderate to severe theophylline intoxication, vomiting can be difficult to control despite antiemetic therapy.³³

Musculoskeletal

Victims of theophylline intoxication often complain of generalized muscle aches. With moderate toxicity, muscular hypertonicity with frank myoclonus may develop. Coarse tremor has also been reported as a manifestation of toxicity.³² These effects have been attributed to the potassium disturbances that accompany theophylline intoxication or disturbances in intracellular calcium transport. Elevations in serum creatine phosphokinase levels have been reported with severe intoxication.

Cardiovascular

Theophylline has several cardiovascular effects, some of which can be life threatening. Even when serum theophylline concentrations are in the therapeutic range, sinus tachycardia is often present. Greater toxicity has effects on vascular tone and cardiac rhythm.

Peripheral vasodilation is invariable with significant theophylline intoxication. This results in a widened pulse pressure and a fall in systemic vascular resistance.³⁴ Hypotension is generally present rather than hypertension.^{22,23} The mechanism of vascular disturbances is thought to be vascular β-adrenergic receptor stimulation, produced by circulating plasma catecholamines.

Theophylline is arrhythmogenic.³⁵ Myocardial irritability appears with mild to moderate theophylline intoxication; electrocardiograms most often reveal ventricular premature beats. These are usually of no consequence. However, more severe myocardial irritability occurs with serious intoxication, producing bigeminy

and other potentially unstable rhythms. These dysrhythmias may be a prelude to life-threatening cardiac arrhythmias such as ventricular tachycardia.

Although sinus tachycardia is one of the most common of manifestations of toxicity, appearing in as many as 82% of cases,³² rhythm disturbances are a sign of severe theophylline intoxication and the most common cause of theophylline-induced fatalities. Sinus tachycardia can quickly progress to life-threatening rhythms, which can be either ventricular or supraventricular in origin.³⁶ Supraventricular disturbances reported after theophylline intoxication include supraventricular tachycardia, atrial fibrillation, atrial flutter, and multifocal atrial tachycardia.³⁷ Many of these rhythms, such as multifocal atrial tachycardia, are characteristic of theophylline intoxication.³⁸ Supraventricular tachyarrhythmias result in increased myocardial oxygen demand, compromised cardiac output, shock, metabolic acidosis, and myocardial ischemia or infarction. Life-threatening arrhythmias of ventricular origin consist of ventricular tachycardia and ventricular fibrillation.

The mechanism of cardiac rhythm disturbances is unclear. They may be secondary to elevated plasma catecholamine activity. Other data now suggest that the mechanism of rhythm disturbances is theophylline inhibition of cardiac adenosine receptors.

Neurologic

Neurologic manifestations of theophylline intoxication appear at relatively low serum concentration; users of theophylline may complain of anxiety and insomnia. In children, theophylline may produce behavioral disturbances (e.g., agitation and motor restlessness) that interfere with school function.^{39,40} Although results of clinical investigations have been mixed, most data have failed to demonstrate a consistent effect on learning, although some children are likely to have a detrimental neurobehavioral response to the medication.^{41,42}

With moderate theophylline intoxication, more striking signs of neurologic disturbance appear. An early sign of intoxication is tachypnea, representing stimulation of CNS respiratory centers and often resulting in respiratory alkalosis. Worsening clinical toxicity is attended by anxiety, agitation, and delirium or hallucinosis.³²

The single most serious neurologic consequence of theophylline intoxication is the appearance of seizures. Theophylline-induced seizures can present in many patterns. These seizures are usually generalized, although focal seizures have been described.⁴³ In young infants, seizures may be subtle, consisting of generalized hypertonicity, posturing, eye deviation, and lip smacking without a clonic component. Theophylline-induced seizures can be single or repeated. They can appear without warning, although irritability, vomiting, and headache may be premonitory signs.¹⁰ Seizures may occur at serum theophylline concentrations less than 20 $\mu\text{g}/\text{mL}$.¹⁰ Once they appear, seizures can be extremely difficult to treat, being resistant to standard anticonvulsant therapy. Seizures due to theophylline use often predict a poor outcome; earlier case series reported a mortality rate of 50% to 100% among those who developed

seizures.^{44,45} Numerous case reports and case series have reported disabling, permanent neurologic sequelae in those who develop theophylline-induced seizures.^{10,46-51} Neurologic and neurobehavioral complications can include amnesia, personality changes, quadriplegia, and intractable seizure disorder. In young infants, associated intracerebral hemorrhage has been reported.⁴⁷ Neurologic sequelae are more common after long-term theophylline overmedication rather than acute single overdose.

The mechanism of theophylline-induced seizures is not completely understood and is likely multifactorial. However, in one series, as many as 34% of children and 12% of adults developed abnormalities on electroencephalogram while taking the medication.⁴⁶ Theophylline-induced seizures have been linked to dysfunction of GABAergic inhibitory neurons and depressed serum pyridoxal levels⁵²; in an animal model, pyridoxine, which promotes γ -aminobutyric acid (GABA) synthesis, was found to ameliorate theophylline-induced seizures.^{6,53}

Theophylline's relationship to CNS adenosine receptors has received considerable attention in recent years. The CNS has a dense population of adenosine receptors. These modulate the activity of various populations of neurons (e.g., cholinergic and glutaminergic). In vitro and in vivo studies have proved the importance of endogenous adenosine in regulating neuronal depolarization. For example, adenosine antagonists lead to marked alterations in seizure pattern after experimental administration of proconvulsant agents, producing uninterrupted electric discharge. Studies with radiolabeled theophylline have also shown it can displace adenosine from its receptor sites. In an animal model of theophylline-induced seizures, Shannon and Maher demonstrated that direct CNS administration of adenosine could forestall theophylline-induced seizures.⁵⁴

In addition to its direct neuroexcitatory effects, theophylline has marked effects on cerebral vascular tone, an action that is also related to adenosine activity.⁵⁵ Adenosine is a potent stimulator of cerebral vasodilation; marked increases in CNS adenosine activity occur in response to cerebral ischemia, representing another cerebroprotective effect. Theophylline antagonizes this action, producing sustained cerebrovasoconstriction, which compromises CNS delivery of oxygen and nutrients as well as removal of toxic metabolic wastes.

Metabolic

Metabolic complications of theophylline intoxication are many.^{56,57} Even in therapeutic doses, theophylline can produce depressions in serum potassium and elevations in blood glucose levels. With more severe intoxication, profound hypokalemia can result. Serum potassium concentrations as low as 1.7 mEq/L have been reported after theophylline poisoning.^{34,58}

The mechanism of theophylline-induced hypokalemia is well defined. Although early theories attributed it to potassium losses as a result of vomiting or diuresis, these are unlikely to be the cause.⁵⁹ For example, Amitai and Lovejoy demonstrated that the hypokalemia often precedes vomiting.⁶⁰ The current belief is that hypokalemia results from increased intracellular transport of potassium ion,

produced by amplification of sodium-potassium adenosine triphosphatase ($\text{Na}^+/\text{K}^+\text{-ATPase}$) or opening of calcium-linked potassium channels. This effect occurs secondary to catecholamine-induced β_2 -adrenergic stimulation.^{59,61-63} As a result, total-body potassium is preserved. Theophylline-induced hypokalemia promptly reverses as serum theophylline concentration declines, without potassium supplementation. The clinical consequences of theophylline-induced hypokalemia are unclear. Although hypokalemia has been implicated in the genesis of theophylline-induced cardiac arrhythmias, this is only speculative and is not supported by available data. Blood glucose elevations also appear to be a result of circulating plasma catecholamines. Serum blood glucose can rise to levels greater than 400 mg/dL; theophylline intoxication can mimic diabetic ketoacidosis.^{34,64}

Metabolic acidosis with depression of serum bicarbonate levels is usually modest but can be severe, resulting in a high anion gap. Serum bicarbonate concentrations as low as 5 mEq/L have been reported after serum theophylline poisoning. Acidosis appears to result from the combination of increased lactate production and lipolysis with increased free fatty acid circulation.⁶⁵

Other metabolic disturbances associated with theophylline intoxication include hypercalcemia, which has been reported in as many as 15% of patients.⁶⁶ Hypomagnesemia, hypophosphatemia, and respiratory alkalosis have also been reported.^{56,58}

Theophylline has not been proved to have significant human genotoxicity or fetotoxicity, although such effects have been observed in experimental models.^{6,15,67} However, it is listed as a pregnancy category C drug by the U.S. Food and Drug Administration.

Acute vs. Chronic Intoxication

The clinical course of patients with theophylline poisoning is highly variable and often unpredictable. The reasons for such wide variations in reaction to a drug whose toxic manifestations are so clearly recognized have been an enigma that continues to challenge clinicians who must provide immediate and appropriate care to theophylline-poisoned patients in order to prevent disastrous outcomes. During the past 20 years, a series of important modulators of theophylline poisoning have been identified.

Early descriptions of the clinical course of theophylline intoxication suggested that serum theophylline concentrations were highly predictive of outcome. For example, in a study of 28 children with acute theophylline intoxication, Gaudreault and colleagues demonstrated that life-threatening toxicity did not appear with serum theophylline concentrations less than 70 $\mu\text{g}/\text{mL}$ and that the lower the serum theophylline concentration, the less likely the risk for major toxicity.⁶⁸ Bertino, Aitken, and others subsequently published case series indicating that serum theophylline concentration was not always predictive of clinical course and that patients with relatively low serum theophylline concentrations often had fatal outcomes.^{46,69-71}

In 1985, Olson and colleagues were the first to clearly demonstrate that the clinical course of patients with

theophylline intoxication was largely influenced by the mechanism of their poisoning.⁷² This study found that victims of acute theophylline intoxication, although they were more likely to have metabolic consequences such as hypokalemia and hyperglycemia, seemed to tolerate elevated serum theophylline concentrations better than those with chronic overmedication. Those in the latter category had a lower incidence of metabolic disturbances but were more likely to have life-threatening seizures or cardiac disturbances. Moreover, these life-threatening events occurred at lower serum theophylline concentrations than in those with acute intoxication who developed life-threatening events.⁷²

Subsequent studies have attempted to clarify differences in outcome as influenced by method of intoxication.⁶ Consequently, three types of patients with theophylline intoxication have been identified: those with acute overdose, those with chronic overmedication, and those with acute-on-therapeutic intoxication. According to current definitions, the victim of acute theophylline overdose is one who has not been taking or receiving theophylline but is then exposed to a single dose exceeding 10 mg/kg. A patient who suffers an acute toxic overdose and who has been taking theophylline for only 1 or 2 days, not having reached steady-state concentrations (which require 4 to 5 half-lives), is also considered a victim of acute overdose. Common causes of acute overdose include ingestion by children, attempted suicide by young adults, and inadvertent administration of an excess dose by clinicians (physician, nurse, or pharmacist). Tenfold errors in drug administration are a common cause of acute intoxication in children.

The findings of Gaudreault and colleagues have been borne out by larger, subsequent clinical investigations: Patients with acute theophylline overdose generally exhibit signs of minor toxicity at serum theophylline concentrations of 20 to 40 $\mu\text{g}/\text{mL}$, moderate toxicity with concentrations of 40 to 80 $\mu\text{g}/\text{mL}$, and severe toxicity with concentrations of greater than 70 to 80 $\mu\text{g}/\text{mL}$. In the absence of prompt, aggressive care, serum theophylline concentrations of greater than 100 $\mu\text{g}/\text{mL}$ are often fatal (although survival with only supportive care has been reported with serum theophylline concentrations of 203 and 300 $\mu\text{g}/\text{mL}$).^{73,74}

Victims of chronic theophylline overmedication differ from those with acute poisoning in several respects. First, epidemiologically, these patients are more likely to be very young (i.e., neonates) or elderly. They invariably have preexisting cardiorespiratory disease, which is the reason they are taking the medication. Unintentional overmedication can result from a number of causes, most commonly inappropriate dosing by the patient or health care provider (Table 65-2). Those with chronic overmedication have a substantially higher risk for major toxicity than those with acute intoxication (49% versus 10% in one study³⁷). This higher incidence occurs despite lower serum theophylline concentrations in those with chronic overmedication.⁷⁵

The most distinctive feature of chronic theophylline overmedication is the complete loss of predictive value provided by serum theophylline concentration. Victims

**TABLE 65-2** Common Causes of Chronic Theophylline Overmedication

CAUSE	PERCENTAGE OF CASES
Increased dosing by patient or parent	31
Physician dosing error	14
Drug interaction	7
Cardiac disease	10
Viral illness	3
Hepatic disease	1
Unknown	35

Adapted from Shannon M, Lovejoy F: The influence of age vs. peak serum concentration of life-threatening events after chronic theophylline intoxication. *Arch Intern Med* 1990;150:2045.

of chronic overmedication may have seizures, arrhythmias, and fatalities at serum theophylline concentrations as low as 20 to 30 $\mu\text{g}/\text{mL}$.⁴⁹ Conversely, patients may survive serum concentrations as high as 100 $\mu\text{g}/\text{mL}$. Olson and coworkers suggested that among those with chronic overmedication, serum theophylline concentrations have some predictive value; however, others have not found this. Studies now indicate that age rather than peak serum theophylline concentration is most predictive of major toxicity after chronic theophylline overmedication; proportional increases in the risk of a life-threatening event occur with advancing age.^{37,76} In the pediatric age group, the opposite is true; the younger the patient, the greater the risk for major toxicity.^{75,76} Age is not a risk factor in the development of major toxicity for those with acute theophylline overdose.

Acute-on-therapeutic theophylline intoxication acts in an intermediate fashion, with metabolic disturbances and clinical consequences occurring in a pattern that lies between the other two populations.^{37,75,77}

Differences between those with acute versus chronic theophylline intoxication are also evident in patients' metabolic profile. For example, in those with acute intoxication, 85% to 95% develop hypokalemia, in contrast to 25% to 32% of those with chronic overmedication.^{72,77} Serum glucose level is typically higher and serum bicarbonate level lower in those with acute theophylline overdose.

Diagnosis of Theophylline Poisoning

The diagnosis of theophylline poisoning is made in various ways. With acute overdose, patients, friends, or caretakers offer a history of recent use. In those with chronic overmedication, the diagnosis may be more elusive, with vague and nonspecific presenting complaints. Complaints of nausea, vomiting, and diarrhea may be erroneously diagnosed as gastroenteritis. In elderly patients, the presenting complaint is often respiratory decompensation; in such cases, the development of chronic theophylline overmedication has likely resulted from improper self-medication (i.e., taking extra doses). In many cases of theophylline

intoxication, seizures may be the presenting feature. Various presenting signs require a high index of suspicion as well as a detailed review of medications that the patient is taking. Because increasing numbers of drugs are being found to inhibit cytochrome P-450 activity, close attention should be paid to those patients taking theophylline in combination with another drug.

In those who receive inadvertent intravenous theophylline overdoses, representing either acute or acute-on-therapeutic poisoning, the error is often discovered when the clinical status deteriorates and tachycardia, agitation, or frank seizures appear.

Serum theophylline concentrations are readily measured. However, theophylline may not be a part of a general toxic screen, and thus the test must be specifically requested. Because serum theophylline concentrations may be of limited value in patients with chronic theophylline overmedication, it is essential that a thorough clinical assessment be performed. After an acute toxic ingestion, theophylline concentrations should be measured every 2 to 4 hours until a plateau is documented because of the risk for delayed peak absorption after ingestion of sustained-release theophylline preparations.^{15,77,78}

Ancillary laboratory tests that are important in the treatment of patients with theophylline intoxication include an electrocardiogram; chest radiograph; measurement of arterial blood gas, serum electrolytes, calcium, and blood sugar; and occasionally liver function tests. Because seizures may be associated with a cerebrovascular accident, cranial tomography should be considered for those who develop convulsions.

Management of Theophylline Poisoning

SUPPORTIVE MEASURES

General management principles are key in the care of patients with theophylline poisoning. For those with respiratory compromise, cardiac disturbances, or seizures, initial interventions must include airway control, assisted ventilation, and vascular access. Patients who present with respiratory failure as a result of exacerbation of their pulmonary disease or seizure require immediate endotracheal intubation. Hypotension may reflect theophylline-induced vasodilation, dehydration, or myocardial infarction. In such cases, based on clinical assessment and, ideally, central venous pressure monitoring, modest fluid boluses should be administered. If vasopressor therapy is needed, there are theoretic advantages to using phenylephrine, a potent peripheral vasoconstrictor. However, more conventional vasopressors, including dopamine, dobutamine, and norepinephrine, are also effective for blood pressure support.

Cardiac arrhythmias also require immediate intervention and can be treated according to advanced cardiac life support algorithms. Isolated ventricular premature beats without hemodynamic compromise require no treatment. More significant signs of myocardial irritability should be treated with appropriate doses of lidocaine. Although the proconvulsant actions of lidocaine pose

theoretic risks, no evidence shows that lidocaine is detrimental when used in appropriate doses. Supraventricular arrhythmias can be treated with agents including β blockers, verapamil, or adenosine. Propranolol has been shown to reverse peripheral vasodilation, hypotension, tachycardia, hypokalemia, and hypercalcemia after theophylline poisoning.^{34,63,66,79} It may, however, produce bronchoconstriction in susceptible individuals. Esmolol, a very short-acting β_1 -specific antagonist, has been used successfully for reversal of tachycardia.^{80,81} The calcium channel blocker verapamil, although effective in the treatment of supraventricular tachycardia, carries the risk for exacerbating hypotension.⁸²

The intimate relationship between theophylline and adenosine justifies the use of adenosine (Adenocard) as first-line treatment for theophylline-induced tachyarrhythmias. Supraventricular tachycardia is very responsive to adenosine therapy. If the basis of theophylline-induced tachyarrhythmias is cardiac adenosine receptor antagonism, exogenous adenosine can be considered an "antidote" in reversing this effect. The dose of adenosine is 6 to 20 mg for adults and 0.1 mg/kg for children. Adenosine is effective only if delivered into the central circulation by rapid bolus. Having an elimination half-life of about 10 seconds, adenosine may not produce sustained control of arrhythmias. Like propranolol, adenosine has been associated with the occurrence of bronchoconstriction.

Seizures are an ominous occurrence with theophylline intoxication because they are often multiple, are highly resistant to anticonvulsant therapy, and are associated with permanent neurologic disability. This recognition has led some physicians to recommend prophylactic anticonvulsant therapy to those patients who present with severe theophylline intoxication.¹⁵ In many victims, however, particularly those with chronic theophylline overmedication (who have the greatest likelihood of seizures), high-risk patients are difficult to identify, making it unclear who should receive preventive anticonvulsant therapy. Certainly, once they appear, seizures should be treated aggressively. The initial anticonvulsant should be a benzodiazepine (e.g., diazepam or lorazepam). Benzodiazepines are considered agents of choice because the benzodiazepine receptor is linked to GABAergic neurons. Large doses of benzodiazepines may be necessary to control seizures. The second anticonvulsant choice is a barbiturate such as phenobarbital.⁸³ Like the benzodiazepines, barbiturates have actions at the GABA receptor; they are effective at terminating theophylline-induced seizures. Barbiturates do, however, have two disadvantages. First, they have a delayed onset of action. Also, being CNS depressants, they may produce severe respiratory depression if administered in conjunction with benzodiazepines. Phenytoin is relatively contraindicated in the treatment of theophylline-induced seizures, based on both empirical observation that it is ineffective in terminating theophylline-induced seizures and animal data that suggest that phenytoin increases the risk for theophylline-induced seizures.⁸³ If anticonvulsants are ineffective in terminating seizures, skeletal muscle paralysis may be

necessary to prevent the complications of prolonged tonic-clonic activity. However, with theophylline intoxication, paralysis carries the risk for masking continued seizure activity. Because experimental data suggest that continued electric discharge and resulting metabolic disturbances are pivotal in theophylline-induced neurologic injury, every effort should be made to provide electroencephalographic monitoring.

GI disturbances, although generally not considered life threatening, have a critical role in the management of theophylline intoxication because they prevent both successful GI decontamination and elimination enhancement with multiple-dose activated charcoal. Therefore, a treatment priority is control of vomiting. Vast clinical experience indicates that conventional interventions, including antiemetic suppositories and low-dose metoclopramide, are ineffective therapies. Phenothiazines are also disappointing as antiemetics; they also may precipitate seizures because of their ability to lower seizure threshold.

Several agents are effective in control of theophylline-induced emesis. Parenteral H_2 antagonists, particularly ranitidine, control gastric acid secretion and reduce the mucosal irritation that contributes to vomiting⁸⁴ (Fig. 65-2). Metoclopramide is an effective antiemetic if given in adequate doses. For control of theophylline-induced vomiting, the recommended dose is 0.1 to 1 mg/kg; lower doses are unlikely to be effective. Because metoclopramide doses of this magnitude have been associated with the development of acute dystonic

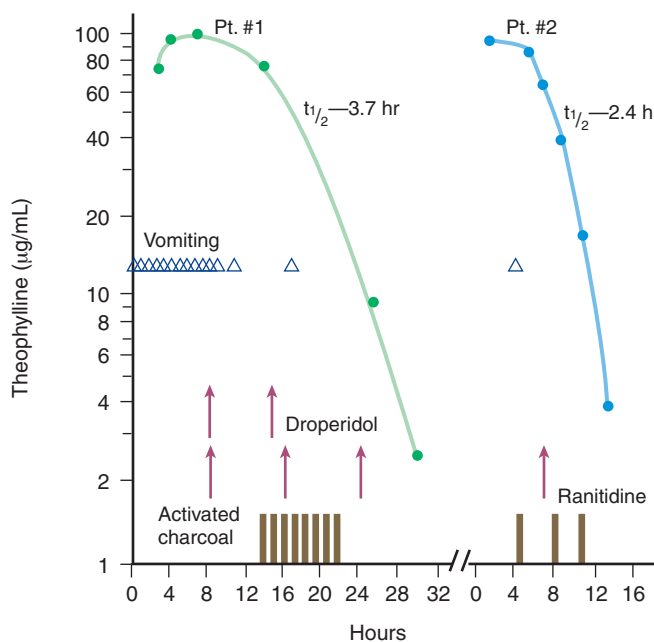

FIGURE 65-2 Serum theophylline concentrations and frequency of vomiting in two patients before and during treatment with ranitidine, droperidol, and repetitive activated charcoal. $t_{1/2}$, elimination half-life of theophylline. (From Amitai Y, Yeung AC, Moye J, Lovejoy FH: Repetitive oral activated charcoal and control of emesis in severe theophylline toxicity. *Ann Intern Med* 1986;105:386.)

reaction, diphenhydramine should be made readily available or administered prophylactically. Ondansetron, a nonsedating antiemetic that acts as an inhibitor of CNS serotonergic neurons, has also been successfully used to control theophylline-induced vomiting.⁸⁵ Another agent that may be effective is droperidol.⁸⁴

Aggressive GI decontamination is important because sustained-release theophylline tablets can coalesce, forming bezoars.⁸⁶ Activated charcoal should be administered as soon as possible. Whole bowel irrigation has been advocated for the treatment of sustained-release theophylline ingestion; however, whole bowel irrigation fluids may promote theophylline desorption from activated charcoal. One study has suggested that whole bowel irrigation offers no additional benefit over activated charcoal.⁸⁷ If confirmed by additional studies, these data would support omission of whole bowel irrigation as an adjunct to use of activated charcoal after theophylline ingestion.

Metabolic disturbances generally do not require aggressive management. Insulin therapy is not recommended for hyperglycemia because blood glucose elevations are transient and inconsequential.³⁴ Significant metabolic acidosis should be treated with administration of sodium bicarbonate.

The most significant metabolic abnormality is hypokalemia, which can be profound. Because total-body potassium is unchanged, exogenous potassium theoretically is not needed. However, because hypokalemia may be a risk factor for cardiac disturbances, it is appropriate to treat severe depressions of serum potassium concentration. Potassium supplementation should be provided cautiously and with close monitoring of serum potassium values to prevent iatrogenic hyperkalemia. D'Angio and Sabatelli described a patient with theophylline intoxication who was treated with aggressive potassium replacement. As the patient's serum theophylline concentration fell, however, serum potassium level rose, resulting in a hyperkalemic cardiac disturbance.⁸⁸

ELIMINATION ENHANCEMENT

Having a favorable pharmacokinetic profile, theophylline can be removed by a number of methods; because of its life-threatening toxicity, the drug should be removed as quickly as possible once the need has been determined.⁸⁹

Multiple-dose activated charcoal is very effective at enhancing the elimination of theophylline from the body, even if toxic doses have been administered intravenously.^{84,90} Theophylline has the unusual property of diffusibility across the gut mucosa, such that if activated charcoal is present in the GI lumen, theophylline adsorbs to charcoal and is eliminated in the stool. This action is referred to as *GI dialysis* or *enterocapillary exsorption* (see Chapter 2). Animal models and case reports have demonstrated the efficiency with which repeat oral charcoal doses can eliminate theophylline that has been administered intravenously. Theophylline clearance rates as high as 100 mL/min, corresponding to serum elimination half-lives as low as 1 to 2 hours, have been reported with use of multiple-

dose activated charcoal.^{15,78,91} Because it is so effective yet noninvasive, multiple-dose activated charcoal is the cornerstone of elimination enhancement procedures in patients with theophylline intoxication.⁹²

For treatment of theophylline intoxication, activated charcoal should be administered in a dose of 1 g/kg (maximum 50 g) every 4 hours. If vomited, the dose should be repeated. Alternative administration strategies include 20 g every 2 hours or continuous nasogastric infusion of activated charcoal.^{93,94} Aggressive antiemetic therapy is usually necessary to permit retention of charcoal. Continuous assessment of bowel motility is important because of the risk for intestinal pseudo-obstruction, which has been associated with use of multiple-dose activated charcoal in theophylline intoxication.⁹⁵ Repeat doses of charcoal can be safely administered to young infants.⁹⁶

In 1979, Russo demonstrated that theophylline could be rapidly removed from the body by hemoperfusion.⁹¹ Theophylline clearance rates that were four to six times greater than endogenous clearance could be produced by hemoperfusion, making this procedure extremely valuable in treating theophylline intoxication.⁴⁸ With hemoperfusion, theophylline extraction ratios as high as 0.75, corresponding to elimination half-lives of 1 to 2 hours, were initially reported. Three hours of hemoperfusion removed more than 65% of a theophylline dose in early experiences.⁹⁷ In contrast, hemodialysis, an alternative to hemoperfusion, could only double theophylline clearance rates.⁷⁸

Hemoperfusion has become widely considered to be the definitive treatment for theophylline intoxication. However, because newer high-flux hemodialysis machines are capable of increasing theophylline clearance rates greater than 300 mL/min, comparable to the rates achieved with hemoperfusion,⁷⁸ hemodialysis is now considered an option equal to charcoal hemoperfusion for serious theophylline intoxication.

The criteria for hemodialysis (or hemoperfusion; HD/HP) after theophylline intoxication are controversial. Park and colleagues proposed the criterion of peak serum theophylline concentration greater than 60 $\mu\text{g/mL}$ or a concentration of greater than 30 $\mu\text{g/mL}$ in patients older than 60 years.⁵⁰ Olson and coworkers have recommended hemoperfusion in those with acute intoxication and serum theophylline concentrations of greater than 100 $\mu\text{g/mL}$ and in those with chronic overmedication and peak concentrations greater than 40 to 60 $\mu\text{g/mL}$.⁷² Greenberg and associates recommended that hemoperfusion be performed only in those with intractable hypotension, ventricular ectopy, or resistant seizures.⁸² Notably, all investigators have emphasized that a criterion for HD/HP is the appearance of seizures or arrhythmias, suggesting that HD/HP is also effective in reducing morbidity and mortality once major toxicity is manifested. However, data now suggest that most patients who received HD/HP after they had a seizure or cardiac arrhythmia continued to have these life-threatening events. In contrast, as few as 5% of patients who receive HD/HP before major toxicity eventually develop a life-threatening event.³⁷ Therefore, HD/HP is

BOX 65-3

RECOMMENDATIONS FOR ELIMINATION ENHANCEMENT AFTER THEOPHYLLINE INTOXICATION

Acute Intoxication

1. Multiple-dose activated charcoal for all patients
2. HD/HP for patients with peak serum [theo] > 80–100 µg/mL*
3. HD/HP for patients with peak serum [theo] > 60–80 µg/mL and intractable vomiting
4. HD/HP for those with seizures or cardiac arrhythmias and serum [theo] > 100 µg/mL

Chronic Overmedication

1. Multiple-dose activated charcoal for all patients
2. HD/HP for all patients younger than 6 mo or older than 65 yr with serum [theo] > 30–40 µg/mL

*Exchange transfusion may be used as an alternative therapy for neonates. HD/HP, hemodialysis or hemoperfusion.

best considered a preventive intervention rather than a procedure that offers great benefit after major toxicity has developed.

Based on the growing data that have analyzed major toxicity and its predictors as a function of method of intoxication, the following recommendations are rational (Box 65-3): For all patients with theophylline intoxication (serum theophylline concentration > 20 to 30 µg/mL), treatment should be initiated with multiple-dose oral charcoal. For those with acute theophylline intoxication, HD/HP should be performed in patients with a serum theophylline concentration of greater than 80 to 100 µg/mL. If uncontrolled vomiting prevents successful charcoal administration, HD/HP should be performed in all those with serum theophylline concentrations that exceed 60 to 80 µg/mL.

The decision to perform HD/HP after chronic theophylline intoxication is more difficult for several reasons. First, the patients at greatest risk for seizures and cardiac arrhythmias cannot be identified on the basis of peak serum theophylline concentration. Second, these victims are usually very young or very old, ages at which HD/HP is technically more difficult. Finally, patients with chronic theophylline intoxication often have seizures and cardiac arrhythmias as their presenting manifestations, making the value of HD/HP less clear. Nonetheless, because of the evidence that high-risk patients are those at extremes of age, hemodialysis should be considered in all patients with a serum theophylline concentration of greater than 30 µg/mL, particularly those younger than 6 months or older than 65 years.

HD/HP is technically difficult to perform in neonates, although it has been proved successful.⁹⁸ Consequently, alternative methods of extracorporeal drug removal have been evaluated. Among these, exchange transfusion is the procedure with the greatest promise. Although an early case report found no benefit of exchange transfusion in infants with severe acute

theophylline intoxication,⁷⁴ two recent case reports have demonstrated that significant amounts of theophylline can be removed with exchange transfusion, making this therapy a viable option in acutely poisoned neonates.^{99,100}

Plasmapheresis has also been successfully used in the treatment of theophylline intoxication, reducing elimination half-life to 1.7 hours.^{101,102}

CAFFEINE

Caffeine is a plant alkaloid found in a wide variety of foods and beverages. Coffee, tea, and chocolate have the largest natural concentrations of caffeine. Caffeine is also added to carbonated beverages and a large number of over-the-counter medications including weight control aids, “alertness” tablets, pain relievers, diuretics, and cold remedies (Table 65-3). Finally, caffeine is prescribed for the treatment of apnea-bradycardia in newborns and as adjunctive therapy for cerebrovascular (migraine) headache.

Clinical Pharmacology

Found in the most popular beverages in the world (coffee and soft drinks), caffeine is a widely consumed drug. Significant increases in caffeine use among children and adolescents has been observed in recent years and has been attributed to increased rates of hypertension, insomnia, chronic headache, motor tics, irritability, learning difficulties, and other adverse health effects.¹⁰³⁻¹⁰⁷

Caffeine can be administered by a number of routes, including oral, intravenous, subcutaneous, and rectal.

TABLE 65-3 Average Caffeine Content of Beverages, Foods, and Pharmaceuticals

	DOSE RANGE (mg)
Beverages	
Coffee (5 oz)	
Brewed	40–200
Instant	30–150
Decaffeinated	1–5
Tea (5 oz)	
Brewed	20–100
Instant	25–50
Iced (12-oz glass)	65–80
Carbonated beverages, 12 oz	25–200
Chocolate milk	2–10
Food	
Dark chocolate, 1 oz	5–30
Nonprescription Pharmaceuticals	
Weight control aids	100–200
Alertness agents	100–200
Analgesics	30–65
Diuretics	100–200
Cold remedies	15–30

After ingestion, it is well absorbed, with an absorption pattern relatively unaffected by the presence of food. Peak plasma concentrations are achieved 30 to 60 hours after ingestion.¹⁰⁸ Absorption after rectal and subcutaneous administration is equally rapid. It has an apparent volume of distribution of 1 L/kg. As with theophylline, caffeine metabolism occurs through biotransformation in the cytochrome P-450 system. The primary metabolic pathway for caffeine is its demethylation. 1-Demethylation produces theobromine (3,7-dimethylxanthine), a pharmacologically active methylxanthine found widely in chocolate. 7-Demethylation of caffeine produces theophylline; as a result, caffeine ingestion produces measurable serum theophylline concentrations. The elimination half-life of caffeine is variable and highly age dependent; the average half-life in a nonsmoking adult is 3 to 6 hours. In contrast, premature neonates can have elimination half-lives that range from 1.5 to 6 days.¹⁰⁸ Agents associated with induction of cytochrome P-450 enzymes (e.g., smoking) produce shorter half-lives. About 5% of caffeine is excreted unchanged in the urine. Significant amounts of caffeine are excreted into breast milk.

Caffeine has a number of pharmacologic actions. Its most important property, mild CNS stimulation, is the basis for the worldwide enjoyment of caffeinated beverages, particularly coffee. This CNS stimulation is associated with increased alertness and concentration as well as mood elevation. In excessive doses, undesirable effects, including hyperactivity (particularly in children), anxiety, and insomnia, appear.⁴¹

Caffeine has become extremely valuable therapy in the treatment of the neonatal apnea-bradycardia syndrome. Newborns with this syndrome have recurrent hypoventilation, often accompanied by bradycardia. Both theophylline and caffeine are effective in treating this syndrome; stimulation of central respiratory centers by methylxanthines results in decreased apnea, increased minute ventilation, normalization of breathing pattern, increased ventilatory response to carbon dioxide, and reduction in both the need for and duration of mechanical ventilation. Another beneficial effect in newborns is increased cardiac output.¹⁰⁹ Caffeine offers the advantages of excellent absorption after ingestion and a longer elimination half-life; these provide more sustained serum concentrations and more predictable pharmacokinetics. The therapeutic serum concentration of caffeine is 8 to 20 $\mu\text{g}/\text{mL}$.

Caffeine is also a cardiostimulant agent, producing positive inotropy and chronotropy. However, it does not consistently produce significant increases in pulse or blood pressure.^{110,111} In susceptible individuals, caffeine occasionally leads to the development of premature ventricular contractions, which are usually of no clinical consequence. Important vascular effects of caffeine include cerebral vasoconstriction and renal vasculature relaxation. Because cerebral vasodilation often contributes to the pathophysiology of headache, constriction of cerebral blood vessels by caffeine can be therapeutic. Enhanced renal blood flow is associated with a modest diuretic effect.

Caffeine has two important GI effects: smooth muscle relaxation and stimulation of gastric secretion. Smooth muscle relaxation is most pronounced at the lower esophageal sphincter, where gastroesophageal reflux can result from caffeine use. In concert with increased secretion of both gastric acid and digestive enzymes, reflux can result in esophagitis (heartburn). These GI effects are also noted after ingestion of decaffeinated coffee, suggesting they are mediated by alkaloids other than caffeine. Metabolic effects of caffeine include increased fatty acid oxidation and glycogenolysis. According to one study, typical doses of caffeine, unlike theophylline, do not usually produce marked increases in circulating plasma catecholamines.¹¹² However, catecholamine elevations have been reported in victims of caffeine intoxication.¹¹³

Caffeine exhibits all the properties of an addictive drug (tolerance, dependence, and an abstinence syndrome on immediate withdrawal). Tolerance to all its pharmacologic effects develops after repeated use.

Clinical Toxicology

Undesirable effects of caffeine can appear after ingestion of as little as 50 mg; at these doses, anxiety, GI upset, and insomnia may occur. More significant toxicity appears after ingestion of 15 to 30 mg/kg. At this range, moderate toxicity is marked by vomiting, myoclonus, and myocardial irritability. Vomiting may be severe; frank hematemesis may occur.¹¹⁴ Fatal oral doses of caffeine have ranged from 5 to 50 g, with a mean of 10 g; the lethal dose is estimated to be 100 to 200 mg/kg.¹¹⁵ Clinical toxicity correlates with serum caffeine concentrations. Several cups of coffee yield a serum caffeine level of 5 to 10 $\mu\text{g}/\text{mL}$. Agitation and myoclonus occur at levels of 15 to 30 $\mu\text{g}/\text{mL}$; cardiac arrhythmias and seizures develop at 50 to 100 $\mu\text{g}/\text{mL}$. Fatalities have been associated with serum caffeine concentrations as low as 80 $\mu\text{g}/\text{mL}$ to as high as 1560 $\mu\text{g}/\text{mL}$,¹¹⁶ although concentrations as high as 200 $\mu\text{g}/\text{mL}$ have been associated with survival. Deaths have also been reported from the use of coffee enemas as a naturopathic therapy.¹¹⁷

Many of the consequences of caffeine poisoning are identical to those of theophylline, although they are associated with comparably higher serum caffeine concentrations. Seizures can appear without warning and are often repeated. Opisthotonos, decerebrate posturing, and generalized muscular hypertonicity are also common.¹¹⁸ Cardiac arrhythmias can be supraventricular or ventricular (ventricular tachycardia or fibrillation). Other manifestations of severe intoxication are rhabdomyolysis with resultant acute renal failure and pulmonary edema.¹¹⁹ Rhabdomyolysis has been attributed to increased muscular activity. Pulmonary edema is a frequent occurrence with severe poisoning and is thought to result, in part, from pulmonary vasculature dilation.^{108,118} Victims of caffeine intoxication develop the metabolic disturbances of hyperglycemia, hypokalemia, leukocytosis, ketosis, and metabolic acidosis.

Chronic caffeine intoxication (caffeinism) is manifested by irritability, insomnia, anxiety, emotional lability, and

chronic abdominal pain. Cardiovascular disease, myocardial irritability, and fibrocystic disease of the breast all have been associated with long-term caffeine consumption.^{112,120,121} However, for all these diseases, the association with caffeine has been controversial and inconsistent in clinical investigations.

Caffeine is both mutagenic and teratogenic in laboratory animal species.¹⁰⁸ A study of women suggested that more than 600 mg of caffeine daily could result in an increased incidence of spontaneous abortion and premature birth.¹⁰⁸ A causal link between caffeine use and birth defects remains tenuous¹²²; however, the Food and Drug Administration has advised pregnant women to avoid or limit caffeine intake.

Caffeine has now been proved to produce a physiologic abstinence syndrome (withdrawal). Although it has been well recognized that abrupt termination of caffeine consumption could produce insomnia, malaise, and headache, little scientific investigation has addressed these phenomena. Silverman¹²³ and Strain¹²⁴ and their colleagues have shown that withdrawal from caffeine can produce an increase in depressive symptoms, anxiety, fatigue, headache, and decreased performance. Abstinence was also associated with a marked increase in the use of medications (e.g., headache relievers).

Management

In patients with an acute caffeine overdose, initial attention should be directed to airway, breathing, and circulation. The sudden appearance of airway compromise and hypoxia as a result of seizures, cardiac disturbances, or pulmonary edema should be anticipated, particularly in patients who ingest more than 30 to 50 mg/kg of caffeine.

Management of seizures and cardiac disturbances parallels their treatment in patients with theophylline intoxication. Therefore, seizures are preferably treated with a benzodiazepine (e.g., diazepam) or phenobarbital. There is no evidence that phenytoin is ineffective or harmful in the treatment of caffeine-induced seizures; however, because all methylxanthines are presumed to have similar mechanism of toxicity, phenytoin's lack of efficacy in theophylline-induced seizures argues against its use. Cardiac disturbances should be treated according to standard management strategies. Adenosine, verapamil, and β -blocking agents all are effective treatments for supraventricular arrhythmias.^{114,125} Ventricular arrhythmias should be treated initially with intravenous lidocaine.

GI decontamination measures should include administration of activated charcoal with a cathartic. Vomiting is likely in those with significant ingestion. Although this provides gastric evacuation, it thwarts efforts at activated charcoal administration. Aggressive antiemetic therapy should therefore be provided. Antiemetic therapy should include the administration of H_2 antagonists, which reduce gastric hypersecretion. Other beneficial agents include metoclopramide, 0.1 to 1.0 mg/kg intravenously, and ondansetron, 0.6 mg/kg intravenously.

Laboratory evaluation should include electrolytes, blood glucose, creatine phosphokinase, arterial blood gas, and an electrocardiogram. Hypokalemia should be treated with modest potassium supplementation (because total-body potassium is preserved). Insulin is not recommended for treatment of hyperglycemia, although it has been suggested by others.¹²⁶

Enhanced elimination is the final component of managing caffeine poisoning. A number of measures have been shown to be effective, including multiple-dose activated charcoal, peritoneal dialysis,^{114,119} and HD/HP.^{118,127} Although a proportion of caffeine is excreted from the urine unchanged, forced diuresis has no role in management. Diuresis should be provided only if patients have clinical evidence of severe rhabdomyolysis.

Multiple-dose activated charcoal has not been clearly shown to enhance caffeine elimination but does eliminate any theophylline that is generated; it is therefore considered an integral component of treatment. Use of several antiemetic agents may be necessary to end vomiting. Peritoneal dialysis has been used but is unlikely to be more helpful than multiple-dose activated charcoal. Hemodialysis is the procedure that provides greatest efficacy with the lowest complication rate. Indications for hemodialysis are not clearly established but should include a serum caffeine concentration of greater than 100 $\mu\text{g}/\text{mL}$ and life-threatening seizures or cardiac arrhythmias, regardless of serum caffeine concentration. Because it is both invasive and unlikely to be more effective than hemodialysis, hemoperfusion has little to no role in the management of caffeine intoxication.

At a Glance...

- There are two main anticoagulant medication mechanisms of action: (1) platelet aggregation inhibition, involving the glycoprotein IIb/IIIa receptor inhibitors eptifibatid and abciximab and the cyclooxygenase inhibitor aspirin; and (2) disruption of the coagulation cascade, involving the vitamin K inhibitors warfarin and superwarfarins, antithrombin III acceleration through factors II and X, the heparins, and fondaparinux, and direct thrombin (factor II) inhibition through leech-derived anticoagulants (hirudins) and ximelagatran.
- Even in overdose situations, anticoagulants rarely precipitate life-threatening hemorrhage.
- Treatment should be based on clinical assessment supported by the results of bleeding time studies (partial thromboplastin time, prothrombin time, International Normalized Ratio, hematocrit concentration, and platelet concentration).

Anticoagulation has become a fundamental basis of medical therapy for patients with cardiovascular and thromboembolic disease. Medications that disrupt or block platelet aggregation and fibrin cross-linkage are now the standard of care in management and prevention of vaso-occlusive events.

The results of multiple studies on the treatment of acute coronary syndrome, deep vein thrombosis (DVT), and pulmonary embolism have led to the development, introduction, and implementation of new anticoagulant and antiplatelet medications as well as their dosing protocols. This increase in the number of available agents, in conjunction with the widespread use of anticoagulants, may explain the changing profile of anticoagulant overdose and exposure. Although anticoagulants have also had long-standing use as rodenticides, Toxic

Exposure Surveillance System (TESS) data from 2000 to 2004 show that the number of rodenticide anticoagulant exposures in the United States stayed constant at about 17,000 per year; the number of anticoagulant overdoses from medical therapeutic use increased each year during the same time period, from 2871 overdoses in 2000 to 4786 in 2004 (Table 66-1).

Anticoagulation medications targeted toward various components of the coagulation cascade and platelet aggregation systems continue to be developed, and new trials to prove efficacy in vaso-occlusive events continue to be held. As such, the scope of the material in this chapter is constantly evolving, and specific product information data sheets should be referred to when encountering new anticoagulant therapies.

REVIEW OF COAGULATION

Understanding the mechanism of coagulation is key to understanding the mechanism of action of various anticoagulants and therapies for overdose. The two components of the coagulation pathway are the platelet system and the coagulation cascade.

The Platelet System

Platelet coagulation is mediated by both vascular wall adhesion through von Willebrand factor (vWF) and platelet aggregation through glycoprotein IIb/IIIa (gpIIb/IIIa) receptors. Vascular injury exposes collagen and releases tissue factor. Circulating inactive platelets adhere to the site of injury by binding either directly to collagen or indirectly through vWF, and then are “activated” by locally generated thrombin. Soluble

Compiled from Annual Reports of the American Association of Poison Control Centers Toxic Exposure Surveillance System, 2000–2002.

FIGURE 66-1 Platelet adhesion and aggregation to injured vascular wall. Platelets bind directly to collagen or to von Willebrand factor (vWF) and are “activated” by locally generated thrombin. Adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2) are released by active platelets to recruit further platelets. Activated platelets bind to each other through fibrinogen linkages to $gpIIb/IIIa$ receptors up-regulated to platelet membrane surface.

factors such as adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2) are released by activated platelets to recruit nonadherent platelets.

Platelets then aggregate by adhering to each other through fibrinogen linkages. Fibrinogen molecules bind to the $gpIIb/IIIa$ receptor, the most abundant platelet surface protein. The $gpIIb/IIIa$ receptors can undergo up-regulation to effectively double in number on the surface of activated platelets (Fig. 66-1).

The Coagulation Cascade

The coagulation cascade is a chain of events that starts with dormant enzymes (proteases) called *coagulation factors* and ends with the activation of the protein thrombin. Thrombin is needed for platelet activation and to cleave fibrinogen into fibrin for cross-linkage (Fig. 66-2). By having this chain of activations rather than one single activation, modifications made early in the cascade can quickly be amplified, leading to timely changes in thrombin production.

Coagulation factor nomenclature uses Roman numerals; many also have eponyms or “given” labels (Table 66-2). An inactive factor will be written as simply the Roman numeral, whereas an activated factor has a small Roman alphabet letter “a” appended to it (e.g., inactive factor VII, when activated is written as factor VIIa).

Although most coagulation factors are made by the liver, factor XIII is derived from platelets and factor VIII from endothelial cells. Factors II (prothrombin), VII (Stable), IX (Christmas), and X (Stuart) and anti-coagulant proteins C and protein S are dependent on γ -carboxylase, a vitamin K-dependent liver enzyme.

Intrinsic and Extrinsic Pathways

The coagulation cascade is triggered by either factors intrinsic to circulating blood (leading down the intrinsic pathway) or tissue-based factors extrinsic to blood (leading down the extrinsic pathway). The intrinsic system is activated when high-molecular-weight kininogens (precursors of bradykinin) and the enzyme

kallikrein activate factor XII in the presence of collagen exposed from an injury. Its major factors are XII, XI, IX, and VIII. Factor VIII, normally complexed to vWF, is activated upon dissociation. Factor X is not activated until both activated factors VIIIa and IXa are in the presence of calcium and platelet phospholipids (PLs). This pathway is measured by the partial thromboplastin time (PTT). The extrinsic pathway is initiated when thromboplastin (i.e., tissue factor [TF]), a lipid-rich protein released on tissue injury, directly activates factor VII, which in turn triggers IX with subsequent activation of factor X. This pathway is measured by the prothrombin time (PT).

After convergence of the cascade at factor X, active factor Xa complexes with factor Va and Ca^{2+} in the presence of PLs to create the factor Va + Xa + calcium + PL complex that cleaves prothrombin (II) to thrombin (IIa).

Control of the Coagulation Cascade

There are two “brakes” that control the coagulation cascade: the thrombolytic system and coagulation factor inhibition. In the thrombolytic system, the inactive precursor protein plasminogen is cleaved into the serum protease plasmin after coming into contact with thrombin. Plasmin then cleaves fibrin to break up the clot and, in doing so, creates fibrin degradation products that inhibit further thrombin formation.

Coagulation factor inhibitors include antithrombin III (ATIII), protein C, and protein S. Protease inhibitor ATIII physically blocks the action of coagulation factors in the coagulation cascade (thrombin, IX, X, XI, and XII). This blockade is accelerated up to 2000 times by heparin. Protein C is activated by thrombin to cleave factor Va into its inactive form, preventing the factor Va + Xa + calcium + PL complex from cleaving prothrombin to thrombin. Protein S is a necessary cofactor of protein C.

Vitamin K and Coagulation

Vitamin K is discussed in detail elsewhere in this text. Because of its important role in coagulation and the

FIGURE 66-2 The coagulation cascade. HMWK, high-molecular-weight kininogens (bradykinin precursors); PL, platelet phospholipids; PT, prothrombin time; PTT, partial thromboplastin time; TF, tissue factor (thromboplastin); vWF, von Willebrand factor.

mechanism of action for some anticoagulants, it is reviewed here.

Vitamin K is a lipid-soluble vitamin found and manufactured in a synthetic and two natural forms. Natural vitamin K₁ (phytonadione, phylloquinone) is synthesized

FIGURE 66-3 Structure of vitamin K subtypes. All subtypes have a recognizable two-ring basic structure.

by plants and algae. Natural vitamin K₂ (menaquinone) is produced by bacteria. Vitamin K₃ (menadione) is synthetic and converted to active K₂ in vivo. All vitamin K subtypes are two-ring structures with variable carbon side chains (Fig. 66-3).

Vitamin K is required for γ -carboxylation of glutamate residues to activate factors II, VII, IX, and X. Vitamin K produces γ -carboxylase (γ -carboxyglutamate), which chelates Ca²⁺, allowing binding of vitamin K–dependent clotting factors to phospholipid membranes during activation of the coagulation cascade. Reduction or absence of vitamin K leaves factors II, VII, IX, and X in their inactive states, halting the coagulation cascade. With an estimated plasma half-life of 1.7 hours,¹ vitamin K₁ depletion resulting in clinically significant change within the coagulation cascade is not expected for at least 24 hours; that is, five half-lives of vitamin K plus five half-lives of the vitamin K–dependent clotting factor with the shortest half-life ($t_{1/2}$ [factor VII] = 6 hours²):

$$= 5(t_{1/2}[\text{vitamin K}]) + 5(t_{1/2}[\text{factor VII}])$$

ANTICOAGULANTS BY MECHANISMS OF ACTION

Vitamin K Inhibition

Warfarins and superwarfarins (4-hydroxycoumarins and inandiones) disrupt the vitamin K cycle by primarily inhibiting vitamin K 2,3-epoxide reductase and, to a lesser degree, vitamin K quinone reductase (Fig. 66-4). These drugs prevent the regeneration of active vitamin K₁ (quinol) with subsequent depletion of vitamin K–dependent coagulation factors (II, VII, IX and X) and disruption of the coagulation cascade.

WARFARIN

Background

Warfarin was developed after the discovery of the agent responsible for a hemorrhagic bovine disorder in which cows that ingested spoiled sweet clover silage would develop internal bleeding associated with plasma

TABLE 66-2 Coagulation Factors and Their Eponymous Names

FACTOR*	EPONYM/"TRIVIAL" NAME
I	Fibrinogen
II	Prothrombin
III	Tissue factor
IV	Calcium
V	Proaccelerin, labile [†]
VI	Accelerin
VII	Stable, proconvertin, serum prothrombin conversion accelerator (SPCA)
VIII	Antihemophilic factor A
IX	Christmas, antihemophilic factor B
X	Stuart-Power factor
XI	Plasma thromboplastin antecedent (PTA)
XII	Hageman factor
XIII	Fibrin stabilizing factor (FSF)

*Activated factors append a letter "a" to the Roman numeral (e.g., inactive factor VII becomes activated factor VIIa).

[†]Note that *labile* is the eponym for factor V, while "factor V Leiden" refers to the gene defect in factor V resulting in diminished anticoagulation and consequent hypercoagulable state.

Adapted from King MW: Blood coagulation. Retrieved July 12, 2004, from <http://web.indstate.edu/theme/mwking/blood-coagulation.html>.

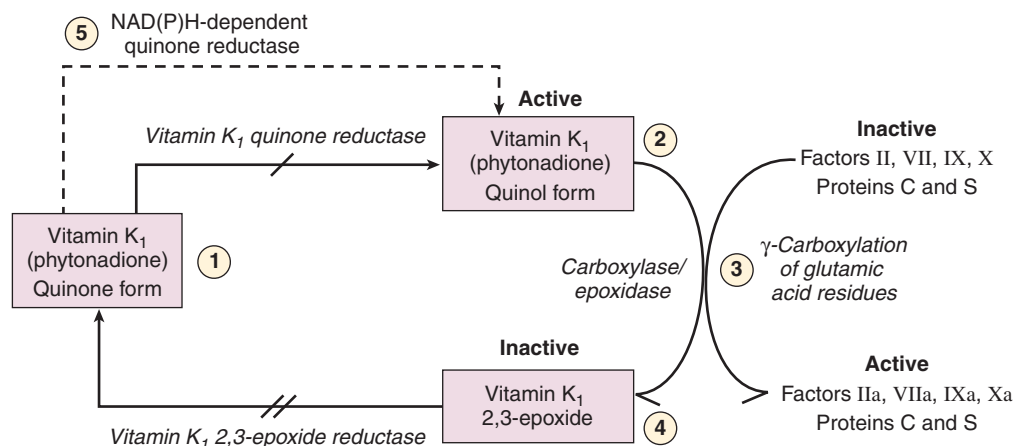

FIGURE 66-4 The vitamin K cycle. Inactive vitamin K–dependent prozymogens are coagulation factors II, VII, IX, and X and proteins C and S. (1) Vitamin K₁ (quinone form) is reduced by vitamin K₁ quinone reductase to its active (quinol) form. (2) Quinol (hydroquinone, vitamin K_{H2}) exists in hepatic microsomes. (3) Carboxylase-epoxidase (coupled) enzyme simultaneously catalyzes γ -carboxylation coagulation factors to active form and converts quinol to the inactive vitamin K₁ 2,3-epoxide. (4) Vitamin K₁ 2,3-epoxide \rightarrow recycled via epoxide reductase to quinone. (5) Alternatively, NAD(P)H-dependent quinone reductase is not affected by warfarins \rightarrow vitamin K administered exogenously may still be reduced and counter anticoagulation. (Adapted from Burkhardt K: Anticoagulant rodenticides. In Ford MD, Delaney KA, Ling LJ, Erickson T [eds]: Clinical Toxicology. Philadelphia, WB Saunders, 2001, p 849.)

prothrombin reduction.³ From this clover, the natural bishydroxywarfarin (dicoumarol) was eventually derived in 1939; later, the Wisconsin Alumni Research Foundation synthesized and named the pharmaceutical agent warfarin, which became commercially available in 1955.³ In 2002, warfarin was the 64th-most frequently prescribed drug based on the number of prescriptions written.⁴

Usage and Indications

Warfarin is a racemic mixture of R- and S-enantiomers. The S-enantiomer is five times more potent than the R orientation at producing hypoprothrombinemia (decreased prothrombin slows the coagulation cascade) in rats⁵ and 1.8 times more potent in humans.⁶ The S-enantiomer is also eliminated more slowly than the R-enantiomer in rats, but is more rapidly eliminated in humans.⁷ This difference in enantiomer potency and rate of elimination makes warfarin an appealing rodenticide. As a therapeutic anticoagulant in humans, warfarin is used for treatment of pulmonary embolism and DVT, to prevent atrial thrombus formation in atrial fibrillation, and for patients with severe peripheral vascular disease and arterial stenoses.

Pharmacokinetics

Warfarin's only route of administration is oral, and it is almost completely absorbed from the gastrointestinal tract.⁴ Maximum plasma concentrations are reached within 20 minutes to 4 hours after ingestion.^{4,8} Warfarin is highly protein bound (99%), but only the free fraction of the drug is active.⁴ Warfarin's half-life is 36 to 42 hours,⁹ and its duration of action after a single dose is 2 to 5 days⁸; it takes about 6 days to reach a steady state. Inhibition of vitamin K regeneration is almost immediate, but effects are delayed until existing stores of vitamin K are depleted and active coagulation factors re-

moved from circulation. Because of the rapid turnover of vitamin K, warfarin's effects are dependent on factor half-life, and PT prolongation is not seen until factors are reduced to 25% of their normal values. For example, factor VII, which is depleted most rapidly, has a half-life of 5 hours; hence, it takes at least 15 hours until PT prolongation is evident.

Metabolism

Warfarin is metabolized in the liver through the cytochrome P-450 system. The R-enantiomer is primarily metabolized by isoenzymes CYP1A2 and CYP3A4¹⁰ and excreted in the kidney. The S-enantiomer is metabolized more rapidly by CYP2C9¹⁰ and secreted into bile. Elimination half-life is 24 to 36 hours. Drugs that inhibit the P-450 system, and subsequently prolong warfarin's action, include erythromycin, metronidazole, thyroxine, isoniazid, and trimethoprim-sulfamethoxazole. Substances that enhance the P-450 system to induce warfarin's metabolism, thus decreasing its effectiveness, include barbiturates, penicillin, carbamazepine, char-broiled foods, and tobacco smoke.

Dosage and Therapeutic Monitoring

Warfarin is dosed once daily orally and titrated to an appropriate international normalized ratio (INR) for different conditions. Warfarin use is monitored by measuring PT and calculating the INR. The INR "normalizes" variations in PT measurement due to different sensitivities of reagents used by different laboratories.

Most clinicians opt for a goal INR of 2.0 to 2.5 in patients with atrial fibrillation; an INR of 2.5 to 3.0 for patients being treated for venous thromboses; and an INR as elevated as 2.5 to 3.5 in patients with mechanical prosthetic heart valves.⁹ The optimal children's dose has been calculated to be $0.07 \times [\text{weight in kg}] + 0.54 \text{ mg},^{11}$

whereas nomograms have been developed to guide initial dosage in adults based on clinical situation and target INR.¹²

Warfarin in Pregnancy

Warfarin is a pregnancy category X drug (adverse effects reported, contraindicated in pregnancy) and is a teratogen that leads to a particular constellation of congenital defects after ingestion during the first trimester, particularly between weeks 6 and 9 of gestation. About one third of infants exposed to warfarin during this time period develop fetal warfarin syndrome (FWS; also known as *warfarin embryopathy* or *fetal Coumarin syndrome*).¹³ Infants with FWS display a range of physical and central nervous system anomalies, including nasal hypoplasia, stippling of uncalcified epiphyses (particularly of the axial skeleton), mild hypoplasia of nails and shortened fingers, low birth weight, and varying degrees of mental retardation.

Patients who are breast-feeding may use warfarin for anticoagulation therapy. An inactive form of warfarin is excreted into breast milk,⁸ but several researchers have confirmed that active warfarin is not detectable in human milk, and there is no evidence of detectable warfarin levels, altered coagulation, or other adverse events in infants exposed to breast milk from mothers taking warfarin.^{14,15}

Overdose

In therapeutic overmedication, warfarin should be held and indications for vitamin K administration should be reviewed in consultation with those monitoring therapeutic dosing. Patients with an abnormally elevated INR or intentional warfarin overdose should be admitted to a hospital and placed on bed rest to minimize the risk for trauma with subsequent internal or intracranial bleeding. Often, depending on a patient's INR, withholding warfarin administration for several days is sufficient to bring an INR down to therapeutic levels. Vitamin K is indicated for those with a significantly elevated INR that does not decrease when warfarin is withheld or when there is evidence of hepatic synthetic dysfunction (e.g., a significant increase in liver transaminase concentrations or in the INR). Fresh frozen plasma is indicated for those with active bleeding. In the absence of recent changes in dosing regimen, clinicians should investigate reasons for an increased INR, such as the use of other medications that may inhibit the cytochrome P-450 system, infection, or misuse or mislabeling.

In acute overdose of warfarin, treating practitioners should determine the nature of the ingestion: unintentional (accidental) or intentional. In most accidental single ingestions, the amount of warfarin ingested is highly unlikely to result in a clinically apparent coagulopathy, and most patients may be monitored safely at home with appropriate caveats to avoid contact sports and situations increasing the likelihood of traumatic injury for several days. Intentional ingestions present the dilemma that a patient may ingest further warfarin when not being monitored. Repetitive

ingestions can lead to a clinically significant coagulopathy. These patients should be dispositioned after consultation with a poison control center (the American Association of Poison Control Centers national poison control center hotline is 1-800-222-1222; www.aapcc.org) and appropriate psychiatric services.

Nonbleeding Complications

Warfarin use has been implicated in the rare development of nonhemorrhagic skin lesions ranging from simple ecchymosis and purpura to urticaria, purple toes, and skin necrosis.¹⁶ Warfarin skin necrosis usually appears over fatty tissues (breasts, buttocks, thighs) 3 to 6 days after warfarin therapy initiation; patients with protein C, protein S, and antithrombin III deficiency appear to be at greater risk for development of this condition.¹⁷ Warfarin should be discontinued in patients who acquire skin necrosis, and alternative anticoagulation should be started to prevent postcapillary thrombosis. Purple toe syndrome is thought to be caused by anticoagulant-induced bleeding into atherosclerotic plaques releasing cholesterol crystal emboli.¹⁸ Changing anticoagulation agents is thus unlikely to prevent or reverse progression.

SUPERWARFARINS

Background

The superwarfarins, 4-hydroxycoumarins and inandiones, were developed in response to genetic resistance to warfarin in rats.¹⁹⁻²¹ They are primarily used as rodenticides and have no role in human medical therapeutic anticoagulation. In fact, warfarin ingestions were deemed "clinically insignificant" until 1976 when the superwarfarins were developed for use as rodenticides. The 4-hydroxycoumarins in use today are difenacoum, brodifacoum (D-Con), bromadiolone, and coumatetralyl. Inandiones include chlorophacinone, diphacinone, and pindone.

Both the hydroxycoumarins and inandiones have a two-ring base structure similar to warfarin (Figs. 66-5 and 66-6). Both groups function just as warfarin does, by inhibiting vitamin K 2,3-epoxidase.

Toxicokinetics

Superwarfarins are highly lipid soluble and are mostly concentrated in the liver. On a mole-for-mole basis, they are 100 times more potent than warfarin.²² In overdose, their elimination half-life is weeks to months,²² up to 60 times longer than warfarin's half-life of 35 hours. They also have a considerably longer duration of action: a rat that dies after a single superwarfarin ingestion would require 21 days of warfarin before meeting the same fate.

FIGURE 66-5 Warfarin.

4-Hydroxycoumarin

Indandione

FIGURE 66-6 Structures of 4-hydroxycoumarin (left) and indanedione (right). Note the two-ring base structure, similar to that of warfarin in Figure 66-3.

Ingestion

Superwarfarin ingestions illustrate the toxicologist's adage that "it is only the dose which makes a thing a poison" (Aureolus Paracelsus, 1493–1541). Given that repetitive dosing is necessary to achieve therapeutic anticoagulation with warfarin alone, it stands to reason that small single acute ingestions (e.g., a mouthful) are unlikely to produce a clinically significant coagulopathy: a 10-kg child would need to ingest 3000 mg/kg of a 0.005% warfarin-based rodenticide for coagulopathy to develop.²³

Management of superwarfarin ingestion should be based on amount ingested as related to circumstance of ingestion. Most cases of superwarfarin exposure are either intentional ingestions by adults or unintentional ingestions by children (including ingestion of rat feces from poisoned rodents²⁴). Case reports have also described warfarin and superwarfarins as agents of ingestion for Munchausen syndrome and Munchausen syndrome by proxy.²⁵⁻³¹

Regardless of amount of superwarfarin ingested, clinically significant anticoagulation in a patient not already taking an anticoagulant agent is not anticipated for about 24 hours, that is, until there is both the depletion of existing vitamin K stores and subsequent loss of vitamin K–dependent clotting factor regeneration (factors II, VII, IX, and X). Table 66-3 lists half-lives of vitamin K and vitamin K–dependent clotting factors.³²

Patients who have ingested superwarfarins intentionally should undergo routine decontamination and have their PT and INR monitored 24 and 48 hours after ingestion. In the acute phase, PT and INR should be reassessed every 6 hours if prolongation is observed.

TABLE 66-3 Half-Lives of Vitamin K and Its Dependent Clotting Factors*

VITAMIN/FACTOR	HALF-LIFE (t _{1/2})
Vitamin K ₁	1.7 hr
Factor II	50–80 hr
Factor VII	6 hr
Factor IX	24 hr
Factor X	25–60 hr

*Disruption of the clotting cascade following warfarin or superwarfarin ingestion is expected when vitamin K is depleted and its dependent clotting factors cease regeneration.³²
From Makris M, Watson HG: The management of coumarin-induced over anticoagulation. *Br J Haematol* 2001;114(2):271–280.

There are no means of enhanced elimination of superwarfarins, and multidose activated charcoal has not shown any clear benefit.³³ In asymptomatic patients, vitamin K₁ (phytonadione) may be administered orally at an initial dose of 5 to 15 mg/day, although an ideal dose has not been established. Bruno and colleagues reported that weight-based dosing of 7 mg/kg over 24 hours divided every 6 hours was needed to treat brodifacoum-induced coagulopathy from 344 g of rodenticide containing 0.005% brodifacoum (17.2 mg brodifacoum).³⁴ Administration of vitamin K₁, 100 to 125 mg/day for several months, has been reported in cases of severe overdose without ill effect; hence, oral dosing of up to 40 to 50 mg three times daily should be considered in those with clinically significant coagulopathy.

Historical recommendations for management of symptomatic patients using parenteral administration of vitamin K₁ are changing³⁵ (Table 66-4). Although intravenous (IV) administration of vitamin K₁ may reverse anticoagulation more quickly than oral administration,³⁶ IV administration remains controversial because it has been associated with anaphylactoid reactions.³⁷⁻³⁹ Lubetsky and associates reported that oral administration of vitamin K₁ is as safe and efficacious in reversal of excessive anticoagulation as when administered intravenously,⁴⁰ making the argument for IV administration of vitamin K₁ a less appealing alternative.

With unintentional single ingestions, PT prolongation is unlikely, owing to the relatively small doses ingested. In Thacker's 14-year case series of children ingesting superwarfarins (1986 to 2000), PT and INR prolongation was seen in less than 0.5% of 11,751 exposures, and only 11 patients developed hemorrhage, all of minimal clinical significance (epistaxis [3], hemarthrosis [2], heme-positive stool [2], vomiting [2], minor bleeding not specified [1]).⁴¹ A prospective study of pediatric superwarfarin poisoning by Smolinske and colleagues showed that PT value prolongation was not seen until 48 hours after suspected ingestion and that clinically significant ingestion was apparent in only 2 of 110 patients.⁴²

Children who ingest a small dose of a warfarin-based rodenticide (0.01%–0.005% strength) do not need to

TABLE 66-4 American College of Chest Physicians' Recommended Dosing of Subcutaneous Vitamin K₁ for Reversal of Warfarin/Superwarfarin-induced Coagulopathy in 1995

INR	BLEEDING	DOSE OF VITAMIN K ₁ ADMINISTERED INTRAVENOUSLY OR SUBCUTANEOUSLY*
Any	Serious	10 mg
<6	None	None
6–10	None	0.5–1 mg
10–20	None	3–5 mg
>20	None	10 mg

*Intravenous or subcutaneous administration is in addition to oral vitamin K₁ administration. Single oral route of administration of vitamin K₁ has since proven equally effective.

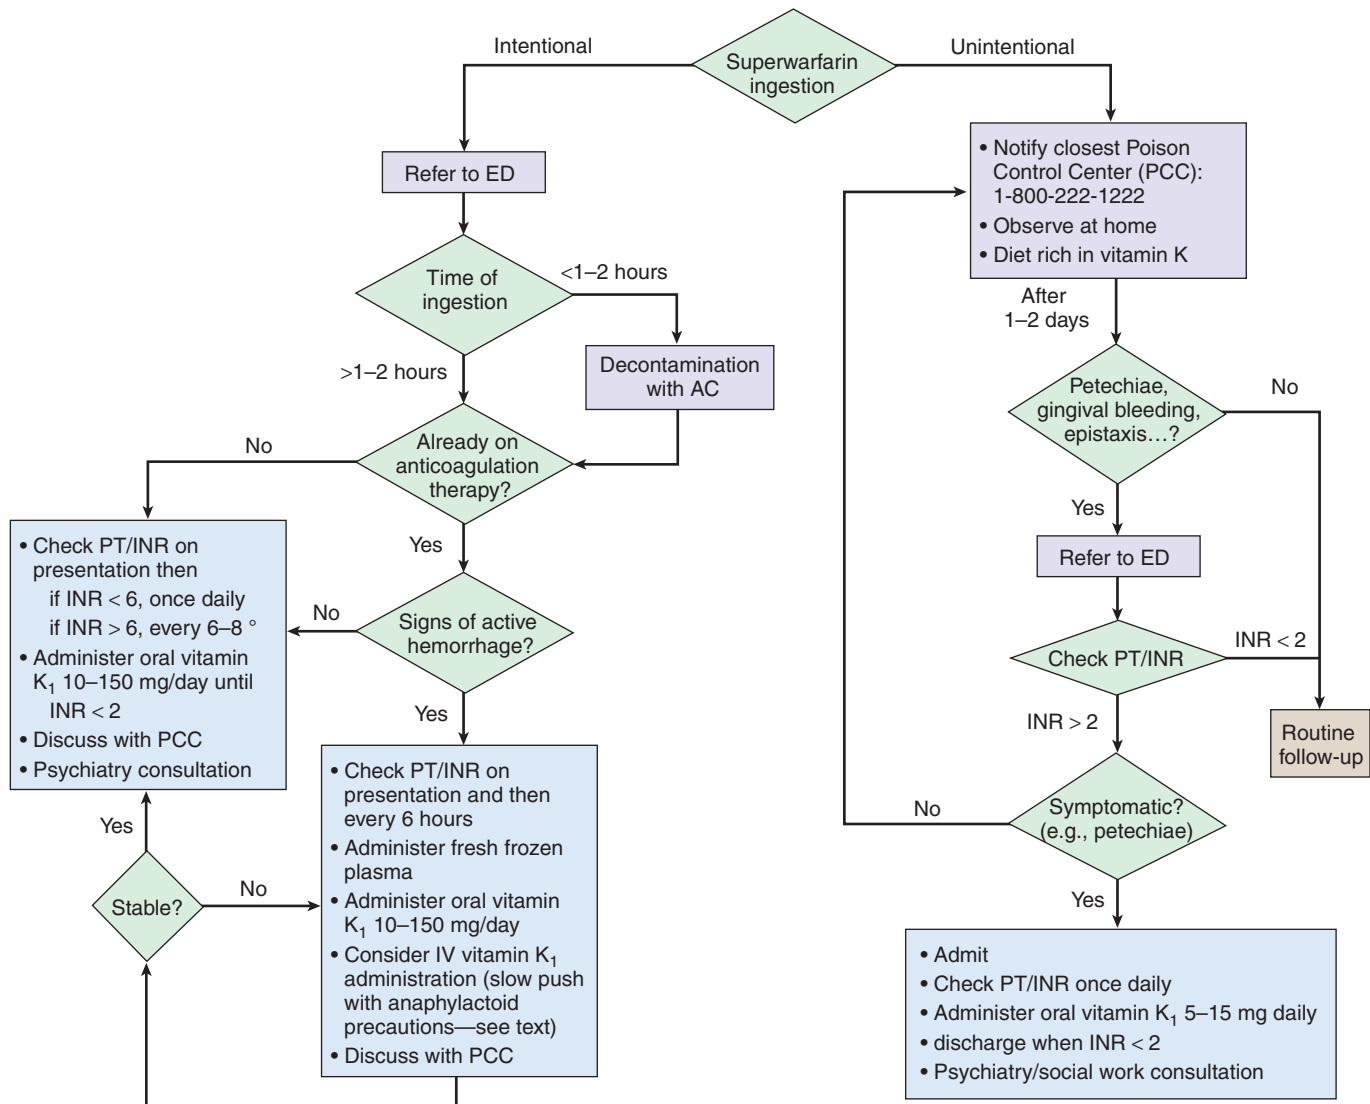

FIGURE 66-7 Proposed general guideline for management of superwarfarin ingestion. Clinicians should take care to assess whether the ingestion is intentional or unintentional. Intentional ingestions are generally by adults; unintentional ingestions are generally by children.

Unintentional ingestions are usually small (fewer than two are three mouthfuls) and are unlikely to cause clinically significant anticoagulation. The local poison control center should always be contacted, and the superwarfarin product should be reviewed for concentration of active ingredient and other possible toxins.

Patients who have ingested intentionally may present hours to days after their ingestion, usually to a local emergency department (ED) secondary to symptoms such as ecchymosis development or petechiae. Active bleeding (e.g., melena, expanding hematoma, bright red blood from rectum, oozing wounds) requires immediate reversal with fresh frozen plasma (FFP). Lubetsky and colleagues concluded in 2003 that oral administration of vitamin K is as effective as IV administration for warfarin anticoagulation reversal,⁴⁰ but patients unable to take vitamin K orally may require it intravenously. Note that IV administration of vitamin K remains controversial, with several reports of anaphylactoid reactions upon administration. In the event of anaphylaxis, IV vitamin K should be discontinued immediately and epinephrine administered in conjunction with antihistamines and steroids. Oral vitamin K may be continued unless a similar reaction is observed. AC, activated charcoal; INR, International Normalized Ratio; PT, prothrombin time. (Courtesy of M. W. Lai, MD, and M. W. Shannon, MD, MPH, Massachusetts/Rhode Island Poison Control Center [M. Burns Ewald, MD, Director], Boston.)

present to an emergency department.⁴³ However, patients and parents should be advised to watch for signs of bleeding diatheses; asymptomatic patients can be observed at home if the history is certain that the ingestion was unintentional. If any symptoms develop, the child should have a routine medical screening examination and PT and INR drawn. Increases in PT and INR should be followed weekly until a downward trend is seen. Oral

vitamin K₁, 5 to 10 mg, or a diet rich in vitamin K-containing vegetables can be encouraged in the interim.

A proposed guideline for superwarfarin ingestion management is shown in Figure 66-7.

Clinicians should take care to assess whether the ingestion is intentional or unintentional. Intentional ingestions are generally by adults; unintentional ingestions are generally by children.

Antithrombin III Acceleration through Factor II and Factor X Inhibition

Antithrombin III blocks coagulation factors II, IX, X, XI, and XII. Heparins bind to thrombin (factor IIa) and factor Xa to accelerate the anticoagulant effect of ATIII up to 2000 times.

UNFRACTIONATED HEPARIN

Unfractionated heparin (UFH) is a naturally occurring, negatively charged mucopolysaccharide (glycosaminoglycan) primarily synthesized and secreted by mast cells. Deriving its name from its particular abundance in liver, heparin was discovered by a medical student who, in studying ether-soluble procoagulants, stumbled on this water-soluble anticoagulant instead. Heparin is manufactured through extraction from bovine lung tissue and porcine intestines. Because UFH has varying polysaccharide side-chain lengths, its molecular weight ranges from 3000 to 30,000 daltons.⁴⁴ UFH accelerates ATIII protease inhibition of thrombin by binding to thrombin (factor IIa) and factor Xa. When ATIII complexes to heparin that is bound to factors IIa and Xa, the complex causes conformational changes in these factors and inactivates them.

UFH is only administered parenterally (intravenously or subcutaneously). Dosing is weight based, and depending on the reason for administration, patients may receive 50 to 80 U/kg IV boluses followed by continuous infusions of 12 to 18 U/kg/hour or subcutaneous injections ranging from 7500 U (for DVT prophylaxis) to 20,000 U (for DVT treatment). UFH is an easily titratable medication because of its short half-life of 1 to 2.5 hours and short duration of action of 1 to 3 hours. Therapeutic monitoring is through the PTT.⁴⁵ The goal PTT for most vaso-occlusive events as well as thrombosis prophylaxis when heparin is used as a single agent is 60 to 80 seconds. Heparin is a pregnancy category C drug and the anticoagulant of choice during pregnancy; its negative charge and large size prevent its passage across the placenta.

Overdose

Because UFH is predominantly administered in the acute care setting, overdose is most often iatrogenic and may reflect transcription errors of the physician's or other health care provider's orders. Initial treatment is discontinuation of the heparin infusion. For patients with active bleeding requiring quick reversal, protamine sulfate (derived from salmon sperm and testes) should be administered. Protamine forms ionic bonds with heparin, preventing its attachment to factors II and Xa, with neutralization of heparin's effects within 5 minutes of administration.⁴⁶ Protamine should be dosed as follows:

- 1 mg protamine per 100 U heparin
 - Administer up to 50 mg intravenously over 10 minutes (more rapid administration may result in hypotension or anaphylactoid reaction).^{47,48}
 - Half the dose of protamine for each half-life of heparin (about 90 minutes) that has passed since initial administration.

- Watch for "rebound" hemorrhage: the half-life of protamine is shorter than that of heparin.

Patients previously given protamine for heparin reversal, such as after cardiac bypass surgery, are at risk for becoming sensitized to protamine. Insulin-dependent diabetic patients face a similar risk because protamine is also used to extend the absorption rate of some insulin preparations. (e.g., neutral protamine Hagedorn [NPH] insulin). Antibodies to protamine that develop from NPH insulin administration or from prior heparin reversal with protamine predispose patients to anaphylactoid reactions from future heparin anticoagulation reversal with protamine.⁴⁹⁻⁵³ There are no published reports of concurrent NPH insulin use interfering with heparin therapeutic goals.

Nonbleeding Complications

Patients who experience a drop in platelet count after initiation of heparin therapy may have heparin-induced thrombocytopenia (HIT). There are two forms of HIT. HIT I is characterized by a mild and transient drop in platelet count occurring within 2 days of heparin administration and is usually asymptomatic, resolving spontaneously.⁵⁴ HIT II (heparin-induced thrombocytopenia and thrombosis, or HITT) is more serious, leading to vascular thromboses and their complications. HIT II appears to be immunologically mediated, with 0.5% to 3% of patients given UFH developing HIT II after first developing heparin-induced antibodies.^{55,56} The frequency of HIT II appears to be less in patients administered UFH subcutaneously compared with intravenously.⁵⁷ Patients who develop HIT II should be taken off heparin immediately and should not have heparin in any form readministered. Clinicians may consider testing patients who develop HIT I for heparin-induced antibodies before administering heparin products in the future.

LOW-MOLECULAR-WEIGHT HEPARINS

Low-molecular-weight heparins (LMWHs) are the fractionated active pentasaccharide segment of heparin. Commonly used LMWHs in the United States include enoxaparin (Lovenox), dalteparin (Fragmin), and ardeparin (Normiflo). Average molecular weights run from 4000 to 6000 Daltons. Because binding to factor IIa requires the heparin molecule to have at least 18 saccharide units, LMWHs display targeted factor Xa activity rather than the factor IIa and Xa binding seen with unfractionated heparin. LMWHs have fixed weight-based dosing and are generally administered either once or twice daily, depending on their reason for administration.

Pharmacokinetics

LMWHs have a higher bioavailability than unfractionated heparin owing to a lower affinity for and decreased binding to endothelium, macrophages, and heparin-binding proteins. Their plasma half-life is 4 to 6 hours, with hepatic metabolism and renal elimination. Patients receiving LMWH therapy do not routinely undergo therapeutic monitoring. Relative effectiveness

and concentration of LMWHs can be determined from serum anti-factor Xa concentrations, as measured in IU/mL, if needed. Because of its fixed-dosing regimen, overdoses of LMWHs are infrequent. Because of its renal elimination, patients with renal insufficiency may experience more potentiated effects if weight-based dosing does not take renal function into account. If a patient does suffer an overdose and has active bleeding, protamine should be administered using the same guidelines as for overdose of unfractionated heparin. Since 1 mg of available LMWHs equals approximately 100 anti-Xa units, 1 mg of protamine should be given for every 1 mg of LMWH for Xa neutralization. Protamine does not completely neutralize the anti-Xa activity of LMWH. This is likely due to decreased binding of protamine to LMWHs.⁵⁸

DIRECT FACTOR XA INHIBITORS (FONDAPARINUX)

Similar to LMWHs, selective factor Xa inhibitors catalyze Xa inactivation by ATIII without inhibiting thrombin. These medications are essentially heparin derivatives, displaying similar structural features as UFH and LMWHs (Fig. 66-8). Fondaparinux (Arixtra) selectively binds ATIII and potentiates ATIII's neutralization of factor Xa by a factor of 300.⁵⁹ Currently, only fondaparinux has been approved for therapeutic anticoagulation in humans by targeting this stage in the coagulation cascade.

Representative of this emerging anticoagulant class, fondaparinux demonstrates 100% bioavailability and is 94% bound to ATIII. Peak plasma levels are seen in 2 hours. The volume of distribution (Vd) is 100 mL/kg. At least half of the drug is excreted unchanged in urine, and its elimination half-life is 17 to 21 hours. Fondaparinux is administered once daily by either IV or subcutaneous routes at a fixed non-weight-based dose. Presently, fondaparinux is approved for DVT prophylaxis, particularly after lower extremity surgery. Once-daily subcutaneous injection without monitoring has been shown to be as safe as adjusted-dose IV heparin for treatment of pulmonary embolus.⁶⁰ Administration in patients who weigh less than 50 kg is contraindicated because of doubling of the incidence of major bleeding.⁵⁹ Patients receiving fondaparinux therapy do

not routinely undergo therapeutic monitoring. Plasma concentration of the drug can be quantified by serum anti-factor Xa activity when the anti-factor Xa assay is calibrated with fondaparinux. Hence, fondaparinux activity is expressed as milligrams of fondaparinux calibrator. The anti-Xa activity of the drug is enhanced by increasing drug concentration, reaching maximum values in about 3 hours.⁵⁹ No specific reversal agent has been developed yet for fondaparinux. Because of its small volume of distribution, however, this anti-factor Xa drug is amenable to hemodialysis. Further direct factor Xa inhibitors are being developed, including idraparinux, a “depo” fondaparinux requiring only once-weekly administration.⁶¹

Direct Thrombin Inhibition

LEECH-DERIVED ANTICOAGULANTS (HIRUDINS)

Background

Leech-derived anticoagulants are small molecules that directly inhibit thrombin (factor IIa). Halting the coagulation cascade at this stage prevents fibrinogen cleavage into fibrin, which is necessary for cross-linkage and subsequent clot formation. Hirudin is the actual 65-amino acid anticoagulant protein found in leech salivary glands. Recombinant DNA hirudins such as desirudin (Revasc) and lepirudin (Refludan) have been developed, as well as hirudin analogs such as bivalirudin (Angiomax). Hirudins are primarily used as heparin substitutes for patients unable to tolerate heparins because of HIT. To date, no published studies have indicated that hirudin use for acute coronary syndrome offers long-term advantage over heparin, but hirudins have been shown to be more effective in preventing postoperative DVT when compared with UFH.⁶²

Hirudins can be administered by either intravenous or subcutaneous routes. Recombinant hirudins are pregnancy category B drugs. Animal studies have not shown teratogenic effects, but hirudins can cross the placental barrier in rats; it is unknown whether hirudins cross the human placenta.⁶³ Effectiveness of hirudin anticoagulation may be assessed through measuring the PTT. Although overdose is rare, hemodiafiltration has been successfully used to manage a 30-fold overdose of lepirudin without bleeding complications.⁶⁴

FIGURE 66-8 Top, Representative repeat unit of unfractionated heparin and low-molecular-weight heparin (LMWH). LMWH contains five repeating units. Bottom, fondaparinux.

XIMELAGATRAN AND MELAGATRAN

Melagatran is a direct thrombin inhibitor with a low molecular weight (429 Daltons). It has poor oral absorption (3% to 7% alone, 1% with food), but its prodrug, ximelagatran (Exanta), possesses better absorptive properties. Rapid hydrolysis and reduction of ximelagatran to melagatran increases melagatran's oral bioavailability to 25%. At present, melagatran and ximelagatran are primarily being used for DVT prevention and anticoagulation for patients with atrial fibrillation. Early studies suggest that it is “superior” to warfarin for prevention of DVTs while maintaining a similar hemorrhagic complication profile,⁶⁵ as well as the advantage of fixed dosing.

Melagatran and ximelagatran reach peak plasma levels in 2 hours and are 0% to 15% protein bound. Their Vd is 200 mL/kg, and they are renally excreted with an elimination half-life of 3.5 hours. Fixed dosing of melagatran, 2 to 3 mg subcutaneously, is followed by oral doses of ximelagatran at either 24 mg twice daily or 36 mg twice daily, depending on the reason for administration. Dose adjustments are made empirically for patients with renal insufficiency. Although there is no monitoring for therapeutic levels of these direct thrombin inhibitors, the PTT may be tested in patients with renal impairment in order to titrate to an appropriate fixed dose.

Overdose

There is no specific melagatran or ximelagatran antagonist in the event of an overdose. Patients with active hemorrhage should be administered fresh frozen plasma for replacement of coagulation proteins or prothrombin concentrate. Although there have been no reports of hemodialysis to remove the drug, its small molecular weight and volume of distribution suggest that it could be effectively hemodialyzed.

Inhibition of Platelet Aggregation (Antiplatelet Anticoagulation Therapies)

GLYCOPROTEIN IIB/IIIa INHIBITION

The gpIIb/IIIa receptor is the most prevalent cell surface protein on platelets. Activation of platelets from their exposure to thrombin at the site of endothelial injury up-regulates gpIIb/IIIa receptors, doubling or even tripling their number. Fibrin cleaved from fibrinogen in the coagulation cascade cross-links to itself as well as between platelets by adhering to the gpIIb/IIIa receptor. Inhibition of the gpIIb/IIIa receptor arrests platelet aggregation through these fibrin connections.

Since their development in the mid-1990s, there are now multiple gpIIb/IIIa inhibitors in use, primarily for the treatment of acute coronary syndromes. Multiple studies have shown the effectiveness of gpIIb/IIIa antagonists in reducing the incidence of death or myocardial infarction in patients who undergo percutaneous coronary intervention (PCI, or cardiac catheterization) for unstable angina (UA) or non-ST elevation myocardial infarction (NSTEMI).⁶⁶ Table 66-5 compares the three gpIIb/IIIa inhibitors used in the United States today.⁶⁷⁻⁷¹ Others are xemilofiban, sibrafiban, orbofiban, and lamifiban.

When used concomitantly with heparin, gpIIb/IIIa inhibitors should lower the PTT goal (to a range of either 50–70 or 40–60 seconds). In overdose, the gpIIb/IIIa infusion should be discontinued, and platelets should be administered for active bleeding or a platelet count of less than $20 \times 10^9/L$.

ADENOSINE DIPHOSPHATE-INDUCED PLATELET AGGREGATION INHIBITION

Platelet activation leads to release of ADP, a soluble factor that induces further platelet aggregation through their recruitment and activation.

Drugs in the thienopyridine class (ticlopidine [Ticlid] and clopidogrel [Plavix]) are platelet aggregation inhibitors that work by irreversibly inhibiting ADP-induced platelet aggregation. They selectively and noncompetitively inhibit the binding of ADP to its platelet receptor (P_2 receptors) by irreversibly modifying the receptor. Doing so halts the ADP-mediated activation of the gpIIb/IIIa complex necessary for platelet linkage.⁷²⁻⁷⁴ The thienopyridine derivatives have similar chemical structures (clopidogrel adds a carboxymethyl side group). Both are metabolized by CYP1A to active metabolites that have not yet been isolated.⁷⁴ They affect

only P₂ receptors and do not inhibit ADP-induced changes in platelet shape.

Thienopyridines are being used as alternative antiplatelet agents in acute coronary syndromes. A single dose of 375 mg of clopidogrel achieves maximal platelet aggregation inhibition of 40% to 50% 2 to 6 hours after ingestion.⁷⁴ The same level of platelet inhibition is achieved in 3 to 7 days when clopidogrel is dosed at 75 mg once daily. Peak response is expected 5 days after the initial dose, and a return to baseline platelet function comes 5 days after discontinuation. Ninety-four percent to 98% protein bound, thienopyridines undergo about 50% to 60% renal excretion and 30% to 50% excretion in bile.^{75,76} Table 66-6 summarizes the pharmacokinetic parameters of clopidogrel and ticlopidine.

Thienopyridine use in patients undergoing PCI has become increasingly popular. This drug class has become an effective alternative antiplatelet medication for aspirin-intolerant patients with atherosclerotic cardiac disease. However, the one exception for thienopyridine use in patients suffering an acute coronary event is when a patient is likely to undergo a coronary artery bypass graft. The delay in recovery of platelet function may complicate intraoperative and postoperative care.

There is no therapeutic monitoring for thienopyridine use. However, routine quantitative platelet analysis (e.g., through a complete blood count) is indicated for patients taking thienopyridines because they can cause neutropenia and thrombocytopenia. The platelet function analyzer (PFA 100, Dade Behring, Illinois) may be used to assess platelet aggregation, although the gold standard for this measurement is optical aggregometry.

Overdose of thienopyridines remains a rare occurrence compared with other anticoagulant overdoses. Ingestion of up to 6000 mg clopidogrel has been reported.⁷⁷ Animal studies have reported dyspnea, seizures, gastrointestinal bleeding, and ultimately death after single acute ingestions of 500 mg/kg ticlopidine in mice and 2000 mg/kg clopidogrel in rats.⁷⁸ Although no thienopyridine antiplatelet reversal agent has yet been developed, DDAVP (desmopressin) administration may temporarily improve primary hemostasis by stimulating release of vWF factor from storage in endothelial cells and platelets.⁷⁴ Patients who overdose with clopidogrel or ticlopidine should undergo routine decontamination with activated charcoal and receive supportive measures.

TABLE 66-6 Pharmacokinetics of the Thienopyridines*

	CLOPIDOGREL	TICLOPIDINE
Trade name	Plavix	Ticlid
Oral bioavailability	50%	80%
Metabolism	CYP1A	CYP1A
Clearance	Linear	Nonlinear
Elimination half-life	8 hr	12.6 hr after single dose 4–5 days with repeated dosing
Protein bound	94%–98%	98%

*Available in 2004.

Because thienopyridines irreversibly change the ADP platelet receptor, return of platelet function is dependent on new platelet formation; platelet transfusion may be indicated for patients with active hemorrhage.

ASPIRIN

Acetylsalicylic acid (aspirin) has become a routine and ubiquitous agent in the treatment and prevention of unstable angina and myocardial infarction. Aspirin acetylates and irreversibly inhibits platelet cyclooxygenase to inhibit thromboxane production and hence interfere with platelet aggregation. A single 81-mg dose of aspirin or as little as 10 mg taken daily for 1 week will impair platelet function for the lifetime of a cohort of affected platelets.

Overdose

Hematologic complications of aspirin overdose are rarely seen, probably because the more active issues of metabolic derangement and subsequent central nervous system depression from salicylate toxicity must first be addressed. PT prolongation is fairly common, whereas disseminated intravascular coagulation, thrombocytopenia, and acute hemorrhage from aspirin overdose are uncommon.⁷⁹ Management of aspirin toxicity is addressed in greater depth elsewhere in this text (see Chapter 48).

BOTANICALS WITH ANTICOAGULANT PROPERTIES

Several botanicals have been demonstrated to show anticoagulant synergy with existing synthetic agents as well as when used as single agents. Garlic has been shown to inhibit platelet aggregation, and patients with previously stable INRs on warfarin have had elevated INRs after adding garlic to their diets.^{80,81} Ginger may inhibit platelet aggregation, but ingestion of up to 40 g of cooked ginger does not seem to affect platelet function. Ginkgo may also affect platelet aggregation and has been implicated in increased bleeding complications in patients taking anticoagulants.⁸² It has been suggested that ginseng can possibly inhibit platelet aggregation; however, a decreasing INR was noted in one case report, and animal studies show no effect of ginseng on INR.⁸³

SNAKE VENOM

Almost all snakes of the Crotalidae, Viperidae, and Crotalinae families have heparin-like substances that can lead to coagulopathy.⁸⁴ Elapidae bites rarely lead to hematologic disturbances; exceptions include *Naja nigricollis*, *Ophiophagus hannah* (king cobra), and the *Naja atra* (Chinese cobra).^{85,86} All patients with snake envenomations should have PT, PTT, INR, and fibrin split products monitored for development of coagulopathies. Detailed management of snake envenomations is discussed in elsewhere in this text (See Chapters 21A and 21B).

SUMMARY

Anticoagulant medications play an important role in the treatment and prevention of thromboembolic and

FIGURE 66-9 Summary of anticoagulant targets in the coagulation cascade. HMWK, high-molecular-weight kinogens.

cardiovascular disease (Fig. 66-9). Even in overdose, they rarely precipitate life-threatening hemorrhage.

In overdose, treatment should be based on clinical assessment of the patient, consideration of the nature of the overdose (unintentional versus intentional), and evaluation of bleeding time studies, hematocrit, and platelet concentration. Reversal agents, if available, should be administered for active exsanguination. In supratherapeutic administration of anticoagulants, most patients still need to maintain a certain degree of anticoagulation. In these cases, expectant management should be coordinated in conjunction with clinicians familiar with a patient's therapeutic monitoring trends. All overdoses of anticoagulants merit consultation with a poison control center.

At a Glance...

- Toxicity from thyroid preparations may result in a hyperadrenergic state with primary effects on the cardiovascular and central nervous systems.
- Although acute thyroid hormone overdose has been associated with moderate thyrotoxicosis and thyroid storm, most patients develop only mild signs and symptoms and do not require hospitalization.
- There does not appear to be a reported pediatric death due to acute thyroid hormone toxicity in the literature.
- Accidental acute ingestions of less than 5 mg of thyroxine may be managed at home and do not require emergent medical assessment and gastrointestinal decontamination.
- Patients with signs of thyroid hormone toxicity should be admitted to the hospital for close observation and expectant treatment.
- Treatments for exogenous thyroid storm include supportive care, hydration, antipyretics, β -adrenergic antagonists, iodine-containing contrast agents, corticosteroids, and gastrointestinal decontamination, as necessary.
- Iodide, propylthiouracil, and methimazole have minimal efficacy in the management of exogenous thyroid hormone toxicity.

Thyroid hormones are essential in normal growth and development, in many metabolic processes, and in the treatment of thyroid disorders. The clinical uses of thyroid hormones include replacement therapy for hypothyroidism, suppressive therapy to abolish thyroid-stimulating hormone (TSH) secretion in patients with differentiated thyroid carcinoma after total thyroidectomy or with diffuse and nodular nontoxic goiter. However, thyroid hormones are also abused by patients with thyrotoxicosis factitia, a syndrome due to surreptitious excess thyroid hormone ingestion because of psychopathologic disorders.¹⁻⁶ Acute thyroid hormone overdose has been associated with either few signs and symptoms that do not require hospitalization,⁷⁻¹¹ a mild to moderate thyrotoxicosis (e.g., flushing, tachycardia, fever, diarrhea, irritability, and insomnia),¹²⁻¹⁵ or a thyroid storm.¹⁶⁻¹⁸ Most cases follow a generally benign clinical course.⁷⁻¹¹ The incidence of life-threatening reactions that require treatment has been low,^{2,12,14-16,19-22} and morbidity^{5,18,23-28} and mortality^{26,29,30} have rarely been reported after an acute single or repeated thyroid hormone overdose. Adverse reactions or toxicity during therapeutic use may occur.^{23,31-34}

EPIDEMIOLOGY

Thyroid hormone-containing tablets are commonly prescribed drugs. Despite the fact that large numbers of

thyroid hormone-containing drugs are prescribed each year in the United States to an estimated 4% of the adult population, only a small proportion of patients suffer accidental or intentional poisoning.^{14,35} In 2004, there were 10,647 thyroid preparation exposures reported to U.S. poison centers, of which 89% were unintentional.³⁵ Moderate to major toxicity occurred in 445 (4.2%) and death occurred in 3 (0.3%) exposures. Deaths could generally be attributed to the effects of co-ingestants and not to the thyroid preparations themselves.

THYROID HORMONE PHYSIOLOGY AND PHARMACOLOGY

The mature thyroid gland contains follicles composed of thyroid follicular cells that surround secreted colloid, a proteinaceous fluid that contains large amounts of thyroglobulin, the glycoprotein precursor of thyroid hormones. The basolateral surface of the thyroid follicular cells is apposed to the bloodstream, and an apical surface faces the follicular lumen.

Dietary iodine is reduced to iodide and is absorbed in the small intestine. Thyroid follicular cells actively transport plasma iodide into their cytoplasm, and it is oxidized to iodine before binding to tyrosyl residues present in the thyroglobulin molecules. Iodination of the tyrosyl residues within thyroglobulin, a process called *organification of the iodine*, is catalyzed by thyroid peroxidase. If one iodine atom replaces a hydrogen atom, then monoiodotyrosine is formed; if two iodine atoms are joined in the tyrosyl ring, diiodotyrosine is the resultant product. Monoiodotyrosine and diiodotyrosine then undergo oxidative condensation to yield various iodothyronines. These include 3,5,3',5'-tetraiodothyronine (thyroxine, T₄) and 3,5,3'-triiodothyronine (triiodothyronine, T₃) (Fig. 67-1). Iodine makes up 66% of T₄ and 58% of T₃ by weight.

Thyroid hormone secretion from the thyroid gland is regulated by the hypothalamic-pituitary-thyroid axis, which begins in the supraoptic nucleus cells of the hypothalamus. These cells secrete thyrotropin-releasing hormone (TRH), a tripeptide, and it is carried through the pituitary portal circulation to the anterior pituitary gland. TRH stimulates the pituitary gland to secrete TSH into the general circulation, which binds to its receptor on the basolateral surface of the follicular cells, resulting in thyroglobulin reabsorption from the follicular lumen and proteolysis within the cell to yield T₄ and T₃ for secretion into the bloodstream.

T₄ and T₃ are reversibly bound to plasma proteins synthesized by the liver. Transthyretin (TTR) has a low affinity and rapid dissociation constant and has a greater role in delivering iodothyronines to various tissues. In

FIGURE 67-1 Chemical structure of thyroxine (T₄) and triiodothyronine (T₃).

contrast, thyroxine-binding globulin (TBG), with its relatively high binding affinity and slower dissociation constant, serves as a stable hormone reservoir in the circulation. Albumin has low binding affinity and may act similarly to TTR to provide tissue delivery of the hormone.

Circulating T₄ is almost entirely bound (99.97%) to these plasma proteins and is predominantly bound to T₄-binding globulin (75% to 80%). TTR binds 15% to 20% and albumin binds 5% to 10%. In contrast, plasma T₃ is bound to a lesser extent. Target tissue responses are related principally if not exclusively to these free fractions of circulating T₄ and T₃. After thyroid hormone overdoses, there is little change in TBG concentration, and free hormone levels increase directly or even disproportionately with the total serum thyroid hormone concentrations.

T₃ is metabolically more active than T₄ and is generated by removal of either iodine atom from the outer ring (at 3' or 5' position) of the T₄ molecule. Peripheral deiodination contributes 80% to 85% of the daily T₃ production and most total daily T₃ production

results from extrathyroidal deiodination in such tissues as the liver and kidneys.

The principal actions of thyroid hormones in target tissues are initiated by the binding to specific nuclear receptors, T₃ receptors, which were first identified as cellular homologs of the avian erythroblastosis virus oncogene (*c-erbA*). These receptors have properties of (1) binding T₃ with high affinity; (2) binding specific oligonucleotide sequences, called T₃ regulatory elements, which are present in the regulatory regions of thyroid hormone-responsive genes; and (3) binding one another to form dimers; an important aspect of T₃ action. Within hours of thyroid hormone administration, T₃ binding to these receptors stimulates transcription of certain messenger RNAs that are then translated into proteins (e.g., β-myosin heavy chain in myocardium), which are ultimately responsible for effecting thyroid hormone actions in various tissues. Those actions include increases in metabolic rate, body temperature, heart rate, and myocardial contractility.

PHARMACOKINETICS

Dosing

The commercially available thyroid preparations and their approximate equivalent dosages are provided in Table 67-1. Recommended therapeutic T₄ and T₃ dosing is listed in Table 67-2.

Absorption

The average T₄ bioavailability is 80% after an oral therapeutic dose, and the time to maximal absorption is 2 hours. The serum T₄ level reaches its peak 4 hours after ingestion of 3 mg T₄.³⁶ Gastrointestinal diseases such as sprue, diabetic diarrhea, short bowel syndrome, and ileal-jejunal bypass surgery may reduce absorption.

TABLE 67-1 Thyroid Preparations*

GENERIC NAME	BRAND NAME	SUBSTRATE	APPROXIMATE EQUIVALENT DOSE	AVAILABLE ORAL DOSES [†]
Liothyronine sodium	Cytomel	3,3,5'-triiodo-L-thyronine sodium T ₃ (synthetic)	25 μg	5, 25, and 100 μg
Levothyroxine sodium	Synthroid Levoxyl Levothyroid Eltroxin	3,5,3',5'-tetraiodothyronine, T ₄ (thyroxine sodium)	100 μg	25 to 300 μg
Liotrix	Thyrolar	T ₄ :T ₃ sodium salts in ratio of 4:1	50/12.5 μg	12.5/3.1 to 150/37.5 μg
Thyroid extract	Armour Thyroid	Desiccated pork thyroid with T ₄ and T ₃ in approximate ratio of 4:1 38 μg T ₄ and 9 μg T ₃ per grain	60–65 mg (1 grain)	¼ to 5 grains (15 to 300 mg)
Thyroglobulin			65 mg	

*Only the preparations available in the United States are listed. Preparations other than the ones mentioned in this table may be available in other countries.

[†]Levothyroxine and liothyronine (Triostat, 10 μg/mL, 1 mL vial) are also available commercially as parenteral preparations.

**TABLE 67-2** Therapeutic T₄ and T₃ Dose

	ORAL T ₄ DAILY DOSE	ORAL T ₃ DAILY DOSE	INTRAVENOUS T ₃ DOSE
ADULT	100–200 µg	10 µg every 8 hr; may increase to 20 µg every 8 hr	5–20 µg every 8–12 hr
PEDIATRIC	25 µg; increase gradually to 3–5 µg/kg/day	0.2 µg/kg/dose (up to 10 µg) every 8 hr; may be increased to 0.4 µg/kg/dose (up to 20µg) every 8 hr	0.1–0.4 µg/kg/dose (up to 20 µg) every 8–12 hr

Cholestyramine, calcium carbonate, sucralfate, aluminum hydroxide, ferrous sulfate, soybean formula, lovastatin, and dietary fiber supplements may also impair T₄ absorption from the gastrointestinal (GI) tract. The maximum effects of T₄ are apparent 1 to 3 weeks after initiating oral therapy, and the effects persist for the same amount of time after discontinuing the drug.

T₃ is 95% absorbed from the GI tract after an oral therapeutic dose, and the serum T₃ level begins to rise at 1.5 to 2.5 hours.³⁷ The serum T₃ level peaks 2 hours after ingestion of 6 grains (360 mg) of desiccated thyroid and 4 hours after ingestion of 75 µg T₃.³⁶

Distribution

T₄ has a 10-L volume of distribution (Vd) and is distributed into most body tissues and fluids, with highest concentrations in the liver and kidneys. T₃ has a volume distribution of 38 L. T₄ and T₃ are primarily bound to thyroxine-binding globulin and to a lesser extent to thyroxine-binding prealbumin and albumin. T₄ is more extensively and tightly bound than T₃. It is estimated that 0.04% of T₄ and 0.5% of T₃ are unbound (free) hormone, which is available to elicit a physiologic effect.

Elimination

Endogenously secreted T₄ (35%) is enzymatically monodeiodinated by type I 5'-monodeiodinase to T₃ in the peripheral tissues (e.g., liver and kidney) and accounts for 80% of total daily T₃ production. T₄ is also enzymatically monodeiodinated to reverse T₃ (rT₃). In the liver, T₄ may undergo glucuronidation and sulfation, which is eliminated in bile; some is hydrolyzed in the intestine and reabsorbed, and the remainder is hydrolyzed in the colon and eliminated unchanged in the feces. After an oral 3-mg T₄ dose, a significant increase in serum T₃ level is evident at 4 hours, and peak level is achieved between 2 and 4 days.³⁶ The elimination half-life of T₄ is 6 to 7 days. Drugs that increase non-deiodinative T₄ clearance include rifampin, carbamazepine, and phenytoin. Selenium deficiency and amiodarone may block T₄ conversion to T₃.

One metabolic pathway for T₃ and rT₃ is peripheral monodeiodination. The half-life of T₃ is 1 to 2 days. The maximum effects of T₃ are apparent within 24 to 72 hours after initiating oral therapy, and the effects persist

for up to 72 hours after discontinuing the drug. Urinary T₃ elimination increases linearly with the rise in urine flow rate and is doubled or tripled when urine flow rate is increased by fivefold to eightfold during acute hydration.³⁸

TOXICOKINETICS

Adult

In a thyroidectomized patient who had ingested an estimated 2000 µg T₄, the serum concentrations of most thyroid hormones reached a peak on the second day.³⁹ The serum T₃ level peaked 1 day later and did not exceed the upper limit of the reference range. The serum T₄ and rT₃ levels returned to the reference range 13 to 17 days after ingestion. The serum TSH level was rapidly suppressed and reached nadir on the 6th day after ingestion. The serum T₄ half-life and metabolic clearance rate were 10.4 days and 0.64 L/day, respectively. An acute single oral ingestion of a large amount of T₄ does not induce a proportional increase in the serum T₃ level in an athyreotic person. The serum T₄ metabolic clearance rate is decreased, and the serum T₄ half-life is prolonged. This is consistent with D1 deiodinase activity in the thyroid being one of the major determinants in the metabolic clearance of serum T₄.

Two hours after an acute oral T₄ overdose, the serum T₄, free T₄, and free T₃ levels were 2.27, 7.17, and 2.85 times the upper limit of the reference range, respectively.⁴⁰ Two hours after an acute oral triiodothyronine overdose, the serum total T₄ and T₃ levels were 1.83 and 25 times the upper limit of the reference range, whereas the T₃ resin uptake (T₃RU) remained in the reference range.¹⁹

Pediatric

Two previously healthy female pediatric patients were hospitalized, treated with ipecac, gastric lavage, propranolol, prednisone, cholestyramine, and propylthiouracil (PTU) after inadvertent ingestion of 2500 µg T₄. The patients remained asymptomatic throughout their hospital course.⁴¹ Serial serum T₄, T₃, rT₃, and thyroglobulin levels were obtained during the 20 days after ingestion. Serum T₄ concentrations were elevated 2 hours after ingestion and returned to the reference range after 13 days. The serum

TSH levels reached their nadir 14 hours after ingestion and remained low until the fourth day, after which they rose gradually. However, the TSH levels remained below their initial values at 20 days after ingestion. The serum T_3 concentrations peaked 11 hours after ingestion and decreased to reference values after 3 days. Both T_3 production and degradation constants were significantly increased. The serum rT_3 concentration peaked on the second day after ingestion and decreased to reference values on the fourth day. Both rT_3 production and degradation constants were below reference values. The T_3/rT_3 ratio decreased from a reference value of 3 to 1 and then increased after 13 days to as high as 8. The serum thyroglobulin concentration continuously decreased, with a half-life of 1 to 5 days, and began rising after 2 to 13 days.

The toxicokinetics data from 15 previously healthy patients aged 12 to 49 months who were treated with GI decontamination within 6 hours of the overdose showed elevation in serum T_4 concentration as early as 1 to 2 hours after ingestion.⁸ In 71% of patients, peak serum T_4 level was reached within 12 hours, whereas the serum T_3 concentration did not peak until after 24 hours after ingestion. The mean elimination half-life of T_4 was 2.8 ± 0.4 days (range, 1.5–4.5 days), and the mean elimination half-life of T_3 was 6 ± 1.7 days (range, 2.2–12.3 days), which is five times longer than that observed in physiologic conditions. Also, in physiologic conditions, the elimination half-life of T_3 is shorter than that of T_4 .

The toxicokinetics data from a 13-year-old boy who was treated with activated charcoal, propranolol, and dexamethasone showed his serum T_4 level began to decline 48 to 72 hours after ingestion, whereas the serum T_3 level began to decline 24 to 36 hours after ingestion.²² The calculated total T_4 and T_3 half-lives were 5.7 and 5.3 days, respectively. The serum TSH concentration was undetectable 19 hours after ingestion and remained suppressed for 10 days after the overdose. Administration of two additional doses of charcoal, 4 hours apart on the second day after ingestion, did not significantly change the T_4 or T_3 half-life. The patient's free T_4 and TSH returned to the normal range 2 weeks later.

Serum T_4 levels may be elevated as early as 30 minutes after an acute overdose²¹; T_3 and rT_3 levels may be elevated after 1.5 hours,⁴² and serum TSH level may be undetectable after 19 hours.²²

DRUG INTERACTIONS

In patients with endogenous thyrotoxicosis, there is a significant increase in serum free T_4 and T_3 levels after intravenous heparin (5000–30,000 U) administration.⁴³ This effect may be due to a hormonal shift from the cellular to the intravascular compartment when both cellular and intravascular hormonal binding sites are blocked by heparin. However, the metabolic significance of this is unknown. Certain drugs may interfere with the GI absorption of T_4 , including sucralbate, cholestyramine resin, iron and calcium supplements, and aluminum hydroxide.⁴⁴ In addition, certain drugs that induce

cytochrome P-450 enzymes may enhance biliary excretion of T_4 (e.g., phenytoin, carbamazepine, and rifampin) and necessitate increased oral T_4 dosing.

THYROID HORMONE TOXICOLOGY

Thyroid hormones regulate normal growth and development and act to maintain normal metabolic homeostasis. Some of the principal effects of thyroid hormones are to stimulate metabolic activity and oxygen consumption of numerous peripheral tissues (e.g., heart, skeletal muscle, liver, kidney) and to enhance the effects of other hormones (e.g., catecholamines). Thyrotoxicosis is the state produced by an excess of thyroid hormone. Although thyrotoxicosis occurs largely as a result of hyperthyroidism, or an overactive thyroid gland, the condition may also occur from ingestion of excess thyroid hormone.

Toxicity from excessive exposure to thyroid preparations manifests as an exaggeration of the physiologic effects of thyroid hormone and results in a hyperadrenergic state with primary effects on the GI, cardiovascular, and central nervous systems.

Thyroid hormone intoxication may occur after accidental or intentional and acute or chronic exposure. Acute thyroid hormone overdose occurs most commonly in children and is generally benign; major morbidity or mortality occurs very rarely in this setting.^{9,11,26,29,30} Chronic exposure to excessive doses of thyroid hormone is more commonly associated with more severe illness and may present with thyroid storm. Mortality, however, is still rare with chronic overdose. Accidental chronic overexposure occurs from medication error (by physician, pharmacists, nurses, or patients) or from continued administration with therapeutic intent in patients with decreased thyroid hormone dose requirements. Intentional chronic overingestion of thyroid hormone is often referred to as *factitious thyrotoxicosis*.⁴⁵ Individuals with factitious thyrotoxicosis are often health care workers who ingest the hormone for weight reduction. "Hamburger thyrotoxicosis" is an unusual cause of exogenous thyrotoxicosis that follows the ingestion of ground beef contaminated with thyroid tissue.⁴⁶ Cooking the contaminated beef does not inactivate iodothyronines. Although inclusion of the thyroid gland in meat product preparations is now banned in the United States, this entity should still be considered in the differential diagnosis of thyrotoxicosis presenting with elevated serum T_3 and T_4 , especially in a cluster pattern. Acute toxicity from thyroid hormone may also occur during the initial stages of thyroid hormone replacement therapy in those with hypothyroidism (see "Adverse Effects").

CLINICAL MANIFESTATIONS

Acute Overdose

The temporal relation between acute overdose and the onset of signs and symptoms is delayed by hours to days.

The latency is longer (3 to 7 days) after ingestion of T_4 because of the time it takes for peripheral conversion to T_3 , the bioactive hormone. Clinical signs and symptoms after acute T_3 ingestion or desiccated thyroid (both T_3 and T_4 present) may occur within a few hours but usually appear after 2 to 3 days. Adult patients primarily present with cardiovascular and central nervous system manifestations.^{14,15,18,40} Vomiting may be evident as soon as 2 hours after ingestion, tachycardia may be noted after 2 to 6 hours, and fever has been reported after 6 hours.^{15,19,40} However, cardiovascular signs and symptoms usually do not become apparent until 16 hours to 4 days after ingestion, and neurologic manifestations may not occur until 2 to 6 days after ingestion.

Cardiovascular effects include tachycardia, shortness of breath, palpitations, vasodilation, systolic hypertension, and increased cardiac contractility. Hypotension, congestive heart failure, tachyarrhythmias, and cardiovascular collapse may occur.¹⁷ Common tachyarrhythmias include sinus tachycardia, atrial fibrillation, paroxysmal atrial tachycardia, and atrial flutter.¹⁷ Electrocardiographic changes are nonspecific.

Common neurologic effects are the result of sympathetic nervous system overactivity and include anxiety, agitation, restlessness, diaphoresis, hyperthermia, tachypnea, mydriasis, hyperactive bowel sounds, vomiting, diarrhea, and tremor.^{17,18} Other neurologic manifestations may include a lack of energy, confusion, acute psychosis, mutism, combativeness, slurred or unintelligible speech, hyperreflexia, seizures, and coma.^{17,18}

Other effects have included acute abdominal pain, peptic ulcer disease, muscle weakness and pain, malaise, weight loss, and delayed onset laminar desquamation of palms and soles and alopecia areata.¹⁷

Laboratory abnormalities include leukocytosis, hyperglycemia, hepatic aminotransferase abnormalities, and elevations of blood urea nitrogen, creatinine, and creatine phosphokinase (rhabdomyolysis). Fluid and electrolyte disturbances may include hypokalemic alkalosis and sodium and water retention.¹⁷

Acute thyroid hormone overdoses are well tolerated by children; there are no reported deaths due to acute toxicity in the literature. In one retrospective review of 92 children (ages 6 years or younger) with acute T_4 ingestion, no significant symptoms developed in those who ingested doses up to 3.75 mg T_4 with GI decontamination and 2.0 mg T_4 without GI decontamination.¹¹ In this study, clinical effects occurred in 8.7% and included irritability, hyperactivity, increased appetite, vomiting, diarrhea, fever, flushing, and rash. In this study, researchers concluded that ingestion of less than 5.0 mg T_4 equivalent of thyroid hormone is not associated with significant toxicity. Other toxic effects reported in children include supraventricular tachycardia, extrasystoles, hypertension, diaphoresis, abdominal pain, lethargy, extremity jerking, and seizures.^{7-9,12,20-22,24,42,47-54} Although children usually tolerate relatively large doses of thyroid hormone without major toxicity, significant toxicity may rarely occur. For instance, Kulig and colleagues reported on a 30-month-old boy who had two grand mal seizures 7 days after acute ingestion of an

estimated 18 mg of T_4 .²⁴ GI decontamination was performed with 3.5 hours of ingestion. There is not consistently a close correlation between the severity and type of symptoms and the ingested amount or serum T_4 levels shortly after ingestion. Tenenbein and colleagues reported an overdose of 30 mg of T_4 in a child with no significant toxicity.¹⁰ The time course of signs and symptoms of toxicity is similar for both children and adults.

Chronic Overdose

As for acute overdose, signs and symptoms of chronic overdose primarily affect the cardiovascular and sympathetic and central nervous systems. Clinical effects may begin within a few days of the first dose.^{6,26,30} Unlike those following acute overdose, cardiovascular and neurologic effects tend to be more severe. For instance, there is a greater incidence of unstable arrhythmias (e.g., atrial and ventricular fibrillation), left ventricular heart failure, and serious neurologic effects (e.g., stupor, coma, aphasia, hemiparesis, and seizures).^{5,26,28} When death occurs, it usually results from a lethal ventricular arrhythmia (e.g., ventricular fibrillation).^{26,30} Other clinical effects noted with chronic excessive exposure include insomnia, heat intolerance, asthenia, sialorrhea, arthromyalgia, diarrhea, weight loss, fatigability, dyspnea on exertion, anxiousness, apprehension, hostility, restlessness, anorexia, jitteriness, depression, heat intolerance, warm moist palms, and generalized muscle weakness.^{2,5,28}

The natural history of signs and symptoms of chronic toxicity is illustrated in one series of six adult patients (ages 46–74 years) who were erroneously administered between 70 and 1200 mg of T_4 for 2 to 12 days.²⁶ All patients developed tachycardia, fever, nervousness, insomnia, heat intolerance, asthenia, arthromyalgia, and diarrhea within 3 days of ingesting the first T_4 dose. Severe neurologic signs and symptoms occurred in all patients between day 7 and 10 after ingestion; coma developed in five patients, stupor in one patient, and aphasia with hemiparesis occurred in one patient. Left ventricular failure, atrial fibrillation, and ventricular fibrillation developed between days 8 and 11 in five patients. One patient developed diffuse ST-T wave changes on electrocardiogram on day 29. Intense laminar desquamation of the palms and soles developed between days 17 and 37 in five patients. One patient died; the other patients recovered completely.

ADVERSE EVENTS

The adverse drug effects associated with chronic thyroid hormone therapy include sinus tachycardia, nonsinus supraventricular tachycardias (e.g., atrial flutter and fibrillation), premature atrial contractions, coronary artery spasm, acute myocardial infarction, left ventricular hypertrophy, cardiac failure, reduced bone density and mass, thyroid storm, coma, and death.^{23,31-34} Tachycardia is often out of proportion to fever. Adverse effects may also occur during acute exposure to thyroid hormones

with therapeutic intent. Initiation of thyroid hormone replacement therapy in hypothyroid patients has been rarely associated with arrhythmias and death.⁴⁴ Thus, in patients older than 60 years and in those with known cardiac disease, thyroid hormone replacement is initiated at a lower daily dose of levothyroxine (e.g., 12.5 to 25 µg/day) and increased slowly to avoid cardiac adverse effects. Idiosyncratic or allergic reactions may occur with animal-derived products such as desiccated thyroid and thyroglobulin.

DIAGNOSIS

There are no essential tests recommended after thyroid hormone exposure. However, serum T_4 , T_3 , and thyroglobulin levels may have some diagnostic and prognostic value. Elevated serum T_4 and T_3 levels help to confirm excessive ingestion of thyroid preparations. In children, a serum T_4 concentration greater than 75 µg/dL within 7 hours after ingestion may be predictive of who will develop toxicity (e.g., fever, tachycardia, and agitation) 12 to 48 hours after ingestion.⁸ Despite this study, measurements of serum T_4 and T_3 do not always correlate with the severity of illness and need for therapy, particularly in those with chronic thyroid preparation overdose. With acute thyroid hormone overdose, the initial serum TSH may not be suppressed until pituitary thyrotrophs respond to thyroid hormone excess and circulating TSH is metabolically cleared.

The serum T_4/T_3 ratio and thyroglobulin concentration may be helpful in distinguishing those patients with thyrotoxicosis factitia from those with endogenous causes of thyrotoxicosis.⁵⁵ The serum T_4/T_3 ratio in patients taking exogenous, excessive doses of T_4 is higher than in patients with endogenous thyrotoxicosis, in whom there is a marked T_3 secretion. In patients with thyrotoxicosis from Graves' disease, the mean T_4/T_3 ratio is 28 (range, 11–57), whereas patients with thyrotoxicosis factitia have a mean ratio of 70 (range, 48–114). Ordinarily, small amounts of thyroglobulin are released into the serum during normal T_4 release from the thyroid gland. Thus, patients with thyrotoxicosis factitia have either low or undetectable serum thyroglobulin levels,³ as compared with those with endogenous thyrotoxicosis, in which thyroglobulin levels are normal or increased. Endogenous hyperthyroidism due to Graves' disease or nodular thyroid disease can also be differentiated from thyroid hormone overdose by measuring thyroidal uptake of iodine-123 or technetium-99m. The uptake is increased in hyperthyroidism due to Graves' disease or nodular thyroid disease, whereas it is suppressed with overdose. However, it should be understood that the uptake is also suppressed in hyperthyroidism associated with thyroiditis, metastatic thyroid cancer, and struma ovarii.

The dynamic pattern of a patient's serial thyroid function tests may provide evidence for diagnosis of exogenous T_3 ingestion.⁶ The serum T_3 concentration

will most likely far exceed that observed in endogenous causes of hyperthyroidism. The rapid fall in serum T_3 concentration indicates that T_3 toxicosis is a transient event rather than a sustained physiologic process. The serum T_4/T_3 ratio will be expected to consistently be less than 20, which is less than that observed in conditions of endogenous hyperthyroidism associated with T_3 toxicosis. This ratio reflects the extreme elevation of serum T_3 concentration and the decreased T_4 concentration with T_3 suppression of TSH.

An increased serum T_4/T_3 ratio may be observed in thyrotoxic states other than ingestion of excess amounts of T_4 . Patients receiving amiodarone therapy have elevated T_4/T_3 ratios (mean, 57; range, 27–120), and it has been associated with increased serum thyroglobulin concentration (mean, 118 ng/dL; range, 17–460 ng/dL).⁵⁶

In addition to thyroid function testing, routine laboratory analysis in patients who have taken excessive doses of thyroid hormones should include a complete blood count and measurement of serum electrolyte, blood urea nitrogen, creatinine, glucose, creatine phosphokinase (CPK), calcium concentrations, and pregnancy testing in women of childbearing age. Serum acetaminophen and salicylate concentrations should be performed in all intentional overdose patients. In patients with chest pain or cardiovascular toxicity, an electrocardiogram should be performed, and laboratory evaluation should include serial measurements of serum CPK and troponin concentrations. Other studies that may be helpful include head computed tomography, lumbar puncture, and toxicology studies of blood and urine.

Differential Diagnosis

The sympathomimetic effects of thyroid hormone overdose may present similarly to many other toxicologic and nontoxicologic entities (Box 67-1). Other toxic etiologies to consider include anticholinergic, neuroleptic-malignant, serotonin, and sedative-hypnotic withdrawal syndromes; and poisoning by hallucinogens, lithium, monoamine oxidase inhibitors, strychnine, sympathomimetics (e.g., cocaine, amphetamines, methylxanthines, cough and cold preparations, decongestants), salicylates, dinitrophenol and pentachlorophenol, and nicotine. Occasionally, thyrotoxicosis may be associated with ingestion of amiodarone, lithium, and excessive doses of iodine. Nontoxicologic conditions that should be considered in the differential diagnosis include endogenous thyrotoxicosis, traumatic head injury, intracranial hemorrhage, heatstroke, systemic infection, pheochromocytoma, hypoglycemia, malignant hyperthermia, and lethal catatonia.

As mentioned, specific thyroid function laboratory testing helps differentiate endogenous thyrotoxicosis from exogenous thyrotoxicosis (overdose). In addition, the relatively short duration of symptoms and the absence of exophthalmos, pretibial myxedema, onycholysis of fingernails, thyroid bruit, and goiter are helpful in ruling out endogenous hyperthyroidism.

BOX 67-1 DIFFERENTIAL DIAGNOSIS OF THYROID HORMONE OVERDOSE
Hyperthyroidism

- Endogenous hyperthyroidism due to Graves' disease, multinodular goiter, solitary functioning adenoma, thyroiditis
- Hyperthyroidism associated with drug use such as thyroid hormone preparations, amiodarone, iodide-containing compounds, interferon, lithium

Acute disorders associated with sympathetic nervous system activation: infection, heatstroke, hemorrhage, trauma, pheochromocytoma, conditions associated with severe pain, and drug withdrawal states

Toxic drug ingestion

- Amphetamine, cocaine, methylxanthines, and other sympathomimetic agents
- Cyclic antidepressants and monoamine oxidase inhibitors
- Salicylates
- Dinitrophenol and pentachlorophenol
- Nicotine overdose
- Central hallucinogens
- Lithium and other psychotropic agents
- Toxic syndromes (e.g., neuroleptic malignant syndrome and serotonin syndrome)

MANAGEMENT

Overview

The treatment plan of patients who have ingested thyroid hormone is dependent on the intent of the exposure (suicidal or accidental), estimated dose ingested, time since ingestion, associated ingestion of other compounds, toxic effects present on presentation, and the patient's age, comorbid conditions, and reliability (when considering outpatient treatment). As noted already, healthy adults and children may tolerate even relatively large doses of thyroid hormone without serious consequences.^{7,8,11,12,52,57,58} On the other hand, life-threatening toxicity can occur in elderly patients or those with underlying cardiac disease.^{44,58-60} Indications for inpatient observation and treatment include (1) signs and symptoms of toxicity; (2) elderly age or the presence of underlying cardiopulmonary disease; (3) ingestion of more than 100 µg/kg of T₄ or 30 µg/kg of T₃; (4) serum T₄ concentrations greater than 75 µg/dL and/or T₃ levels greater than 350 ng/dL; and (5) unreliable patients or caretakers. Patients with mild to moderate signs of toxicity can be admitted to a monitored floor bed, whereas those patients manifesting significant cardiovascular or neurologic signs and symptoms should be managed in an intensive care unit.

Emergent medical assessment and GI decontamination are not recommended for every patient exposed to thyroid hormones. Most cases of accidental ingestion can be managed with home observation and telephone follow-up by health care professionals for a period of 7 days. Gastrointestinal decontamination is unnecessary

for children younger than 12 years who accidentally ingest an estimated 2 mg or less of T₄ and may not be necessary for ingestions up to 5 mg.^{9,11} These patients may be observed at home pending the onset of symptoms. Although the absence of initial symptoms does not preclude the possibility for delayed significant toxicity (e.g., seizures),²⁴ prophylactic treatment with antithyroid agents (e.g., propranolol, PTU, and corticosteroids) is not recommended in the absence of toxic effects.⁷⁻¹¹

Patients who have ingested thyroid hormone with suicidal intent should be emergently assessed in a hospital, receive GI decontamination, and be observed for signs and symptoms of thyroid hormone toxicity or coingestants. After GI decontamination and an emergency department observation period of several hours, it may be acceptable to transfer an otherwise healthy, asymptomatic patient who ingested thyroid hormone with suicidal intent to an inpatient psychiatric facility. This is provided that the receiving facility is knowledgeable of the delayed toxic effects that can occur from thyroid hormone, can monitor for these effects, and will transfer the patient back to an acute care facility should these effects occur. Otherwise, it is more prudent to admit these patients to the hospital for close observation for a period of 3 to 5 days.

Decontamination

GI decontamination is recommended after intentional or accidental thyroid hormone overdose (greater than 5 mg T₄ equivalent), provided it can be initiated within a few hours of ingestion. Although it has not been well studied, single-dose administration of activated charcoal (1 g/kg orally or by nasogastric tube) is the preferred method of gastrointestinal decontamination. The bile acid sequestrant, cholestyramine, is an acceptable alternative agent for GI decontamination. Clinical studies have shown that cholestyramine significantly interferes with T₄ absorption from the GI tract and interrupts T₄ and T₃ enterohepatic circulation.^{61,62} One *in vitro* study showed that 50 mg of cholestyramine resin is capable of irreversibly binding 3 mg of T₄.⁶¹ The typical cholestyramine dose is 50 to 150 mg/kg/dose (adult, 3–9 g), and this dose can be repeated every 6 to 8 hours. Neither cathartic nor whole bowel irrigation has been formally studied as a decontamination method after thyroid hormone overdose.

Supportive Care

Supportive measures should include treatment of hyperthermia; correction and maintenance of fluid, electrolyte, and acid–base balance; and monitoring of cardiac rhythm and respiratory status. Intravenous fluid should be administered such that urine output is at least 1 to 2 mL/kg/hr. Hyperthermia should be managed using standard measures. Case reports suggest that dantrolene may be effective adjunct therapy for endogenous thyrotoxicosis,⁶³⁻⁶⁵ but its efficacy remains to

be established in exogenous thyroid hormone toxicity. Dantrolene inhibits the effects of high circulating T_4 levels on calcium flux across the sarcoplasmic reticulum.⁶³ Hypertension requiring medical treatment is rare and, if clinically indicated, should be managed as a hypertensive emergency.

Specific Treatment Measures

Specific treatment measures for exogenous thyroid storm include the administration of β -adrenergic antagonists to suppress the signs and symptoms and administration of agents that block conversion of T_4 to T_3 (active hormone) and block the release of thyroid hormone from the thyroid gland.

β -ADRENERGIC ANTAGONISTS

Agents in this class (e.g., propranolol and esmolol) rapidly reduce catecholamine-dependent signs and symptoms, such as tachycardia, supraventricular tachyarrhythmias, hypertension, tremor, palpitation, tension, and psychomotor agitation.^{14,15,20,21,28,34,47,49,54} Propranolol, and possibly other β blockers, also partially inhibit the conversion of T_4 to T_3 .⁶⁶ The typical oral propranolol dose is 0.2 to 0.5 mg/kg/dose (adult, 10–40 mg) every 4–6 hours; the dose should be adjusted according to the response, and large doses (240–280 mg/day) may be required in severely toxic patients. The intravenous propranolol dose is 0.1 mg/kg (adult, 2–10 mg) over 10 minutes and may be repeated up to three times as clinically indicated. An esmolol infusion can be initiated by administering 0.5 mg/kg over 1 minute, then 50 μ g/kg/min for 4 minutes; if the response is inadequate, rebolus with 0.5 mg/kg and then 50 to 200 μ g/kg/min for up to 48 hours.

CALCIUM CHANNEL ANTAGONISTS

Diltiazem appears to be an effective alternative therapy in controlling thyrotoxic symptoms in patients in whom β -blocker therapy may be contraindicated.^{67,68} The oral diltiazem dose is 1 to 3 mg/kg/dose (adult, 60–180 mg) every 6 to 8 hours. Diltiazem may be administered intravenously as a bolus injection (0.25 mg/kg), typically 20 mg intravenously given initially followed by 5 to 10 mg/hr.

IODINATED RADIOCONTRAST AGENTS

Oral iodinated radiocontrast agents (e.g., sodium ipodate and iopanoic acid) are potent inhibitors of peripheral T_4 bioconversion to T_3 and appear to be effective adjunct treatment for patients with either exogenous^{8,42,47,69} or endogenous thyrotoxicosis.⁷⁰⁻⁷³ After administration of these contrast agents, there is marked prolongation in serum T_4 half-life, with a concurrent sharp increase in serum rT_3 level and a marked decrease in serum T_3 level.^{42,47,69} Although not important for exogenous thyroid hormone overdose, these agents also release large amounts of iodide with their

metabolism, which subsequently blocks the release of T_4 and T_3 from the thyroid. The typical sodium ipodate and iopanoic acid dose for adults is 3 g and that for children is 150 mg/kg/dose, and may be repeated for recurrence of symptoms. Sodium ipodate, 250 mg/kg/dose every 3 days for 18 days followed by 500 mg/kg/dose every 3 days for 21 days, has been successfully used to treat a patient with moderately severe neonatal Graves' disease.⁷¹

CORTICOSTEROIDS

The major effect of corticosteroids, particularly dexamethasone (2 mg every 6 hours for four doses), is to alter peripheral T_4 metabolism such that conversion from T_4 to T_3 is diminished and to rT_3 is enhanced.⁷⁴⁻⁷⁶ In those with endogenous thyroid storm, relative adrenal insufficiency is often present, and corticosteroid administration (hydrocortisone at 200 to 400 mg daily) is important as part of treatment to reduce mortality. The presence of relative adrenal insufficiency in exogenous thyroid storm is unclear.

PROPYLTHIOURACIL AND METHIMAZOLE

The antithyroid thionamide drugs PTU and methimazole (MMI) inhibit the synthesis of both T_4 and T_3 . These agents interrupt thyroid peroxidase-catalyzed inorganic iodide oxidation and thyroidal T_4 secretion.^{66,77} PTU and MMI have limited to no efficacy in the management of exogenous thyroid hormone toxicity (see below for toxicity from these agents).

IODIDE

Iodide acutely inhibits thyroid hormone biosynthesis and release, and, like the thionamides, has no proven clinical utility in the treatment of exogenous thyroid hormone exposure.

Enhancement of Elimination

Multiple doses of activated charcoal have been used and case reports suggest it does not appreciably alter serum thyroid hormone levels or improve clinical outcome.^{8,22} However, multiple doses of cholestyramine may be an effective means of decreasing the body's exogenous hormone load by binding GI tract T_4 and disrupting enterohepatic recirculation. Cholestyramine has been used successfully to treat iatrogenic thyrotoxicosis (Fig. 67-2).^{61,62}

Hemodialysis is ineffective because of the high protein binding and limited renal excretion of thyroid hormones. Exchange transfusion,^{40,48} plasmapheresis,^{26,40,78} and hemoperfusion²⁶ have been used in the management of acute and nonacute thyroid hormone poisoning, but conclusive studies are lacking. Observations suggest that these extracorporeal techniques do not remove significant amount of thyroid hormones relative to the total ingestion and that their efficacy decreases with time.

FIGURE 67-2 The use of the bile acid sequestrant cholestyramine to lower serum thyroid hormones in iatrogenic hyperthyroidism. Two patients with iatrogenic hyperthyroidism were administered 4 g of cholestyramine four times a day. The alterations in serum total T_4 , free T_4 , total T_3 , and thyroid-stimulating hormone (TSH) levels in the two subjects (●—●; ▲—▲) and one control (■—■) ($n = 3$, values = mean \pm SE) are shown. The normal serum values are as follows: total T_4 , 51 to 142 nmol/L; free T_4 , 10 to 36 pmol; total T_3 , 1.2 to 3.4 nmol/L; and TSH, 0.4 values for T_4 and T_3 and the lower normal range values for TSH. (From Shakir KMM, Michaels RD, Hays JH, et al: The use of bile acid sequestrants to lower serum thyroid hormones in iatrogenic hyperthyroidism. *Ann Intern Med* 1993;118:113.)

TOXICOLOGY OF THYROID ANTAGONISTS

Thyroid antagonists are drugs that interfere with one or more steps in iodine metabolism, thyroid hormone synthesis, or hormone release by the thyroid gland. Drugs that prevent the secretion of thyroid hormones include iodides and lithium. The toxicity of iodine (see Chapter 96) and lithium (see Chapter 30) are discussed elsewhere. Amiodarone may produce both hyperthyroidism and hypothyroidism; its toxicity is discussed in Chapter 63. The toxicity of the thionamides, PTU and MMI (Tapazole), is discussed here. Another thionamide available in Great Britain, carbimazole (Neo-Mercazole), is converted to MMI after absorption.

PTU and MMI inhibit organification of iodide and the coupling of iodotyrosines for hormonally active iodothyronines. PTU also partially inhibits the peripheral deiodination of T_4 to T_3 . Both agents are readily absorbed from the GI tract within an hour, and inhibition of thyroid iodine organification begins within 20 to 30 minutes.⁴⁴ The Vd for PTU is about 0.3 L/kg, and 75% is protein bound. The Vd for MMI is 0.6 L/kg, and protein binding is minimal. The plasma elimination half-lives of PTU and MMI are 1 to 2 hours and 4 to 6 hours, respectively. Intrathyroidal accumulation of drug occurs. Both PTU and MMI cross the placental barrier and appear in human breast milk.

There is a paucity of information regarding acute PTU or MMI overdose. Acute ingestion of an estimated 5 to 13 g of PTU in a 12-year-old patient did not result in any clinically significant effects.⁸² A low incidence of adverse effects (3% to 7%) has been associated with therapeutic use of both PTU and MMI.^{16,44,79-85} Most toxic reactions to thionamides occur with a few weeks or months of beginning therapy. Adverse drug events associated with PTU use include skin rash (purpuric or urticarial), granulocytopenia, eosinophilia, lupus-like syndrome, acute hepatitis, cholestatic hepatotoxicity, hepatic necrosis, liver failure, and death. Diagnostic laboratory studies may reveal complete blood count and liver function test abnormalities, hepatocellular necrosis around the central veins with moderate to severe lymphocytes and neutrophils infiltration in the portal areas and lobules on liver biopsy, positive migration inhibition factor test to PTU, and PTU-induced peripheral lymphocyte transformation.^{81,85,86} PTU may traverse the placenta and cause neonatal hepatitis and lymphocyte sensitization.⁸⁶ Management of PTU toxicity includes immediate discontinuation of the drug, supportive care, steroid therapy, and, in cases of fulminant liver failure, orthotopic liver transplantation.^{16,80,81,87,88}

Adverse drug events associated with MMI use include agranulocytosis, pancytopenia, plasmocytosis, serum sickness, acute include hepatitis, cholestatic jaundice, granulomatous hepatitis, hepatocellular necrosis, and death.^{79,89-94} Diagnostic laboratory studies may reveal abnormalities in the complete blood count, liver function tests, liver biopsy, and bone marrow biopsy.^{89,90,92} Management of MMI toxicity includes immediate discontinuation of the drug, supportive care, and, in cases of severe bone marrow toxicity, reverse isolation, antibiotics, dexamethasone, and granulocyte colony-stimulating factor therapy.^{89,92}

Agranulocytosis from both agents has an overall incidence of about 1 in 500 patients. Like other adverse effects, agranulocytosis occurs with greatest incidence in the first few weeks of treatment. Agranulocytosis is usually heralded by fever and a sore throat. This adverse drug effect is reversible upon discontinuation of the offending thionamide.

The treatment of thionamide overdose is entirely supportive. Previously euthyroid patients who ingest these agents are not expected to become hypothyroid, as because these agents have a relatively short duration of action (<24 hours).

Herbal, Traditional, and Alternative Medicines

RICHARD L. KINGSTON, PHARMD ■ CHRIS FOLEY, MD

At a Glance...

- Alternative medicines, which include herbal, traditional, and many other dietary supplements, are used or relied on by more than half of the world's population.
- Despite an inherently wide margin of safety, selected alternative medicines have been associated with significant adverse effects.
- DSHEA, the law that regulates most commercially available alternative medicines, does not require manufacturers to undergo a premarket approval process for safety or efficacy. Despite this fact, relatively few serious adverse events involving most alternative medicines have been reported.
- The most serious concerns with alternative medicines have been related to adulterated products, selected herbs often used in traditional applications, and misidentification and inadvertent use of various botanicals.
- The greatest challenge for the future will likely relate to identifying which herbs or other alternative medicines possess the potential to pharmacokinetically alter or otherwise adversely affect the use of mainstream pharmacologic interventions.
- Absent a more stringent premarket approval process for safety, a national system of postmarket surveillance must be developed and embraced by regulators, manufacturers, health professionals, and the general public.

HERBAL MEDICINE AND MISCELLANEOUS AGENTS

Despite the continued development of medical and pharmacologic therapies for the treatment of illness, as many as 50% of people worldwide use alternative treatments, including herbal and traditional medicines.¹ Even in industrial nations, where there is no dearth of pharmaceutical agents, many seek “natural” products for their ailments. In one of the few studies of its kind, Eisenberg and colleagues, investigating the prevalence of use of unconventional medicine in the United States, found that one third of a sample population had used at

least one unconventional therapy in the prior year.² Highest use was found among those with relatively more education and higher incomes. Annual prevalence was 3% for herbal medicines, 1% for homeopathy, and almost 1% for folk remedies. Reasons for using these therapies were extensive, including treatment of back pain, anxiety, headaches, cancer, and insomnia. In a similar pediatric study, 11% of children were found to have received one or more forms of alternative therapy since birth.³ Parents stated that they chose alternative medicines after hearing about them from a friend, because of a fear of drug side effects, because they were dissatisfied with conventional medicine, or because they received more personal attention from alternative medicine practitioners. In a study conducted in a New York emergency department near the Chinatown district, Pearl and associates found that 43% of patients had used a traditional Chinese therapy within 1 week of their emergency department visit.⁴ Fifty-eight percent of these had used at least one oral herbal preparation. Eleven patients reported using therapies that included unidentified tablets, nose drops, or topical preparations and animal preparations such as deer antler. Finally, although it may be of some epidemiologic importance that psychoactive plant materials such as jimsonweed, nutmeg, and morning glory seeds are often ingested as substances of abuse, most botanical and supplement use is generally benign. The major areas of concern will continue to be the potential for drug interactions when combined with conventional therapies and sorting out those substances, the dosing, and the routes of administration that are of true therapeutic value. Despite the relative wide margin of safety with most herbal products, in those rare circumstances in which a product is adulterated with unlabeled and unauthorized ingredients, there will be an opportunity for adverse consequences.

The increasing interest in alternative medicines as well as their proven therapeutic value⁵⁻⁸ led in 1992 to the establishment of the Office of Alternative Medicine at the National Institutes of Health and subsequently the

Office of Dietary Supplements. Through these organizations, investigators can obtain support for research designed to determine the range of benefit that alternative medicines or dietary supplements offer, with the goal of “integrating validated alternative medical practice with current conventional medical procedures.”⁹ Additional evidence of the public’s interest in alternative medicine was shown in a survey that found that 10% of American pharmacies carry herbal remedies.¹⁰ The potential routes of administration of alternative medicines include topical, rectal, and vaginal application as well as ingestion, injection, and inhalation.¹¹

Nonetheless, alternative medicines, including herbs and other “dietary supplements,” have been associated with examples of toxicity. The U.S. Food and Drug Administration (FDA) is given responsibility for protecting the public from dietary, nutritional, and pharmaceutical hazards. Oftentimes, however, the FDA has fallen short in terms of its capacity to offer the appropriate amount of regulation enforcement. Some have argued that this happens because substances in the dietary supplement classification fall into an ambiguous category.¹² When Congress passed the Dietary Supplement Health and Education Act (DSHEA), some felt that the FDA’s ability to regulate alternative medicines was further weakened.^{9,10} Seven major features of this law are as follows:

1. Dietary supplements can be marketed without any premarket efficacy studies.
2. Companies bear the burden of insuring product safety before marketing and sale. FDA must prove that the product is unsafe in order to remove a product from market.
3. Until recently, there were no guidelines for Good Manufacturing Procedures (GMPs) related to dietary supplements. New guidelines have since been promulgated by the FDA and will likely improve manufacturing accountability substantially.
4. Although specific health claims have been strictly regulated, certain product claims are permitted. For example, products cannot be claimed to cure a disease, but the label can discuss how a supplement affects the body’s function. These are referred to as *structure function claims* and typically are more loosely defined than health claims.
5. Structure function labeling statements do not require extensive supportive evidence.
6. The FDA must be notified of proposed labeling, but no approval process is required. Accordingly, each label must contain a disclaimer related to any claims that states, “This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease.”
7. Although there was a recommendation related to the establishment of a viable system of postmarket surveillance, none has been implemented. In the wake of reports of adverse consequences associated with ephedra, which resulted in its removal from the market, Congress has begun to consider options for mandatory adverse event reporting by manufacturers

of dietary supplements. Currently, dietary supplement manufacturers are not required to collect, document, and report to the FDA any reports of adverse consequences potentially associated with their products.

Although there is a clear need for the full implementation and enforcement of DSHEA as regards the manufacture, standardization, and postmarketing surveillance of dietary supplements, some of the risks and hazards claimed to be associated with this class of product are probably exaggerated. Despite their inherently wide margin of safety, monitoring for herb safety should remain a high priority, especially as pertains to interactions with mainstream pharmaceuticals, unexpected adverse effects during routine use, or potential contamination or adulteration issues. Although practitioners have been encouraged to report adverse effects directly to the FDA MedWatch system for both drugs and dietary supplements, it is believed that most events are underreported. Still, serious adverse reactions from alternative medications can and should be reported immediately to the FDA (telephone: 1-800-332-1088).¹² The dietary supplement industry has been examining options for the establishment of a voluntary system of adverse event management and reporting. This may provide an alternative system of surveillance that practitioners can participate in and utilize when assessing herbal product safety. Whether or not the overall system of postmarket surveillance for herbs and dietary supplements is improved remains to be seen.

Herbal Medicines

An herbal medicine can be defined as a plant extract that is used in various forms of refinement to achieve a preventive or therapeutic effect. For example, crude extracts of mushrooms and other fungi are considered to be herbal medicines alongside much more definitive formulations of ginseng and hawthorn extract. There is no controversy that many of these medicines have potent pharmacologic action, nor that they may provide some very useful benefits.¹³⁻¹⁶ It is this same potency that often makes them responsible for inadvertent adverse effects as well as very useful alternatives to more toxic drugs.

The use of herbs and medicinal plants spans history and has been universal, occurring in every culture on earth. For example, Egyptian writings chronicled the use of medicinal herbs more than 4000 years ago; at that time, for example, poppy extracts were used to quiet crying children. Ayurvedic medicine (literally, “knowledge of how to live”) emphasized the value of herbal medicines in texts dating back to 2500 BC. The Chinese *Materia Medica* lists about 5800 medicinal plants; about 2500 medicinal herbs are listed in Indian medical texts, and at least 800 are used in tropical Africa. As a general rule, herbalists regularly use a repertoire of 150 to 200 plants. Herbalists uncommonly prescribe animal parts, metals, and minerals.

One of the most widely practiced and enduring herbal traditions has been that of Chinese herbal medicine.

This form of herbal medicine has been traced back to about 2500 BC. In Chinese culture, herbs are considered basic to the treatment of all illness, in conjunction with aids such as acupuncture or acupressure. Generally speaking, among all alternative medical practices, Chinese herbal medicine has become a form familiar to many practitioners as a result of its incorporation into traditional Chinese medicine and acupuncture as practiced in many Western countries.

Herbs are prescribed in a number of different contexts. Standard formulas created by a trained herbalist or an individual with limited knowledge of herbal medicine are often used as an exclusive method of treatment by unlicensed practitioners. These typical prescriptions often may consist of 10 to 15 herbs.¹⁷ When herbs are used to make herbal remedies, any or all parts of the plant can be used. These include flowers, leaves, seeds, roots, sap and resins, fruit, bark, or bulbs. These herbs can be administered in a number of tea forms (decoctions or infusions); they can be eaten in isolation or with food. Common terminology for how herbal remedies may be applied includes the following¹⁴:

Infusion—herbs that are steeped in hot water, similar to tea

Decoction—a technique that extracts more of the plant's ingredients by soaking and then boiling the plant in water

Tincture—an herb extract prepared by steeping the herb in a 25% solution of alcohol in water

Syrup—an herb extract prepared in honey or sugar in order to make its taste less unpleasant

Compress—a cloth pad soaked in a hot herbal extract and applied to a painful area

Poultice—similar to a compress, except that the entire herb is applied rather than an extract

Herbal Preparations and Adverse Effects

Despite the fact that the Western press often sensationalizes adverse reactions to certain specific herbals, systematic studies of poisoning due to herbal remedies are few. In a study conducted in China, 0.2% of all hospital admissions were the result of adverse reactions to Chinese herbal medicines.¹⁷ Another Chinese study reviewed 33 hospitalizations resulting from toxicity related to herbal medicine.^{17,18} The most common herb leading to toxic reactions was aconitine (accounting for 61%). In nine patients, adverse effects were life threatening; one fatality was reported. These numbers are hardly daunting when compared with typical adverse events histories from many over-the-counter drugs. Even in the United States, the reporting of the adverse reactions to ephedra—notwithstanding its dangers—greatly exaggerated its risks when properly used. For example, the investigational review of ephedra with respect to clinical efficacy and side effects done by the RAND organization and prepared by the Southern California Evidence-based Practice Center concluded that scientific studies are necessary to assess the possible

association between consumption of ephedra-containing dietary supplements and serious adverse events. Given the rarity of such events, they suggested that a properly designed case-control study would be necessary before drawing any additional conclusions.¹⁹ Recently, Federal courts in Utah have agreed that the risk analysis relied on by the FDA to remove ephedra from the market needs to be reevaluated. Whether or not this will result in ephedra being returned to the supplement market remains to be seen, but it does suggest that data documenting its risk may not be as conclusive as previously believed.

Another issue that complicates the monitoring for adverse effects relates to the ability to standardize herbal products for both potency and quality. Although substantial strides have been made with the promulgation of GMPs for herbal products by the FDA, there are still challenges associated with ensuring potency and quality from product to product and brand to brand.

DOSE

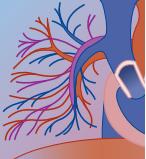

Unlike the pharmaceutical industry, in which the quantity of active agent is consistent from pill to pill, quantities of active drug in a plant can be highly variable. Also, the content of active constituent is influenced by the particular species of plant, the growing conditions, the part of the plant, and its form when used (wet versus dry). Knowledgeable experts in the field of pharmacognosy have argued that this specific variability in diversity is actually desirable. Nonetheless, it can be problematic, particularly with respect to certain classes of substances such as those that might otherwise affect blood pressure, cardiac rhythm, level of consciousness, and so forth. Standards should be applied when possible, but these will likely never be uniformly achieved.

ROUTE OF EXPOSURE

Many herbs are applied topically, particularly those used to treat skin and musculoskeletal conditions. Although topical herbs occasionally produce systemic toxicity, their adverse effects are usually confined to development of contact dermatitis or phyto dermatitis.²⁰ There are several herbals that have been traditionally smoked as substitutes for tobacco, but these play very minor roles in the overall medicinal application. Most botanicals are taken orally in the forms of extracts, tinctures, teas, and so forth. Inhalation is generally restricted to very traditional or illicit uses that usually do not find their way into medical practice. However, when dealing with a culturally diverse population, one must always be knowledgeable of the potential for toxic or hallucinatory effects of these. Examples include yohimbine, lobelia, cannabis, and others.²⁰

DURATION OF USE

Many herbs with little to no toxicity after short-term use can produce adverse effects if they are ingested for a considerable time. For example, chronic use of pyrrolizidine alkaloids produces hepatic veno-occlusive disease, whereas short-term ingestion has no apparent hazards. Chronicity is also an important factor in the development of malignancies after use of carcinogenic

teas such as sassafras and comfrey.^{21,22} As with any drug, botanicals must be used properly to maximize safety and efficacy. In an unsupervised environment with no professional oversight, botanicals with otherwise fairly safe therapeutic margins could become toxic over a period of time. The traditional benefits of comfrey, which contains pyrrolizidine alkaloids, include the management of inflammation, diarrhea, and gout. Generally, it should not be used for more than a few days. This is a good example of the potential for toxicity when individuals with poor professional advice seek to apply a botanical over a longer period of time.

PREEXISTING DISEASE

As the study by Eisenberg and colleagues illustrates,² herbal remedies are often sought as alternative treatments for illness or disease. Therefore, those using them may have preexisting disease that modulates the effect of that agent. For example, there are any number of botanicals that reportedly have or theoretically can affect the kinetics of warfarin. This is a good example of the necessity for professional supervision when a botanical is consumed with an anticoagulant therapeutic agent. However, that is not to say that botanicals might not be otherwise applied in a setting that involves anticoagulation. Pharmacists and physicians skilled in the chemistry of botanicals are necessary to help with the sorting-out process. Increasingly, it is becoming evident that there may be value in the application of functional foods, nutraceuticals, and botanicals in the context of prescription drug use. As a matter of fact, there are cases in which the simple application of a *nutraceutical* (defined as a naturally occurring dietary, microbiologic, mineral, or botanical substance exhibiting an inherently wide margin of safety when administered in doses or quantities that possess either functional or therapeutic value) may actually allow the more liberal use of a drug. Combining coenzyme Q with statin drugs appears to be advantageous. The knowledgeable application of probiotics will likely greatly reduce some of the side effects on the lower gastrointestinal (GI) tract from any number of antibiotics. There are numerous other examples for which the application of botanicals or nutraceuticals is not only desirable but perhaps will eventually become a standard of care as companions to certain drugs.

IMPROPER IDENTIFICATION

In circumstances in which crude herbs or other botanicals are harvested or used by individuals, there is a possibility of misidentification. Although trained herbalists can confidently prescribe herbs, an untrained or poorly trained herbalist sometimes misidentifies an herb and prescribes it, with disastrous consequences. For example, comfrey is similar to foxglove in appearance. Ingestion of foxglove, from which digitalis is derived, could lead to severe cardiac disturbances. The same risk for misidentification can occur when names are confused. Cohosh, a common herb used as a sedative and anti-inflammatory agent, generally refers to *Cimicifuga racemosa* (black cohosh) or *Caulophyllum thalictroides* (blue

cohosh). However, in other regions, cohosh refers to the toxic baneberry.²¹

HERB PREPARATION

How an herb is prepared has the most important influence on both the pharmacologic and toxicologic actions of the herb. Again, it is highly unlikely that an untrained herbalist might prescribe the wrong part of a plant when a standardized preparation that uses the appropriate part is available. The bark of the elder has considerable therapeutic value, but its stem is extremely toxic, containing cyanogenic alkaloids.²¹ Equally important, an herb may be administered according to its dry weight rather than wet weight. Because the dried product almost always has a higher concentration of active agent than the fresh form, inadvertent overdose can occur. As the application of botanicals comes under the supervision of trained professionals, it becomes less likely that these types of errors will be made. In addition, with standardization and commercialization of products, individual preparation of remedies from crude botanicals will occur less and less. However, it will certainly still be possible for crude herbs or other botanicals to be provided directly to consumers or through an unlicensed practitioner.

CONTAMINATION

Herbs can become contaminated by toxins or toxicants through a number of means. The herbs sold by herbalists, as well as those that are picked in the wild, can be contaminated by agents including metals if they are grown in regions with contaminated soil, particularly if the plant is capable of incorporating the toxin. Teas prepared from herbs have been reported to contain lead, cadmium, mercury, copper, zinc, fluoride, and arsenic.²²

Another means by which contamination can occur is by using plant products from improper sources. For example, commercial plant seeds may be used to prepare an herbal remedy. However, these seeds often contain pesticides or fungicides designed to lengthen their shelf life. If these seeds are ingested, serious toxicity can result. Finally, because herbs are often processed into tablets, capsules, and other pharmaceutical forms (commonly referred to as *Chinese proprietary medicine*), accidental or intentional adulteration by pharmaceutical agents can occur. Table 68-1 summarizes the clinical toxicity of popular herbs.

Herbal Teas

The preparation of teas is the most common use of herbal medicines. The illnesses associated with the use of herb teas can be placed into system categories of GI (including hepatic), hematologic, autonomic, neurologic, cardiac, allergic, and carcinogenic.

GASTROINTESTINAL

GI upset is the most common adverse effect associated with the use of herb teas. Although this is generally mild, severe vomiting and diarrhea can be produced by ingestion of poke root (*Phytolacca americana*), buckthorn (*Hippophae rhamnoides*), and senna (*Cassia augustifolia*).

**TABLE 68-1** Clinical Toxicity of Selected Herbs

COMMON NAME	BOTANIC NAME	THERAPEUTIC USES	POTENTIAL TOXICITY
Aconite (monkshood, wolfsbane)	<i>Aconitum</i> spp	Sedative, analgesic, antihypertensive	Cardiac arrhythmias
Aloe	<i>Aloe</i> spp	Burns, skin diseases	Nephritis, GI upset
Betel nut	<i>Areca catechu</i>	Mood elevation	Bronchoconstriction, oral cancers
Bloodroot	<i>Sanguinaria canadensis</i>	Emetic, cathartic, eczema	GI upset, vertigo, visual disturbances
Chaparral (greasewood)	<i>Larrea tridentata</i>	Aging, free radical scavenging	Hepatitis
Compound Q	<i>Trichosanthes kirilowii</i>	Anthelmintic, cathartic	Diarrhea, hypoglycemia, CNS toxicity
Dandelion	<i>Taraxacum officinale</i>	Diuretic, heartburn remedy	Anaphylaxis
Figwort (xuan shen)	<i>Scrophularia</i> spp	Anti-inflammatory, antibacterial	Cardiac stimulation
Ginseng	<i>Panax quinquefolium</i>	Antihypertensive, aphrodisiac, stimulant, mood elevation, digestive aid	Ginseng abuse syndrome
Goldenseal	<i>Hydrastis canadensis</i>	Digestive aid, mucolytic, anti-infective	Uterine, cardiac stimulation; GI upset, leukopenia
Hellebore	<i>Veratrum</i> spp	Antihypertensive	Vomiting, bradycardia, hypotension
Hyssop	<i>Hyssopus officinalis</i>	Asthma, mucolytic	Seizures
Juniper	<i>Juniperus communis</i>	Hallucinogen	GI upset, seizures, renal injury, hypotension, bradycardia
Kava kava	<i>Piper methysticum</i>	Sedative	Inebriation
Kombucha		Stimulant	Metabolic acidosis, hepatotoxicity, death
Licorice	<i>Glycyrrhiza</i> spp	Indigestion	Mineralocorticoid effects
Lily-of-the-valley	<i>Convallaria</i> spp	Cardiotonic	GI (nausea, vomiting), cardiac arrhythmias
Linn	<i>Salix caprea</i>	Purgative	Hemolysis with glucose-6-phosphate dehydrogenase deficiency
Lobelia (Indian tobacco)	<i>Lobelia</i> spp	Stimulant	Nicotine intoxication
Ma Huang	<i>Ephedra sinica</i>	Stimulant	Sympathetic crisis, especially with monoamine oxidase inhibitors
Mandrake	<i>Mandragora officinarum</i>	Hallucinogen	Anticholinergic syndrome
Mormon tea	<i>Ephedra nevadensis</i>	Stimulant, asthma, antipyretic	Hypertension, sympathomimetic
Nutmeg	<i>Myristica fragrans</i>	Hallucinogen, abortifacient	Hallucinations, GI upset
Oleander	<i>Nerium oleander</i>	Cardiac stimulant	Cardiac arrhythmias
Passion flower	<i>Passiflora caerulea</i>	Hallucinogen	Hallucinations, seizures, hypotension
Periwinkle	<i>Vinca</i> spp	Anti-inflammatory, diabetes	Alopecia, seizures, hepatotoxicity
Pokeweed	<i>Phytolacca</i> spp	Arthritis, chronic pain	GI upset, seizures, death
Sabah	<i>Sauropus androgynus</i>	Weight loss, vision	Pulmonary injury
Sage	<i>Salvia</i> spp	CNS stimulant	Seizures
Snakeroot	<i>Rauwolfia serpentina</i>	Sedative, antihypertensive	Bradycardia, coma
Squill	<i>Urginea maritima</i>	Arthritis, cardiac stimulant	Seizures, arrhythmias, death
Thorn apple	<i>Datura stramonium</i>	Hallucinations	Anticholinergic
Tonka bean	<i>Dipteryx odoratum</i>	Anticoagulant	Bleeding diathesis
Valerian root	<i>Valeriana</i> spp	Sedative	Sedation, obtundation
Wild (squirting) cucumber	<i>Ecbalium elaterium</i>	Constipation, anti-inflammatory, rheumatic disease	Airway obstruction
Wormwood (mugwort)	<i>Artemisia</i> spp	Stimulant, hallucinogen	Hallucinations, seizures, uterine stimulation
Yohimbine	<i>Coryanthe yohimbe</i>	Aphrodisiac, stimulant	Hypertension, sympathetic crisis

CNS, central nervous system; GI, gastrointestinal.

The term *herbal hepatitis* has been coined to describe the relatively frequent occurrence of herb-associated liver injury.²³ For example, fatal hepatitis has been associated with ingestion of wild germander (*Teucrium chamaedrys*).²⁴ Use of “chaparral” teas was associated with development of hepatitis (leading to the need for liver transplantation in one patient). This tea, which is derived from the ground leaves of the creosote bush (*Larrea tridentata*), has been promoted as an antioxidant, a blood purifier, and an inhibitor of aging.^{25,26} Another reported outbreak of hepatitis was associated with the use of Chinese herbs²⁷; in this case, the responsible toxin

was not identified. As training and public awareness have increased, fewer of these problems have occurred. The herbs mentioned above are not used nearly as much as they were 20 years ago. Many pharmaceutical companies have taken the lead in producing highly standardized forms of botanicals. This has helped a great deal with respect to purity, labeling, and minimizing side effects.

HEMATOLOGIC

Herbs may contain alkaloids that are toxic to red blood cells. Among these are salicylate-containing agents such as willow bark; these can lead to hemolysis if ingested by

an individual with glucose-6-phosphate dehydrogenase deficiency. Other herbs contain Coumadin-like agents, including Tonka beans (*Coumarouna oppositifolia*), melilot (*Melilotus officinalis*), and woodruff (*Galium odoratum*); excess consumption can produce a coagulopathy.²² This is no different from what can occur when certain drugs are taken injudiciously. However, oftentimes there is no package insert to the botanical regardless of its quality. This emphasizes the role of trained professionals in the application of these substances.

AUTONOMIC

Herbs that affect the autonomic nervous system include those containing the anticholinergic drugs atropine, scopolamine, and hyoscyamine.²² These include mandrake (*Mandragora officinarum*), thorn apple (*Datura* spp), lobelia (*Lobelia inflata*), burdock root (*Arctium lappa*), and jimson root (*Datura stramonium*).²⁸ Other agents acting on the autonomic nervous system include sympathomimetics, such as Mormon tea (*Ephedra nevadensis*), which contains ephedrine; snakeroot tea (*Rauwolfia serpentina*), which contains reserpine; and yohimbe bark (*Corynanthe yohimbe*), which contains yohimbine, a central nervous system α_2 -adrenergic antagonist.

NEUROLOGIC

A large number of herbal teas contain psychoactive substances that are the basis of their use (e.g., those containing caffeine). Although many, such as kava kava or chamomile, possess valuable and desirable therapeutic effects, excess dosing can produce toxicity. Teas associated with central nervous system toxicity include kava kava (*Piper methysticum*), jimson root (*Datura* spp), and nutmeg (*Myristica fragrans*).^{22,29}

CARDIAC

Herbal teas associated with cardiotoxicity include those prepared from squill (*Urginea maritima*), lily-of-the-valley (*Convallaria majalis*), and oleander (*Thevetia* and *Nerium* spp). Some cardiac glycosides (e.g., those in oleander) produce toxic manifestations that resemble digitalis poisoning and that, like digitalis, respond to the administration of digoxin antibody fragments (Digibind).³⁰

ALLERGIC

Chamomile (from *Chamomilla* spp) is a popular sedative. However, it is closely related to the ragweed and chrysanthemum families. Exposure to this tea can therefore produce a variety of reactions, although they are uncommon.

CARCINOGENIC

Sassafras is a popular tea that was once prescribed for a number of therapeutic effects. However, its active principal, safrole, is a recognized hepatic carcinogen. As a result, safrole has been banned from use by the FDA.³¹ At this point, it is exceptional to find sassafras sold as an herb.

PYRROLIZIDINE TOXICITY

Many herbal teas contain pyrrolizidine alkaloids. These are a group of about 200 distinct substances found widely

among plants.³² The teas, such as comfrey, are prescribed as sedatives and as treatment for amenorrhea. However, since the first description of *Senecio* species disease (hepatic veno-occlusive syndrome) in 1920, small outbreaks of pyrrolizidine-associated hepatic disease have occasionally occurred. These alkaloids are highly hepatotoxic and, in some cases, carcinogenic.³³

The hallmark of pyrrolizidine intoxication is the development of veno-occlusive disease, a hepatic disorder that is similar but not identical to the Budd-Chiari syndrome. The mechanism of pyrrolizidine toxicity appears to be formation of toxic pyrroles by cytochrome P-450 enzymes; these pyrroles alkylate nucleophilic groups on cell macromolecules.³⁴ Pyrrolizidine alkaloids can be transmitted across the placenta; in one case in which a woman ingested an herbal tea during her pregnancy, her newborn developed fatal hepatic veno-occlusive disease.³⁵ Because of their well-characterized toxicity, which can occur after ingestion of as little as 85 mg of pyrrolizidine alkaloid, pyrrolizidine-containing teas are not nearly as widely available in herbal and health food stores as they were 20 years ago.³³ The herbs most commonly associated with hepatic veno-occlusive disease are *Heliotropium*, *Crotalaria*, *Senecio*, and *Symphytum* species. Other herbs containing pyrrolizidine are listed in Table 68-2. Plant roots can contain 10 times more alkaloid than the leaf. Other toxicities associated with pyrrolizidine alkaloids include disturbances of GI, pancreatic, and renal function. Interestingly, inadvertent exposure to pyrrolizidine agents can also occur through their contamination of dietary staples. For example, as a result of contaminated grain, epidemics of hepatic veno-occlusive disease occurred in both Afghanistan and India in 1976, affecting more than 2000 persons and causing more than 30 deaths.^{32,34} Epidemiologically, consumption of pyrrolizidine-containing plants is widespread in Africa, South and Central America, and Jamaica.³⁴ Jamaican bush tea, a popular drink, is largely prepared with *Crotalaria* species, making veno-occlusive disease endemic on this island.³⁴ Pyrrolizidine poisoning has also been blamed for major cases of livestock loss in the Pacific Northwest.^{32,34}

The clinical presentation of hepatic veno-occlusive disease begins with severe abdominal pain and vomiting. Physical examination reveals hepatomegaly, abdominal distention, and ascites. In children, the clinical picture can mimic Reye's syndrome.³⁴ On biopsy, characteristic histopathology consists of perivenular congestion,

TABLE 68-2 Pyrrolizidine-Containing Teas

COMMON NAME	BOTANIC NAME
Coltsfoot	<i>Tussilago farfara</i>
Comfrey	<i>Symphytum officinale</i>
Gordolobo	<i>Senecio longilobus</i>
Groundsel	<i>Senecio vulgaris</i>
Mate	<i>Ilex paraguayensis</i>
Tansy ragwort	<i>Senecio jacobea</i>
T'u-san-chi	<i>Gynura segetum</i>

sinusoidal dilation, and occlusion of terminal venules by connective tissue. This is also the pattern seen in the Budd-Chiari syndrome, but course and outcome in Budd-Chiari syndrome are much more severe and life threatening without treatment.

The diagnosis of pyrrolizidine hepatotoxicity is made on the basis of history, clinical evidence of veno-occlusive disease, and pathognomonic histopathology. This disorder is restricted to those areas in which the traditional use of pyrrolizidine teas is commonplace. Treatment is supportive.

Clinical Toxicity of Specific Herbs

ARISTOLOCHIA SPECIES BOTANICALS

Chinese-herb nephropathy (CHN) was observed among women after the intake of weight-reducing pills containing a Chinese herb labeled as *Stephania tetrandra*.³⁶ Phytochemical analyses of the herb revealed the presence of aristolochic acids instead of tetrandrine.³⁷ *Aristolochia fangchi* (guang fangji) had been substituted for the *Stephania tetrandra*, leading to aristolochic acid exposure and nephropathy. Aristolochic acids are known for their nephrotoxic effects in rodents as well as for their carcinogenic and mutagenic properties.³⁸ Exposure in humans that resulted in nephropathy has been reported when contamination of herbal products with the *Aristolochia* species botanicals has occurred. The FDA took action in 2001 to ban all products containing any *Aristolochia* species so as to avoid exposure to aristolochic acids. Subsequent to the identification of nephrotoxic effects leading to kidney failure in humans, a study conducted in Belgium reported 18 cases of urothelial carcinoma among 39 patients with end-stage renal failure associated with *Aristolochia* toxins.³⁹

GINSENG

Ginseng is a Chinese word meaning “the essence of man.”⁴⁰ This herb has been used for centuries to treat a broad range of illnesses.²¹ From the botanic genus *Panax*, ginseng is promoted as a respiratory, digestive, and central nervous system stimulant; a cure for fatigue; a treatment for ulcers; and a cholesterol-lowering agent. Ginseng’s most active principals are alkaloids known as *saponins* (also referred to as *panaxosides* or *ginsenosides*). Scientific investigations have shown that these agents can release histamine; block calcium mobilization in smooth muscle, producing hypotension; stimulate α_2 -adrenergic receptors; stimulate erythropoiesis; increase adrenocorticotropic hormone, antidiuretic hormone, and cortisol secretion; raise sperm count; increase glucose utilization; increase levels of circulating immunoglobulins; and inhibit the cells of tumor cells cultivated in vitro.⁴⁰ Therapeutically, ginseng has been prescribed for the treatment of shock, hypertension, hyperlipidemia, diabetes mellitus, depression, cough, headaches, and fever.

Excessive use of ginseng (more than 3 g daily) is associated with a ginseng abuse syndrome consisting of diarrhea, anxiety, insomnia, nonspecific dermatitis, depression, amenorrhea, and hypertension.²¹ However,

as we have learned more and more about this beneficial botanical, it is rarely used in these doses. The wide therapeutic margin makes toxicity unlikely. Treatment of this transient, self-limited condition is supportive.

ACONITE

Aconites are among the most popular yet toxic herbs. At one time, execution of criminals was performed by the administration of aconite decoctions. The *Aconitum* genus includes many species, the most common being *Aconitum napellus*, popularly referred to as monkshood, wolfsbane, or friar’s cap. Aconite is found in Chinese decoctions or soups, including Fu Zi, Wu Tao, Cao Wu, Chuan Wu, Ts’ao Wu, Futxu, Xue Shang Yi Zhi Gao, Shi-I, Fu Zi, and Sen Fu. Herbalists generally prescribe aconite for treatment of musculoskeletal complaints, angina, and congestive heart failure and as a sedative. The active principals of aconite have been shown to have pharmacologic properties that include stimulation of adrenocorticotropic hormone secretion.⁴¹

With the GI tract, nervous system, and heart as target organs, aconites, when taken in overdose, produce a distinctive clinical picture. GI effects occur initially, consisting of nausea, vomiting, and hypersalivation. These are followed by neurologic effects, including paresthesias, blurred vision, skeletal muscle weakness or frank paralysis,⁴² coma, and seizures. Cardiac disturbances, which can be fatal,^{43,44} include bradycardia, hypotension, ectopy, cardiac conduction disturbances (prolonged QRS or QT interval), and intractable ventricular tachyarrhythmias.

Treatment of aconite poisoning consists of stabilization of the airway, aggressive treatment of cardiac disturbances, and early GI decontamination. Subsequent treatment is supportive because there are no known antidotes and no identified mechanism for enhanced elimination of the toxin.

NUTMEG

The mood-elevating, aphrodisiac, narcotic, and hallucinogenic effects of nutmeg have been exploited for centuries. This spice remains popular, particularly as a hallucinogen. Prepared from the fruit of the evergreen tree *Myristica fragrans*, nutmeg is an easily obtained spice. The nutmeg seed contains a number of alkaloids, including myristicin, eugenol, isoeugenol, methyleugenol, methylisoeugenol, safrole, geraniol, borneol, and elemicin. Among these, myristicin is the most psychoactive compound. Myristicin is metabolized to the hallucinogen 3-methoxy-4,5-methylenedioxyamphetamine (MMDA), a substance closely related to methylenedioxymethamphetamine (MDMA, “Ecstasy”). Another alkaloid in nutmeg, elemicin, is metabolized to a hallucinogen.

Ingestion of 5 to 30 g of nutmeg produces symptoms promptly, with GI upset predominating. Within 3 hours, hallucinogenic effects appear, consisting of vivid visual hallucinations. The duration of this action can be as long as 2 to 3 days. Chronic abuse of this potent hallucinogen is limited by the GI disturbances it produces. Treatment of acute nutmeg intoxication consists of reducing environmental stimuli and attempting to calm the patient. Benzodiazepines may be valuable as adjunctive therapy.

KOMBUCHA MUSHROOM

Kombucha is a plant that has recently gained popularity as a “fountain of youth.” It has been promoted as a treatment for cancer, hypertension, fatigue, declining T-cell counts, arthritis, wrinkles, constipation, and gray hair. Prescribed and marketed by naturopathic healers in the United States, kombucha is often cultivated at home and passed on to friends.⁴⁵ Not a true mushroom, the plant is a yeast-bacterial aggregate surrounded by a membrane. Use of this mushroom has been blamed for sporadic cases of hepatotoxicity and severe metabolic acidosis, which was fatal in one case.^{45,46} The toxic principals have not been identified; toxicity may result from kombucha contamination by other yeasts or bacteria.

SABAH

Marketed in the United States under the name “Defat,” this vegetable has been associated with an epidemic of pulmonary disease in Taiwan. One report described 44 individuals, primarily women, who developed respiratory distress, insomnia, and obstructive pulmonary disease after consumption of the Sabah vegetable (*Sauropus androgynus*).⁴⁷ This vegetable, which is a regular part of the diet in many parts of the world, was being ingested in large daily quantities as a means of improving vision, reducing lipids, and treating constipation and hemorrhoids, or as a weight loss measure. An epidemiologic investigation was undertaken after repeated reports to the Taiwan Poison Center of illness related to ingestion of this vegetable. Victims were primarily females who had been taking the vegetable whole or in juice form. The average duration of consumption before the appearance of disease was 35 days. Initial symptoms consisted of insomnia and excitation, followed by difficulty in breathing, cough, and chest tightness. In many cases, illness developed after consumption of the vegetable had ceased. In a patient who underwent a lung biopsy, histopathology suggested bronchiolitis obliterans with organizing pneumonia. Four fatalities occurred. By December 1, 1995, 169 cases of Sabah-associated illness had been reported. An exact cause has yet to be determined.⁴⁸

Chinese Patent (Proprietary) Medicines

In addition to herbs being prescribed and sold in their unadulterated form, herbs are often combined to form Chinese patent medicines. Chinese patent medicines, unlike Chinese herbal medicines, are mass-produced in a fashion similar to pharmaceutical manufacture.

The potential problems with these medicines are several. First, Chinese proprietary medicines are often sold in unlabeled or poorly labeled packages. Second, they typically contain a combination of products such that a distinctive clinical syndrome may not be present after intoxication. Jin Bu Huan tablets, prescribed for muscle spasm, pain, and insomnia, were associated with the poisoning of three children when they were discovered to contain an herb not usually a part of them.⁴⁹ In a later report, hepatitis was also associated with Jin Bu

Huan.¹² Third, combining herbs from various sources poses a greater probability of product contamination. Fourth, because of sometimes relatively poor quality control in production, proprietary medicines can be entirely mislabeled, containing a product completely different from what is stated. Finally, these products can be adulterated with pharmaceutical agents. Several cases of intoxication have been attributed to these preparations.⁵⁰ For example, Gan Mao Tong Pian, a remedy prescribed for viral illness, produced aplastic anemia in a child as a result of its adulteration by phenylbutazone.⁵⁰ One Chinese proprietary product, *Chui-Fong-Tou-Gen-Wan*, has been found to contain agents including phenacetin, phenylbutazone, mercuric sulfide, lead, cadmium, and arsenic.^{17,18,50,51} In one study, eight of nine Chinese patent medicines tested were found to be contaminated with arsenic and mercury.⁵¹ In a 5-year study of hospital admissions resulting from use of Chinese proprietary medicines, Chan and colleagues identified 71 patients, of whom 42 were found to have elevated serum concentrations of aspirin or acetaminophen.⁵² Products containing acetaminophen included Superior Yinchiao, Chieh, Tu Pien, Yinchiao Chieh Tu Pien, Ganyanqing Pian, and Suxiaao Shangfeng.

TRADITIONAL (“FOLK”) MEDICINE

A *folk remedy* can be defined as an unrefined product that is taken for medicinal purposes. Unlike herbal medicines, folk remedies are regularly derived from animals, plants, or minerals. The use of folk medicines has a strong component of religious ritual (e.g., shamanism). Folk treatments may consist of physical modalities (e.g., “coining” or “cupping”), widely practiced in Asian cultures, as well as religious practices.⁵³ The use of so-called ethnomedical therapies is most prevalent among minority groups, especially among families who have either recently emigrated or who have a family member who has inherited knowledge about folk remedies. In many cases, the basis of therapies is an unorthodox belief about disease processes (e.g., the humoral [hot-cold] theory).⁵⁴ However, folk medicines are also used to treat well-defined Western diseases. These diseases may be referred to by archaic names such as rheumatism (musculoskeletal inflammation), dropsy (congestive heart failure), or consumption (tuberculosis). Folk medicines are also sought by those under the care of physicians because of frustration with the inability of Western medicine to cure a disease or because of the understandable desire to use natural remedies rather than pharmaceutical agents. With increasing frequency, these traditional medicines can be purchased in the United States. For example, in Hispanic populations, local *botanicas* usually provide religious objects as well as folk remedies.⁵⁴

A list of folk medicines associated with clinical toxicity is found in Table 68-3. For example, the remedy alcanfor contains 20% camphor, sufficient to produce toxic manifestations.⁵⁴ Several folk remedies used in the treatment of GI disturbances contain lead. In some cases,

**TABLE 68-3** Common Folk Medicines by Cultural Origin

NAME	CONTENTS	POTENTIAL TOXICITY
Hispanic		
Siete jarabes	Almond, castor oil, tolu, wild cherry licorice, cocillana, honey	GI upset, catharsis, electrolyte disturbances
Agua maravilla	Witch hazel, ethanol	Ethanol toxicity
Jarabe maguey	Maguey (<i>Agave</i> spp)	GI upset
Alcanfor	Camphor	Camphor toxicity
Azarcon	Lead	Lead intoxication
Greta	Lead	Lead intoxication
Azogue	Elemental mercury	Mercury intoxication
Ipecacuanha	Ipecac	Vomiting, myopathy
Southeast Asian		
Paylooh	Lead	Lead intoxication
Indian and Ayurvedic		
Surma	Lead	Lead intoxication
Deshi Dawa	Lead	Lead intoxication

GI, gastrointestinal.

use of these agents can produce lead-induced abdominal pain (lead colic), resulting in further use and more severe lead poisoning.

Identifying the ingredients in folk remedies is often assisted by knowledge of the cultural origins of the disease being treated. For example, empacho, one of the most common illnesses among Hispanic cultures, is treated by various means, including massages with olive oil (or other type of oil or grease), laxatives, conventional stomach remedies (e.g., bismuth subsalicylate [Pepto-Bismol]), chamomile tea, and antacids, as well as the folk remedies *greta* and *azarcon* (both of which contain up to 90% lead).⁵⁵ Other lead-containing folk medicines are listed in Table 68-3.

Pachter and associates described other potential toxicities from traditional medicines.⁵⁴ For example, azogue, which contains elemental mercury, is generally used as a talisman. However, if it is dispersed about the room to ward off evil spirits, inhalation of toxic mercury vapors could occur.

Ayurvedic Medicine

Ayurveda is a traditional system of medicine practiced primarily in Asian countries (Tibet, Burma, Pakistan, Sri Lanka, India, Bangladesh). Practitioners of Ayurvedic medicine not only rely on herbal remedies but also sometimes prescribe animal products, metals, and minerals as well. Increasingly, Ayurvedic remedies are being used in Western areas, including Europe and North America. Also, in becoming a commercial industry, Ayurvedic medicine has begun to include large-scale distribution of these herbs.

Because Ayurvedic medicine includes therapy with metals and minerals, inadvertent metal intoxication is the most significant potential occurrence. Ayurvedic medicines are typically sold in an “ash” powder form, packaged in capsules, and produced by the repeated

pyrolysis of the metal. Zinc, iron, lead, tin, mercury, and silver are among the metals that may be contained in an Ayurvedic “tonic.” As such, both consumers and manufacturers of these products are at risk for metal intoxication. Lead intoxication has been reported with the use of these medicines.^{56,57}

ALTERNATIVE MEDICINES

Practices that can be placed in this category include homeopathy, naturopathy (the science of applying natural substances that enable the body to heal itself and maintain natural homeostasis), nutritional supplementation for medicinal purposes, and novel therapies, such as hyperoxygenation and oligotherapy (the administration of trace elements to improve health).³

Homeopathy

Homeopathy is a popular alternative therapy that advocates the use of toxic substances in small amounts. It is extremely popular in Europe, Latin America, and Asia and has been used by an estimated 1% of the American population.⁸ The concept was introduced by Samuel Hahnemann in the late 18th century. Treatments in homeopathic medicine are based on three principles: “like cures like,” “efficacy improves with increasing dilution,” and “treatments need to be individualized.”⁵⁸ Under these rules, a toxin, when administered in small doses, can have therapeutic value. Such a theory is not a great departure from Western medicine because it is the basis of desensitization therapy for allergies. However, the theory that the smaller the dose of medicine, the more effective, has not been well documented in scientific study. Homeopathy also requires that therapy be individualized; therefore, in principle, homeopathic medications should not be shared with another person.

Homeopathic medicines are generally toxins derived from plants, animals, or minerals.⁸ Common agents include strychnine, ipecac, arsenic, mercury, podophyllin, and sulfur.⁸ Preparations of accepted therapeutic value are recorded in the *U.S. Homeopathic Pharmacopoeia*, published by the American Institute of Homeopathy.⁵⁸ Homeopathic products often are packages of capsules or tablets with the ingredients listed by their Latin names. Scientifically rigorous studies have suggested efficacy of some of these medicines.^{5,7,8}

Homeopathic tinctures are generally made by adding 1 part of a toxin to 20 parts of alcohol. This tincture is diluted as needed to 1:1000, 1:10,000, and even further dilutions. A homeopathic product may therefore contain on its label a symbol of 1× (1:10 dilution), 2× (1:100 dilution), 3×, and so forth. Another dilution technique is the centesimal (“c” or “cH”), in which 1 part of active substance is diluted in 99 parts of an alcohol mixture.⁵⁸ Therefore, a substance labeled 30C has had the active substance diluted 1:100 in a water/alcohol solution 30 times, yielding a final concentration of 1×10^{-60} .⁸

Because of the minute quantities of toxin, ingestion of homeopathic medications should rarely produce toxicity, even if as many as 100 tablets are ingested. Important exceptions to this rule would be if the product were homemade, thereby potentially having dilutions less than planned, or in the potential case of an allergic reaction, which could occur after exposure to small quantities of the active agent. Reports have described homeopathic products adulterated with active agents.⁵

Nutrition Supplements

In addition to using herbal and alternative medications, the public commonly takes substances that are promoted as nutrition supplements, designed to improve health or treat disease. Additionally, the concept of adding or supplementing with so-called “native molecules,” now known as *natural medicines*, seems to be gaining validity. Ames postulates that individuals can be “tuned up” metabolically with the strategic use of nutraceuticals based on an understanding of their individual metabolic genetics.⁵⁹ By adding orthomolecular amounts of specific vitamins, amino acids, minerals, and other cofactors, the K_m of specific metabolic reactions can be normalized in individuals who might otherwise have metabolic defects as a result of genes or aging. The validation of this concept may have a significant impact regarding the value of using higher doses of specific nutraceuticals in restoring or maintaining optimal human health.⁵⁹

In the past, the use of nutritional supplements for these purposes has been widespread and in some instances less responsible. For example, an examination of advertisements in 12 health and bodybuilding magazines disclosed 311 supplements, containing 235 unique ingredients. Most common among these were amino acids, followed by herbs, vitamins, minerals, and steroids.⁶⁰ The toxicity of vitamins is discussed in Chapter 69. The few specific nutritional supplements that have been reported to have clinical toxicity are

discussed next. Based on the volume of use, there is remarkably little toxicity reported other than the specific cases outlined below.

γ-HYDROXYBUTYRATE

γ-Hydroxybutyrate (GHB) is a health food supplement that became popular in 1990 after its promotion as a bodybuilding and diet aid. Shortly after widespread use began, cases of a toxic syndrome related to its ingestion were reported. Dyer described a series of 16 cases of GHB toxicity reported to the San Francisco Regional Poison Center; manifestations included coma and seizures.⁶¹ Other signs of toxicity were confusion, agitation, hallucinations, and bradycardia. These effects occurred after ingestions of as little as 1 to 4 tsp of GHB (sold as a white powder). Shortly after similar reports throughout the country, individual states banned the product.⁶¹ GHB is now sold as a controlled substance as the drug Xyrem. It now has an FDA-approved indication for the management of narcolepsy. Other indications may follow. This is a good example of a natural molecule that does possess a much more narrow therapeutic margin and therefore should not be considered a nutraceutical.

L-TRYPTOPHAN

L-Tryptophan is an essential amino acid. As a precursor to the neurotransmitter serotonin, it has been touted as an effective treatment for ailments including insomnia, depression, and premenstrual syndrome. Its use, however, has been associated with at least two syndromes of intoxication.

An epidemic of multisystem disease occurred in the fall of 1989, when patients who had been ingesting L-tryptophan developed eosinophilia and severe myalgia. During the course of 6 to 9 months, an estimated 5000 to 10,000 developed this syndrome, and more than 36 fatalities occurred. Eighty-four percent of victims were female. Prominent symptoms were peripheral eosinophilia (with eosinophil counts $> 1000/\text{mm}^3$), severe diffuse myalgias, and dermatologic changes resembling scleroderma. Termed the *eosinophilia-myalgia syndrome* (EMS), this disease had other features that included pulmonary disturbances (dyspnea, cough, pulmonary infiltrates, and pulmonary hypertension, which occurred in about 60%), peripheral neuropathy, alopecia, edema, coronary artery spasm, and cardiac arrhythmias.^{48,62} The illness bore a striking resemblance to the unexplained “toxic oil” epidemic that occurred in Spain in 1981.^{48,63} When it was found that all cases of EMS could be traced to L-tryptophan synthesized by a single manufacturer, analysis revealed that owing to changes in the manufacturing method, the tryptophan was contaminated with an impurity, 1,1'-ethylidenebis [L-tryptophan].⁴⁸ There is still controversy about whether the true cause of EMS was discovered. Nonetheless, after the FDA's ban of tryptophan-containing products, the disease quickly and almost completely disappeared. This important mass poisoning has been extensively reviewed by others.^{62,64-69}

Adverse effects have also occurred with the simultaneous use of tryptophan and antidepressants of the

monoamine oxidase (MAO) inhibitor or serotonin reuptake inhibitor classes. In the case of MAO inhibitors, tryptophan was once recommended as adjunctive therapy for those who had a poor response to MAO therapy.⁷⁰ However, after this combination began being used more consistently, reports began to describe hypertensive crises, myoclonus, and delirium after their combined use.⁷¹ This syndrome, now referred to as a *serotonergic* syndrome (see Chapter 10A), appears to result from excess stimulation of central nervous system serotonin receptors and can include other features such as myoclonus, hyperreflexia, diaphoresis, priapism, and tremor. At its extreme, the serotonergic syndrome can produce seizures, coma, and death. In addition to MAO inhibitors, the newer serotonin reuptake inhibitors (e.g., fluoxetine, paroxetine, and sertraline) have the potential to produce this syndrome after ingestion of tryptophan, although there has not been a sudden increase in reports of these cases. Tryptophan has been reintroduced to the market as an amino acid supplement following a great deal of diligence in improving its manufacturing. Thus far, there have been no new cases of EMS, nor a rise in the incidence of so-called serotonergic syndrome since it has become more readily available.

CALCIUM SUPPLEMENTS

Use of calcium supplements has increased considerably during the past decade as the diminishing calcium intake of Americans is documented and the relationship between deficient calcium intake and osteoporosis, particularly in women, is recognized. Some calcium supplements that are derived from bone meal are reported to contain lead.

Hyperoxygenation Therapy

Hyperoxygen therapy is being increasingly promoted as a health aid. It has become particularly popular as an alternative treatment for AIDS. Acting in a fashion similar to white blood cells in their destruction of microbial agents, ingestion of oxygen-liberating agents is thought to augment host defense mechanisms. Hydrogen peroxide is the most common agent used for hyperoxygenation therapy. Hydrogen peroxide used for this purpose is generally sold in a 25% to 50% concentration, in contrast to the 3% to 5% concentration of household hydrogen peroxide. The user is directed to ingest several drops daily. Because the agent is refrigerated, the potential for inadvertent ingestion is increased.⁷²

Toxicity from hyperoxygen therapy has been reported after ingestion of excess amounts. The two major consequences of this ingestion are corrosive injury of the GI tract and excess liberation of oxygen, resulting in the formation of gas emboli. One milliliter of a concentrated hydrogen peroxide solution can liberate about 115 mL of oxygen; ingestion of 2 ounces of 35% hydrogen peroxide could release 6.9 L of oxygen in the stomach.^{72,73} Several researchers have described life-threatening or fatal gas emboli after ingestion of concentrated hydrogen peroxide.⁷²⁻⁷⁴

Treatment of concentrated hydrogen peroxide therapy includes supportive care, assessment of the esophagus

and stomach for corrosive injury, and anticipation of air emboli. Diluting agents should not be administered because of their potential to enhance oxygen liberation.

Other Therapies

The promotion of tonics, extracts, and elixirs has a consistent ability to entice consumers. Their list is constantly changing. In rare circumstances, these alternative medicines prove to have therapeutic value. In most cases, they have no beneficial action but also no toxicity. These agents can occasionally be highly toxic, however. For example, laetrile was promoted in the early 1980s as an alternative treatment for cancer. Prepared from crushed apricot pits, this agent contained high concentrations of amygdalin, a cyanogenic alkaloid. Although it was not proved to have therapeutic value, laetrile did result in cases of cyanide intoxication after overdose.⁷⁵

Other therapies, including ingestion of shark cartilage, boiled urchin, and algae, continue to be promoted without clear, scientifically proven benefit.

The Vitamins

ALLISON A. MULLER, BS, PHARM D ■ FRED M. HENRETIG, MD

At a Glance...

- The most crucial specific intervention for vitamin A poisoning is immediate discontinuation of vitamin A; this measure alone suffices in most cases.
- Prompt withdrawal of vitamin D supplements and implementation of a diet low in calcium and vitamin D are sufficient therapy for mild to moderate cases of vitamin D poisoning.
- It probably is prudent to caution against the use of high-dose vitamin C therapy for patients with known nephrolithiasis, G6PD deficiency, iron overload conditions, pregnancy, and perhaps for women taking oral contraceptives.

INTRODUCTION AND RELEVANT HISTORY

The vitamins are a defined group of essential organic micronutrients that are required in the human diet for optimal nutrition and to prevent specific deficiency syndromes.^{1,2} This requirement is due to either a complete inability to synthesize these nutrients *de novo* or an inadequate rate of synthesis to maintain optimal health. Medical uses for the vitamins include the prevention or treatment of deficiency states and the treatment of rare vitamin-responsive inborn errors of metabolism.

A less accepted current usage of vitamins has been routine high-dose consumption by healthy adults. This practice has gained popularity with the lay public and some health care workers in an effort to enhance appearance, longevity, or athletic performance or to prevent or ameliorate nondeficiency-specific disease states. The clinically significant vitamin exposures occur most often under these circumstances of intentional chronic overdose. The water-soluble vitamins typically are excreted renally when ingested in excess, although very large doses taken chronically have resulted in adverse effects. The fat-soluble vitamins are stored in tissues, and excessive consumption is thus more likely to result in toxicity. Accidental overdose of pediatric multivitamin preparations by children also occurs frequently, although this is rarely a cause for significant concern aside from co-ingested iron in combination products. Serious iron toxicity is rare even in this context. Occasionally, vitamins are chosen as an intentional acute overdose agent. An unfortunately not uncommon scenario is the acute overdose by a young pregnant woman of her prescribed prenatal vitamin and mineral supplement. In this context, with a typical elemental iron content of 62.5 mg per tablet, serious iron poisoning may occur, although toxicity related to

co-ingested vitamins is again rarely of significance (see also Chapter 72).

The medical use of vitamins can be traced to the 1753 discovery by British naval surgeon James Lind of the protection from scurvy afforded to sailors by the addition of fresh citrus fruits to their diets during long voyages.¹ Ascorbic acid (vitamin C) was, of course, subsequently identified as the antiscorbutic factor and became the first of the 13 named vitamins. Vitamins are currently classified as water soluble (nine vitamins: ascorbate, thiamine, riboflavin, niacin, pyridoxine, biotin, pantothenic acid, folate, and cyanocobalamin) or fat soluble (four vitamins: A, D, E, and K). Several of the vitamins exist in nature or *in vivo* as different but closely related chemical compounds or precursors and are referred to as *vitamers*. Many vitamins require processing *in vivo* to become biologically active. The water-soluble vitamins or their derivatives function primarily as coenzymes for apoenzymes. An example is pyridoxine (when converted to pyridoxal phosphate) as coenzyme to the glutamic acid decarboxylase apoenzyme, forming a holoenzyme that synthesizes γ -aminobutyric acid from glutamic acid. The fat-soluble vitamins A and D interact with specific intracellular receptors and have hormonal or prohormonal effects.²

Amounts of vitamins necessary daily to protect normal, healthy persons from vitamin deficiency states range from micrograms to milligrams and are designated the *minimum daily requirements* (MDRs). Currently in the United States, recommendations on daily intake are expressed as reference daily intakes (RDIs) for vitamins and minerals (Table 69-1). These replace the U.S. recommended daily allowance (RDA) and are based on average RDI values for the U.S. population over the age of 4 years.^{2,3} Megadose usage typically involves self-administration of doses 20 to 660 times these recom-

TABLE 69-1 Reference Daily Intakes (RDIs)³

VITAMIN	RDI

Thiamine	1.5 mg
Riboflavin	1.7 mg
Niacin	20 mg
Folic acid	0.4 mg

IU, international units.

mended amounts. In the United States, efforts to regulate vitamin usage have had a complex and politically charged history. Currently, the U.S. Food and Drug Administration (FDA) has the authority to regulate the labeling of vitamin and mineral supplements. Currently, the FDA does not regulate the nutrient content of vitamin supplements, except those intended for use by children less than 12 years of age and by pregnant or lactating women, despite the well-recognized hazards of megadose vitamin usage.²

A number of vitamin-responsive metabolic disorders have been described, involving at least eight of the nine water-soluble vitamins and vitamin D.^{1,4,5} Classic examples include pyridoxine-dependent infantile convulsions, pernicious anemia, and vitamin D-sensitive rickets. Pyridoxine dependency was first described in the early 1950s,¹ and the same era witnessed the observation that the dementia associated with pellagra (niacin deficiency) was similar in some ways to that of schizophrenia.^{4,5} Early studies in the psychiatric literature suggested beneficial results in treating schizophrenia with massive doses of niacin, prompting further extension of this concept to other vitamins and to other illnesses.^{4,6}

Pauling's 1970 monograph *Vitamin C and the Common Cold*⁷ helped popularize the use of megadoses of vitamins for prevention and treatment of a number of illnesses ranging from viral infections to cancer. The increased interest in personal fitness and preventive health of the 1970s provided fertile ground for the expansion of this concept of vitamin megadosing. By the 1980s, more than 70% of Americans believed that vitamins could prevent fatigue, and 21% believed that diseases such as cancer and arthritis were caused by vitamin deficiency.^{4,8} A 1987 survey found that half of adult Americans took occasional vitamin supplements, and more than 20% took vitamins daily.⁹ The popularity of vitamin supplements is a reflection of broad media coverage of studies detailing the roles of vitamins in preventing and treating cancer, cardiovascular disease, ocular disorders, respiratory disorders, and osteoporosis.¹⁰⁻¹² Nutritional authorities caution that insufficient scientific evidence exists to support the megadosing of dietary antioxidants to prevent chronic illnesses such as cardiovascular disease or cancer.¹³ It has been recommended that all adults take one multivitamin daily, since most people do not obtain a sufficient amount of all vitamins from dietary consumption alone.¹⁴

FAT-SOLUBLE VITAMINS

In general, toxic effects of vitamins are most often related to overdosing of the fat-soluble vitamins and have been observed particularly with excessive ingestion of vitamins A and D (Table 69-2). Adverse effects ascribed to vitamins E and K have been uncommon and noted primarily with parenteral use. In view of the prominent place afforded to vitamin A toxicity in reported medical literature, this vitamin is reviewed in some detail relative to the other vitamins covered in this chapter.

Vitamin A

INTRODUCTION AND RELEVANT HISTORY

Vitamin A has a long and fascinating history. As early as 1500 BC, night blindness that could be remedied by the topical application of roasted liver was described in Egypt, and Hippocrates later recommended the ingestion of cow liver as a cure.¹⁵ In 1865, ophthalmia brasiliensis, an eye disorder of poorly nourished slaves, was described. Further linkage of keratomalacia to nutritional deficiency was provided in the 1880s with descriptions of night blindness among Russian Orthodox Catholics who fasted during Lent and particularly with the description of corneal sloughing in breast-fed infants of fasting mothers.¹⁵ Perhaps the oldest and largest recorded experience with vitamin toxicity is associated with both acute and chronic exposure to excess vitamin A. The 19th-century Arctic explorer Elisha Kane described a syndrome of severe headache, vomiting, drowsiness, and irritability occurring a few hours after the ingestion of polar bear liver.¹⁶ This syndrome is recognized today as being quite likely due to acute hypervitaminosis A-induced pseudotumor cerebri. Modern authors continue to describe similar phenomena, for example, the 1984 report of a 25-year-old Sri Lankan woman who developed pseudotumor and markedly elevated serum vitamin A levels 1 week after consuming a meal of shark liver (see Toxicology).¹⁷

STRUCTURE

The vitamin A family consists of several related compounds, with their respective stereoisomers, which exhibit the vitamin's biologic effects. Retinol, also referred to as vitamin A₁, is the alcohol form, which is found primarily as an ester in the liver of many animals and saltwater fish (Fig. 69-1). Retinal, which is the vitamin A aldehyde, functions as the chromophore of the retina when it combines with the protein opsin to form rhodopsin. β -Carotene, or provitamin A, is a dimer of retinal that occurs in many pigmented plants. Retinoic acid, the carboxylic acid of retinol, is believed to be the relevant vitamin at the cellular level for most functions of vitamin A other than in the visual cycle.

Vitamin A is classically quantified by bioassay in rats, although purified preparations may also be determined spectrophotometrically.¹⁵ The "retinol equivalent" is equal to 1 μ g of all-*trans*-retinol (3.3 IU) or 6 μ g of dietary β -carotene (10 IU).

PHARMACOLOGY AND PATHOPHYSIOLOGY

Vitamin A is believed to act through hormone-like activity on intracellular receptors, in addition to the well-understood specific effect of one of its vitamers, retinal, as the chromophore in the visual light-sensing cells. Vitamin A is essential in the visual cycle, in the maintenance of the functional and structural integrity of epithelium in mucus-secreting or keratinizing tissues, in bone growth, and in reproduction and embryologic development. It has an important role in enhancing immune function and reducing sequelae of some

**TABLE 69-2** Vitamin Toxicity Overview

VITAMIN	TOXIC DOSE	PRINCIPAL TOXIC EFFECTS
A	Acute: 75,000–100,000 IU (P) >1 million IU (A) Chronic: 18,000 IU/day (P) 20,000–50,000 IU/day (A)	Initial: CNS; increased ICP with headache, irritability, lethargy, ophthalmoplegia, papilledema Later: hair loss, peeling skin, hepatomegaly CNS: increased ICP, pseudotumor cerebri Mucocutaneous: dry, scaly, peeling skin; hair loss, brittle nails; cheilitis, stomatitis, gingivitis Hepatic: early–hepatomegaly, anorexia, vomiting, +/- abnormal LFTs; late–hepatic fibrosis, ascites, cirrhosis, esophageal varices Skeletal: bone pain, cortical hyperostoses; premature epiphyseal closure (P)
D	Teratogenic: >10,000 IU/day 1600–2000 IU/day (P) 60,000 IU/day (A) Teratogenic: (?) 2000–4000 IU/day Probably variable, with idiosyncratic hypersensitivity	Reproductive: teratogenic effects on face, ears; occasional CNS, cardiac (less so than with isotretinoin) Metabolic: hypercalcemia Renal: hypercalciuria, nephrocalcinosis CV: metastatic calcifications in heart, vessels CV: infantile hypercalcemia, supraaortic stenosis syndrome
E	(?) 400–3000 IU/day	CNS: headache, weakness GI: nausea, cramps, diarrhea Heme: increased effect of anticoagulants
K	(?) (Occurs with therapeutic IV dose)	Anaphylactoid reaction Heme: hemolysis, jaundice in newborns (especially with G6PD deficiency)
Pyridoxine Niacin	117–500 mg/day 3.0–4.5 mg/day	Peripheral sensory neuropathy Cutaneous: flushing, pruritus GI: cholestatic jaundice, hepatitis Heme: thrombocytopenia CV: atrial fibrillation Misc: gout, myopathy
Thiamine	Acute: (?) (rare, occurs with therapeutic IV dose) Chronic: 5 mg/day	Anaphylactic reaction Misc: headache, irritability, tachycardia
C	(?), probably > 4 g/day	GI: nausea, cramping, diarrhea Renal: nephrolithiasis (especially in predisposed patients) Heme: hemolysis with G6PD deficiency Misc: rebound scurvy after withdrawal

infections (e.g., measles in young children¹⁸) and may play a significant role in anticarcinogenesis. Several synthetic analogs of vitamin A have been developed as pharmaceutical agents for dermatologic applications.

In the visual system, both rods and cones utilize 11-*cis*-retinal as the chromophore. In the photoreceptor cells of the rods, especially sensitive to low-intensity light, this vitamin combines with the membrane protein opsin to form rhodopsin, which is the light-absorbing holoreceptor. The cones, which are the color-sensitive photoreceptor cells, are of three types, each having a separate protein that when combined with 11-*cis*-retinal responds optimally to red, green, or blue wavelengths of light. The visual cycle involves an interaction of the photon-activated rhodopsin with a G protein and interconversions of 11-*cis*-retinal to several stereoisomers.¹⁹

The basal mucus-secreting cells of many epithelia depend on vitamin A for normal structure and mucus secretion. These influences appear to be mediated primarily by retinoic acid, via changes in nuclear

transcription. Retinoic acid receptors have been described that belong to a receptor “superfamily” that includes receptors for calcitriol as well as thyroid and steroid hormones.¹⁵

Possible anticarcinogenic effects of vitamin A have been attributed to its ability to induce differentiation of malignant cells and to function in the synthesis of cell-surface glycoproteins and glycolipids that may play an important role in cell adherence and communication. Splenic lymphocyte proliferation and killer cell cytotoxic activity is impaired in vitamin A deficiency. Therefore, differentiation of these immune cells may play a role in the vitamin’s beneficial effect on immunity and resistance to infection.²⁰

The primary food sources for vitamin A are liver, dairy products, egg yolk, and fish (providing retinol or retinol esters) and yellow and green vegetables (providing β -carotene).¹⁵ In the average American diet, about 50% of the vitamin intake comes from animal-based products and 50% from vegetable sources. Absorption and

A

B

FIGURE 69-1 Fat-soluble (A) and water-soluble (B) vitamins reported to have toxic effects in humans.

utilization of the vitamin is complex and varies with the source. Most animal-derived vitamin A is consumed in the form of retinol esters, typically retinyl palmitate, and when vitamin A is ingested in usual dietary amounts, absorption is virtually complete. These esters are hydrolyzed in the intestinal lumen and brush border and then taken up by the intestinal cells bound to a cellular retinol-binding protein (CRBP). There they are re-esterified and incorporated into chylomicrons for transport to the liver, where they are stored. Hepatic vitamin A storage capacity is considerable (average content of retinyl esters is 100 to 300 $\mu\text{g/g}$), with reserves sufficient to withstand several months of a vitamin A-free diet before the plasma concentration decreases markedly or deficiency symptoms appear. The liver normally releases vitamin A after hydrolysis to retinol, 95% of which is bound to an α_1 -globulin, the retinol-binding protein (RBP). When the liver becomes saturated with vitamin A as a result of excessive ingestion or hepatic disease or both, retinyl esters may appear in the blood, eventually accounting for as much as 65% of the total circulating retinoids. Circulating retinol is carried to cells of various target organs, where it is taken up by a membrane-bound protein very similar to CRBP, re-esterified, then hydrolyzed and delivered to the appropriate intracellular sites by a cytosolic CRBP. The

fate of ingested carotenoids is slightly different.^{15,21} Only about one third of the carotene content of a meal is absorbed. Some β -carotene is cleaved in the intestinal mucosa and esterified and transported to the liver via the lymphatics, while some is absorbed intact. When carotenoids are present in large amounts in the diet, they may cause an elevated blood carotene level (normal range, 50 to 200 $\mu\text{g/dL}$), associated with a benign and reversible yellowish (or “golden suntan”) discoloration of the skin (but not the sclera, as occurs in jaundice). In most cases, excessive consumption of carotene does not lead to hypervitaminosis A, presumably because only limited conversion to retinol occurs. However, this occasionally occurs, as it did in a 20-year-old Japanese woman whose diet consisted mainly of pumpkin for 2 years. She subsequently developed vitamin A poisoning with hepatotoxicity, confirmed via liver needle biopsy.²² In addition to hepatic storage and tissue uptake, some retinol is glucuronidated. Other water-soluble metabolites are also excreted, with no retinol normally found unchanged in the urine.¹⁵

SPECIAL POPULATIONS

In adults, vitamin A deficiency is usually related to chronic illnesses associated with fat malabsorption such as inflammatory bowel disease, biliary or pancreatic

insufficiency, and cirrhosis. Children suffering from general malnutrition are especially susceptible, and it is believed that vitamin A deficiency is responsible for more than 250,000 cases per year worldwide of irreversible pediatric blindness, in addition to greatly enhanced mortality from infectious diseases, especially measles.^{15,18} Features characteristic of vitamin A deficiency include night blindness and keratomalacia progressing to permanent blindness, keratinization and drying of the skin with follicular hyperkeratosis, increased incidence of respiratory infections, urinary calculi due to associated changes in the urinary tract epithelium, diarrhea, and occasional impairment of hearing, taste, and smell.¹⁵

TOXICOLOGY

With excessive vitamin A intake, hepatic storage capacity is exceeded, and the previously noted normal pattern of almost all circulating vitamin A existing as retinol bound to RBP is altered, with an increasing proportion of plasma retinoids being present as retinyl esters loosely associated with lipoproteins. Clinical case reports of vitamin A toxicity typically involve normal or only slight elevation of retinol (normal range, 30 to 70 $\mu\text{g}/\text{dL}$), with markedly elevated retinyl esters (normal, $<7 \mu\text{g}/\text{dL}$, or 5% to 8% of plasma retinol).^{23,24} In more advanced cases of hypervitaminosis A, one may find an elevation of retinol to more than 100 $\mu\text{g}/\text{dL}$, and some authors suggest that excess circulating free retinol (e.g., a molar ratio of retinol to RBP of greater than 1) is important to clinical toxicity.²⁵ However, most reviews suggest that retinyl esters, which exhibit surfactant properties, are more likely responsible for toxic effects.²⁴ Retinyl esters—and perhaps free retinol—probably cause cellular toxicity via altered membrane lipoprotein phenomena. The precise mechanism of the increased intracranial pressure that is so characteristic of vitamin A toxicity is unclear, but it may relate to such altered membrane function in the choroid plexus.²⁶ As hepatic stores of vitamin A become saturated, another characteristic feature, hepatotoxicity, is observed when marked accumulation of retinyl esters and lipid develops in the perisinusoidal fat storage cells (Ito cells in the space of Disse). This process may stimulate transformation of these cells to fibroblasts²⁴; clinically, progression is observed to sinusoidal fibrosis, portal fibrosis, central vein sclerosis, and eventually cirrhosis.

Toxicity may occur as the result of either acute or chronic overdose.²⁴ In children, single doses of 75,000 to 100,000 IU are necessary to produce toxicity, whereas in adults the range is usually in excess of 1 million IU. Chronic exposures of 18,000 to 60,000 IU/day in infants and children, and 50,000 to 100,000 IU/day in adults will result in toxicity. One adult patient has been reported with hepatotoxicity resulting from habitual daily ingestion of 20,000 IU.²⁷ Clinical manifestations of chronic toxicity may vary in terms of total dosage and duration of exposure; most case reports observe periods of excessive intake of months to years, although infants treated with 18,000 IU/day became symptomatic within 6 weeks.²⁸ Persons with underlying liver disease, or who

develop acute hepatitis, are at increased risk. For acute intoxication, most reported cases are due to the ingestion of liver with high vitamin A content (e.g., bear, seal, or fish livers), with iatrogenic cases representing another sizable group. With chronic exposures, the most common cause is excessive intake via self-medication or food faddism in adults, or overzealous vitamin treatment of children by their parents.^{15,24,28,29}

CLINICAL MANIFESTATIONS

Classically, vitamin A intoxication is stratified by age of patient and chronicity of exposure, although there is considerable overlap of symptomatology. The target body areas most typically affected are the central nervous system (CNS), liver, bone, and skin and mucous membranes.

Accounts of acute vitamin A toxicity are relatively uncommon, but typical early features are primarily neurologic. These include irritability, tiredness with intense sleep desire progressing to somnolence, increased intracranial pressure that may manifest as a bulging fontanelle in infants or signs of acute pseudotumor cerebri in older children and adults, anorexia, and vomiting.²⁴ Within a few days, cheilitis, hair loss and skin peeling, hepatomegaly, and epistaxis or miscellaneous hemorrhages may ensue. Laboratory abnormalities may include increased serum retinyl esters (and retinol in severe cases), hypercalcemia, and slight changes in liver function tests. An illustrative case report was provided by Misbah and colleagues.¹⁷ A 25-year-old Sri Lankan woman ingested a meal of cooked shark liver and presented after several days of headache, vomiting, and diplopia. The examination was notable for bilateral flord papilledema, enlarged blind spots, and bilateral partial abducens palsies. Routine serum chemistry, liver function, and hematology values were normal, but total serum vitamin A level (retinol versus retinyl esters not specified) was elevated at 177 $\mu\text{g}/\text{dL}$. She recovered over an 8-week period, becoming asymptomatic with only residual but receding papilledema.

Far more common is the occurrence of chronic vitamin A toxicity, which tends to involve all four of the major target organ systems. The CNS and ophthalmologic effects include headache, fatigue but difficulty sleeping, visual disturbances, anorexia and weight loss, and signs of increased intracranial pressure with bulging fontanelles in infancy and pseudotumor cerebri in older children and adults. Changes of the integument and mucous membranes, including dry, pruritic, scaly, and peeling skin; hair loss; and brittle nails; and cheilitis, stomatitis, and gingivitis are regular and often early signs. Involvement of the liver is manifested as hepatosplenomegaly, nausea, abdominal pain, ascites, esophageal varices, and cirrhosis. Liver function tests may be abnormal, but patients with severe hepatic involvement and ascites and without jaundice have been reported, as have patients with minimally altered or normal liver function tests, although prothrombin time may be increased owing to hypoprothrombinemia.^{23,25,28,29} A vicious cycle may be conceptualized wherein early vitamin A hepatotoxicity results in decreased liver

storage capacity or RBP synthesis or both; continued chronic excessive ingestion results in escalating release of retinyl esters, and in some cases unbound retinol, with resultant systemic toxicity. The skeletal system is also frequently affected, particularly in children with growing long bones. Bone pain and tenderness is often noted, and children may manifest painful swelling of overlying soft tissues.²⁹ Radiographic findings may include areas of osteoporosis or hypermineralization, periosteal calcifications and cortical hyperostosis of the cranium, clavicles, long bones, and metatarsals, as well as cup-shaped deformity of the metaphyses.^{30,31} Permanent deformity and growth retardation may occur in children owing to partial or complete premature epiphyseal closure. Associated laboratory abnormalities of hypercalcemia and increased alkaline phosphatase are noted on occasion; these may represent effects of stimulation of osteoclastic resorption or inhibition of osteoblastic activity or both.³¹

Another area of concern related to vitamin A and its derivatives involves potential *teratogenic* effects. Isotretinoin, 13-*cis*-retinoic acid, has been used widely in the United States and Europe as a systemic agent for the treatment of nodulocystic acne vulgaris. A specific embryopathy has been well characterized for this agent, with a calculated relative risk of 26.5%.³² Typical malformations include those related to four main structural areas: the brain, head and face, heart and great vessels, and thymus. These include hydrocephalus with or without areas of cerebral agenesis or hypoplasia; micrognathia, cleft palate, microtia with or without anotia; transposition of the great vessels, Fallot's tetralogy, or truncus arteriosus; and thymic hypoplasia or aplasia. Further studies have found that the crucial exposure period occurs during the first trimester (especially the second to fifth postconceptional weeks), and that the prevalence of malformations averages 85% for involvement of the brain, 70% for the ears, and 50% for the cardiovascular system.³³ Although used with caution in pregnant women, topical tretinoin has not been shown to achieve sufficient serum levels to cause teratogenic effects in humans to date.³³ Acitretin is an oral retinoid used for the treatment of severe or refractory psoriasis. This drug is contraindicated not only in pregnant women but also in women who are planning to become pregnant sooner than 2 years following discontinuation of the drug. Those women who used an older oral retinoid for psoriasis, etretinate, are advised by some physicians to avoid pregnancy indefinitely, as it may take 2 years, or longer, for the drug to be eliminated. Congenital malformations noted after high-dose maternal vitamin A therapy have also been reported; these tend to primarily involve facial and otic defects, with less frequent neurologic and cardiac involvement.^{24,34} An attempt to calculate relative risks for vitamin A prenatal exposure has been reported from data collected on more than 20,000 pregnant women in the United States as part of a large prospective cohort study of congenital malformations.³⁵ These researchers compared outcomes in women taking supplements of more than 10,000 IU/day with those taking less than

5,000 IU/day and found a relative risk for cranial–neural crest defects of 4.8 (95% CI 2.2 to 10.5). They concluded that doses of supplemental vitamin A in excess of 10,000 IU/day pose a significant risk of teratogenicity.

DIAGNOSIS

Recognizing the characteristic clinical syndromes of acute or chronic hypervitaminosis A, along with finding a history of exposure, are the most important steps in diagnosis. As noted above, routine serum chemistries and liver function tests may be normal or only minimally elevated. Some patients manifest hypercalcemia or hypoprothrombinemia. Characteristic radiographic findings have been described and may be present in patients with chronic toxicity. Patients may be symptomatic at a time when serum vitamin A levels are normal. However, a retinol serum level exceeding 100 µg/dL is highly suggestive of toxicity, as is an elevated proportion of retinyl esters (more than 5% to 8% of total, or over 7 µg/dL), if specific tests are available. Characteristic liver pathology and an elevated liver vitamin A content may be found on biopsy in occult cases.

MANAGEMENT

The most crucial specific intervention is immediate discontinuation of vitamin A; this measure alone suffices in most cases. Most symptoms resolve over several weeks to months. Routine principles of gastrointestinal decontamination are probably appropriate in the uncommon situation of a patient seen soon after an acute overdose exceeding 75,000 to 100,000 IU in children or 1 million IU in adults. Patients with severe hepatotoxicity obviously require significant supportive care. Vitamin K may be of value for patients with hypoprothrombinemia. Associated increased intracranial pressure may occasionally require intervention depending on duration and severity. Neurologic consultation is probably advised prior to instituting a regimen that might include repeated lumbar punctures; diuretics (e.g., furosemide, initial IV dose 0.5 to 1 mg/kg up to 40 mg); mannitol (initial IV dose 0.25 g/kg); acetazolamide (5 mg/kg, up to 250 mg PO or IV every 6 hr); and/or steroids (e.g., prednisone 0.5 to 1.0 mg/kg up to 40 mg PO per day) as necessary. Hypercalcemia may also require specific treatment, although initial management with intravenous normal saline to enhance hydration usually suffices.³¹ If hypercalcemia is severe or persistent, additional treatment may be warranted. Adjuvant therapy has included diuretics such as furosemide to enhance renal calcium excretion. Corticosteroids (e.g., prednisone in doses of 0.5 mg/kg/day, up to 20 mg/day) may also lower serum calcium by increasing renal excretion as well as decreasing intestinal calcium absorption and bone resorption.³⁶

Vitamin D

INTRODUCTION

Vitamin D is another fat-soluble vitamin that produces a classic toxic syndrome following excessive ingestion. Vitamin D shares with vitamin A the properties of a

hormone. However, in some respects it is not truly a vitamin because, for most persons living in tropical or temperate geographic zones, cutaneous photobiosynthesis of the nutrient is sufficient to supply optimal nutritional needs.^{37,38}

PHARMACOLOGY

Vitamin D congeners are secosterol (split sterol) derivatives of the cholesterol precursor 7-dehydrocholesterol.³⁷ Vitamin D₃ (cholecalciferol) is formed when this precursor absorbs ultraviolet light in the skin and splits the C9–C10 bond in the B ring of the sterol skeleton. Preformed vitamin D congeners with biologic equivalency to endogenous skin-derived vitamin D₃ may be absorbed from the diet, especially fish liver oils. Vitamin D₃ from all sources enters the circulation bound to a specific α_1 -globulin, the vitamin D-binding protein, and is transported to the liver where it undergoes hydroxylation to 25-hydroxyvitamin D₃ [25(OH)D₃]. The production of 25(OH)D₃ is influenced by feedback inhibition but is not tightly controlled, and levels of this congener rise dramatically in states of excess vitamin D exposure (normal range, 5 to 80 ng/mL). At physiologic levels, 25(OH)D₃ is not thought to exhibit significant biologic activity, but it appears to be active at very elevated concentrations and may be responsible for much of the toxicity associated with hypervitaminosis D. The 25(OH)D₃ is transported to the kidneys bound to the vitamin D-binding protein, where under the influence of parathyroid hormone, it is further hydroxylated to 1,25(OH)₂D₃, also known as *calcitriol*.

The synthesis of calcitriol is closely regulated by fluctuations in serum calcium. Hypocalcemia stimulates parathyroid hormone secretion and thus the synthesis of calcitriol, which is believed to be the significant biologically active congener at physiologic levels. Calcitriol is carried to target organs—particularly the intestine and bone—by the vitamin D-binding protein. (Normal serum concentration of total calcitriol ranges from 16 to 65 pg/mL.) Free calcitriol is taken up by cells and exhibits its hormone-like effect by complexing with a specific nuclear receptor, a member of the same receptor superfamily that includes receptors for retinol, steroids, and thyroid hormone. The calcitriol-receptor complex activates transcription of genes for the synthesis of an intestinal calcium-binding protein and bone osteocalcin, which increase intestinal calcium absorption and bone resorption, respectively, and result in increased serum calcium. Thus, vitamin D plays a central role in calcium homeostasis. Receptors for calcitriol have been identified in several other tissues, but their function is less well understood.

Daily requirements for vitamin D range from 200 to 400 IU (5 to 10 μ g) per day.² In latitudes where and during seasons when sunlight intensity is limited, this MDR must be met by dietary intake, which was difficult to achieve in the era before widespread fortification of milk and bread products. The classic nutritional vitamin D deficiency state manifests as rickets in infants and growing children and as osteomalacia in adults. Several disorders in synthesis or response to calcitriol may

require treatment with supraphysiologic doses of vitamin D analogs (e.g., vitamin D-resistant and vitamin D-dependent rickets and renal osteodystrophy). Today, most persons in the United States receive adequate vitamin D through their diet, unless they suffer from a primary intestinal malabsorption syndrome or from hepatic or biliary dysfunction. Rickets and osteomalacia have also been observed in patients on chronic anticonvulsant therapy with phenobarbital or phenytoin, although the mechanism is not well understood.

TOXICOLOGY

Hypervitaminosis D has been recognized for decades,²⁶ principally in persons treated with pharmacologic doses for diseases unrelated to vitamin D deficiency but thought likely to benefit from such treatment, such as rheumatoid arthritis. Occasional acute vitamin D exposures may occur from ingestion of vitamin D-containing rodenticides or massive ingestions of multivitamins. Chronic vitamin D consumption in excess of even four times the RDI may be hazardous to young infants; adults may experience toxicity at doses of 60,000 IU/day for weeks to months. Large numbers of infants were oversupplemented in England during World War II, typically with daily intakes of 2000 to 4000 IU/day. A number of such children developed hypercalcemia, a nonfamilial congenital syndrome related to maternal hypervitaminosis D, and abnormal fetal or infantile vitamin D sensitivity was also described with cerebral, cardiovascular, and renal anomalies, particularly supra-valvular aortic stenosis.³⁹ Vieth and colleagues reported cases of vitamin D poisoning within a family following the mixing of crystalline vitamin D₃ into their table sugar.⁴⁰ The toxicity of excess vitamin D is thought to be due primarily to its exaggerated physiologic effects, resulting in hypercalcemia, hypercalciuria, and metastatic soft tissue calcification.

CLINICAL MANIFESTATIONS

Classically described clinical effects include initial symptoms of systemic hypercalcemia, including weakness, headache, fatigue, nausea, and vomiting. Subsequently, manifestations of soft tissue calcification may occur, including hypertension, polyuria, and polydipsia related to nephrocalcinosis, which may progress to uremia, as well as signs referable to calcifications in myocardium, vessels, muscle, lung, and skin; death may result. An outbreak of hypervitaminosis D due to overfortification of milk (up to 200,000 IU per quart) by a dairy in Massachusetts in 1988 to 1991 has allowed for case-control studies that have reinforced the association of these effects with excess vitamin D exposure.^{41,42}

DIAGNOSIS AND TREATMENT

The clinical findings and exposure history may be characteristic. Observed laboratory abnormalities include hypercalcemia with variable phosphate levels, decreased renal function with albuminuria and anemia,

and elevated levels of 25(OH)D₃ and free calcitriol. (Total calcitriol is usually normal or only slightly elevated.⁴³) Radiographic findings may include ectopic calcifications in kidneys, heart, and vessels as well as skeletal changes of periosteal thickening.

Prompt withdrawal of vitamin D supplements and implementation of a diet low in calcium and vitamin D are sufficient therapy for mild to moderate cases. In the acute overdose situation, as of a vitamin D–based rodenticide, appropriate gastrointestinal decontamination is warranted. Patients with persistent hypercalcemia may benefit from further measures as detailed above for vitamin A toxicity. Renal failure may require dialysis for a period of time. The induction of hepatic enzymes with glutethimide to facilitate degradative metabolism of vitamin D has been reported successful in one case.⁴⁴ Other case series have suggested a benefit in treating hypercalcemia and hypercalciuria with the biphosphonates, clodronate,⁴⁵ and pamidronate.^{46,47}

Vitamin E

INTRODUCTION

Although vitamin E was isolated in 1936, its role in human nutrition is still controversial, and there is currently little unequivocal evidence that a specific deficiency state exists for it in otherwise normal full-term infants, in children, or in adults.¹⁵ In premature babies, persons with severe fat malabsorption, and those with the rare genetic disease abetalipoproteinemia, vitamin E seems to protect against hemolytic anemia, although other nutrients may play a role. In animals, particularly rodents, vitamin E appears vital for normal reproduction and neuromuscular function. α -Tocopherol (see Fig. 69-1) is believed to be the most important vitamin and displays the most biologic activity in most bioassays. The vitamin has come under intense scrutiny in recent years because of its known antioxidant properties and the publicity surrounding studies evaluating its possibly protective effect from atherosclerosis and carcinogenesis.^{10,11}

TOXICOLOGY

Case series of persons taking large doses of vitamin E (400 IU to more than 3000 IU) have reported a variety of symptoms, including fatigue, headache, muscle weakness, nausea, intestinal cramps, and diarrhea.⁴⁸ In addition, vitamin E may antagonize vitamin K, with resulting increased clotting time and effect of oral anticoagulants.^{48,49} However, most large controlled studies (typical dose, 400 to 800 IU) have failed to find significant differences in the incidence of adverse effects between treated cases and controls.^{11,50} Of historical interest was the tragic epidemic of morbidity (pulmonary deterioration, hepatic and renal failure, and thrombocytopenia) and 38 deaths in premature infants treated in the winter of 1983–1984 with an intravenous preparation of vitamin E (E-Ferol). This syndrome was subsequently determined to be due to the carrier, a mixture of polysorbate 80 and polysorbate 20 (oleate and laurate esters of sorbitol condensed with ethylene oxide).⁵¹

Vitamin K

PHARMACOLOGY

Vitamin K activity is found in two natural sources: a plant-derived form (phytonadione, vitamin K₁) and the form synthesized by intestinal bacteria (menaquinone, vitamin K₂).¹⁵ Both are utilized as essential cofactors in the hepatic biosynthesis of blood coagulation factors II, VII, IX, and X. Other vitamin K–dependent proteins include the anticoagulant proteins C and S, as well as bone osteocalcin. Deficiency of vitamin K results in a hemorrhagic diathesis. A coumarin embryopathy has been described for skeletal abnormalities that may represent the effects of fetal vitamin K deficiency on osteocalcin synthesis.

TOXICOLOGY

Chronic ingestion of excess vitamin K is unusual because it is not available in the typical multivitamin supplements subject to abuse.²⁶ Large amounts may inhibit the desired effects of anticoagulant medications.⁴⁸ Water-soluble congeners (menadiones) given to newborns for hemorrhagic disease prophylaxis, particularly if there is glucose-6-phosphate dehydrogenase (G6PD) deficiency, may cause hemolysis and jaundice; phytonadione is rarely associated with this effect.^{26,48,46} Intravenous administration of phytonadione may result in an anaphylactoid reaction of flushing, chest pain, hypotension, and death; it is unclear whether this is due to the vitamin itself or the vehicle. Concern has been raised about a potential association between the routine use of prophylactic vitamin K in healthy newborns and increased risk of subsequent childhood cancer; however, careful controlled studies have failed to substantiate this association, and authorities continue to recommend this use of vitamin K.⁵²

WATER-SOLUBLE VITAMINS

Significant toxicity is well established for chronic excessive consumption of pyridoxine and niacin (see Table 69-2). Adverse effects have also been ascribed to thiamine and ascorbate and are briefly reviewed.

Pyridoxine

INTRODUCTION

The pyridoxamine congeners are utilized by mammals after hepatic conversion to the active form, pyridoxal phosphate, which in turn is an important coenzyme in numerous metabolic reactions of amino acids.⁵³ Pyridoxine is supplied by meats, whole grains, soybeans, and various vegetables. A deficiency state has been observed with mucocutaneous manifestations (seborrhea-like lesions and stomatitis) and seizures due to diminished γ -aminobutyrate (GABA) production. This role of pyridoxine as a cofactor in GABA synthesis underlies its use as an antidote in the treatment of isoniazid overdose and hydrazine-mushroom poisoning (see Chapter 23), as well as its previously noted use in pyridoxine dependency, an inherited disorder of pyridoxine metabolism resulting in

neonatal seizures. Pyridoxine has found similar use in the treatment of xanthurenic aciduria and homocystinuria.

TOXICOLOGY

Pyridoxine toxicity is most likely to occur with chronic ingestion in excess of 500 mg/day, often taken for self-treatment of premenstrual syndrome or as a body-building adjunct. Toxic effects have been reported with consumption of average total doses as low as 117 mg/day for 3 years.⁵⁴ The toxic syndrome manifests as a striking sensory axonal neuropathy, typically without weakness or CNS involvement.⁵⁵ Patients have an unsteady gait and difficulty in handling small objects. Neurologic findings include ataxia, severely impaired position and vibration sense, and less dramatic effects on light touch, pain sensation, and temperature. Diminished deep tendon reflexes and Lhermitte's sign (neck pain and tingling that shoots down the spine to the legs and feet after neck flexion) are also present. Dose response characteristics were studied in five healthy volunteers administered 1 or 3 g/day and closely followed for clinical symptoms and sural nerve electrophysiology.⁵⁶ Subjects receiving higher doses became symptomatic earlier, and symptoms persisted for 2 to 3 weeks after discontinuation of pyridoxine, a phenomenon termed *coasting* by the authors. An infant exposed to pyridoxine in utero (maternal dose 50 mg/day) was born with amelia of one leg.⁵⁷ At least one patient has been reported who developed motor weakness after 5 years of 10 g/day consumption.⁵⁸ An unusual episode of acute toxicity occurred in two patients who received an iatrogenic parenteral, massive (exceeding 100 g) pyridoxine overdose during treatment of *Gyromitra* mushroom poisoning.⁵⁹ These patients manifested weakness, lethargy, nystagmus, and respiratory depression in addition to severe sensory neuropathy. At follow-up 4 years after exposure, one of these patients had persistent profound sensory loss, although the motor abnormalities had disappeared.⁶⁰ Chronic pyridoxine intake at doses as low as 25 mg/day have been reported to antagonize the antiparkinsonian effect of L-dopa, and similar antagonisms have been observed for barbiturates and phenytoin.⁴⁸ The treatment of pyridoxine toxicity consists of its withdrawal, which usually results in gradual recovery,⁵⁴ although some patients may have long-term or permanent sequelae.

Niacin

INTRODUCTION AND RELEVANT HISTORY

Niacin has been long recognized as the antipellagra factor missing in diets based largely on corn.⁵³ The vitamin exists as nicotinic acid (niacin) and nicotinamide (niacinamide) (see Fig. 69-1), with equivalent biologic vitamin activity but different pharmacologic effects. In both forms, niacin is converted to either nicotinamide adenine dinucleotide (NAD) or its phosphate (NADP), which are vital coenzymes for a variety of enzymes involved in oxidation-reduction reactions necessary for tissue aerobic metabolism. Tryptophan may also be utilized in the biosynthesis of NAD, and diets rich in tryptophan

will offset low niacin intake in preventing deficiency. Pellagra is rare in the United States today, where dietary intake of animal protein tends to be high, but is classically manifested by cutaneous, gastrointestinal, and neurologic abnormalities. This clinical syndrome is often recalled with a mnemonic, the “three Ds”: dermatitis, diarrhea, and dementia.⁵³ Typical clinical findings include desquamating skin rash; sialorrhea, stomatitis, and diarrhea; and headache, depression, memory loss, hallucinations and dementia, and motor and sensory changes.

Niacin toxicity has been primarily associated with the chronic therapeutic use of large doses of nicotinic acid as a lipid-lowering agent, although an epidemic has been reported in 17 persons after an acute “overdose” of pumpernickel bagels.^{48,61-65} A 56-year-old man, attempting to treat his schizophrenia with high doses of niacin (19,500 mg), developed severe, persistent hypotension requiring intensive care management and dopamine.⁶⁶ Clinical effects predominate in the skin and gastrointestinal tract. Cutaneous manifestations of flushing and pruritus are common and classically have been attributed to histamine release⁴⁸ although more recent work suggests that prostaglandin E₂ is responsible and that pretreatment with prostaglandin inhibitors such as aspirin ameliorate this effect.⁶³ Hyperkeratosis and acanthosis nigricans have also been described in chronic users. Gastrointestinal effects include those that are likely mediated by prostaglandin, such as exacerbation of peptic ulcer disease, and hepatotoxicity, which may range from mild cholestatic jaundice to severe hepatitis with fulminant hepatic failure.⁶³⁻⁶⁵ Hepatitis is typically associated with dosages ranging from 3 to 4.5 g/day for 1 to 18 months, although a patient has been reported to have developed hepatic dysfunction after 10 years of treatment without apparent prior side effects.⁶⁴ Recent studies suggest that time-release forms of niacin are more hepatotoxic.^{63,64} Occasional additional findings include thrombocytopenia,⁶⁴ increased serum uric acid and gouty arthritis, glucose intolerance,⁶¹ skeletal muscle myopathy,⁶² and increased incidence of atrial fibrillation and other arrhythmias.^{26,61} In most cases, all these effects have regressed with discontinuation of the niacin.

Thiamine

INTRODUCTION AND RELEVANT HISTORY

Thiamine was the first identified of the B-complex vitamins. Its history is traced back to the 19th-century Japanese navy; it was shown that adding fish, meat, and vegetables to the sailors' poor diet of polished rice reduced the incidence of beriberi.⁵³ Today thiamine deficiency is still common in Western societies among chronic alcoholics and is observed in patients with other malnourished states including AIDS, cancer, hyperemesis gravidarum, and eating disorders. It is also endemic among breast-fed infants in developing countries where rice consumption is high. Thiamine deficiency is classically associated with neurologic and cardiovascular abnormalities and includes the neurologic syndromes of alcoholic neuritis, Wernicke's encephalopa-

thy, and Korsakoff's psychosis^{53,67,68} and the cardiovascular effects of peripheral vasodilation, biventricular heart failure, and peripheral edema. Thiamine pyrophosphate, the biologically active form of the vitamin, is a vital coenzyme in numerous metabolic pathways involving carbohydrate metabolism. It has been observed that rapid infusion of hypertonic glucose solutions to treat endogenous hypoglycemia may precipitate both neurologic and cardiac deterioration in thiamine-deficient patients, and concomitant thiamine administration is recommended.⁶⁸

TOXICOLOGY

Oral absorption of thiamine is relatively limited, and large doses (e.g., 100 mg, or almost 100 times the RDI) are usually administered intravenously for the emergency treatment of suspected thiamine deficiency. In this context, a few severe anaphylactic reactions have been described,⁶⁹ while in a series of more than 1000 IV thiamine treatments given to 989 consecutive patients over a 6-month period only one patient with generalized pruritus was considered to have a possible precursor of anaphylaxis (less than 0.1%) and 11 patients with localized burning at the infusion site.⁷⁰ Of note, any patient with a history of thiamine reaction (number not stated) was excluded. The incidence of local reactions may be decreased if thiamine is administered slowly via relatively larger veins.^{67,70} While thiamine is no longer used commonly in chronic therapeutic regimens, there are reports from the 1940s of headache, irritability, insomnia, tachycardia, and weakness said to resemble hyperthyroidism with doses as low as 5 mg/day for 4 to 5 weeks.^{61,70}

Vitamin C (Ascorbic Acid)

INTRODUCTION AND RELEVANT HISTORY

Scurvy, the vitamin C deficiency state, has been recognized as a disease since the Middle Ages, and its relation to diets lacking fresh fruit and vegetables has been understood since the 16th to 18th centuries.⁵³ The human (along with other primates, guinea pigs, and Indian fruit bats) is one of the few mammals unable to synthesize vitamin C from glucose. This vitamin functions as an important cofactor for numerous hydroxylation and amidation reactions and has antioxidant properties. It is vital to normal synthesis of collagen, proteoglycans, and other components of the intercellular matrix, and therefore the structural integrity of tooth, bone, and capillary endothelium.⁵³ Scurvy is rarely encountered today, but occasional cases are still reported in malnourished persons, especially shut-ins and those espousing exaggerated food faddism.⁷¹ One of the authors recalls from his medical school days a patient who developed scurvy by eating only at a fast-food restaurant. He felt this food would be free from contaminants, since it had been sold to millions of customers. Cutaneous findings include perifollicular hemorrhages, hyperkeratotic papules, petechiae, ecchymoses, and poor wound healing.^{53,71} Additional effects

include bone pain with subperiosteal hemorrhage, gingivitis and loosening of the teeth, and anemia.

TOXICOLOGY

The antioxidant (or free radical scavenger) effects of vitamin C effects have prompted widespread and largely unsupervised experimentation with megadose treatment (e.g., in excess of 1 g/day).^{48,50,61} Numerous adverse effects have been ascribed to such usage, although with little controlled study.⁷² These effects may include diarrhea and urinary calculi from oxalates or cysteine.⁷³ Rebound scurvy has been seen in persons abruptly discontinuing long-term high-dose therapy and also occurs in infants of mothers taking such doses.^{48,53} Concern has been raised about increased blood estradiol levels noted in women taking oral contraceptive pills and high-dose vitamin C, as well as about this vitamin's potential to increase iron absorption in patients with iron overload states such as hemolytic anemia and hemochromatosis.^{48,72} In contrast, most recent reviews have found that dosages of up to 4 g/day are actually unlikely to result in significant toxicity in otherwise healthy persons.^{49,50,74} In particular, a prospective cohort study on over 45,000 men aged 40 to 75 years compared those taking 1500 mg/day or more with those taking less than 250 mg/day, and found no increased incidence of kidney stones in the high-dose patients.⁷⁵ Withdrawal of vitamin C (with surveillance for rebound scorbic effects) and supportive care should suffice for treatment of presumed toxicity. It is probably prudent to caution against the use of high-dose vitamin C therapy for patients with known nephrolithiasis, G6PD deficiency, iron overload conditions, pregnancy, and perhaps for women taking oral contraceptives.

70 Performance Enhancers (Steroids, Creatine, DHEA)

DUNG THAI, MD, PHD ■ CHRISTINE A. HALLER, MD

At a Glance...

- Use of anabolic steroids, steroid precursors, and other performance enhancers violates antidoping policies of the IOC and most collegiate and professional athletic associations; creatine supplementation is permitted.
- Anabolic steroids are structural relatives of testosterone and have virilizing effects in females, cause gynecomastia and testicular atrophy in males, and produce short stature in children.
- Organ system effects of anabolic steroids include hepatotoxicity, left ventricular (LV) hypertrophy, unfavorable blood lipid profiles, polycythemia, infertility, and aggression.
- Steroid precursors such as androstenedione and DHEA are sold as dietary supplements because they are produced “naturally” in the body.
- Steroid precursors do not increase strength or lean muscle mass in healthy users.
- Short-term creatine supplementation is generally well tolerated but may produce muscle cramping and diarrhea; cases of compartment syndrome, rhabdomyolysis, and renal failure have been described.

Use of performance-enhancing drugs and supplements among amateur and professional athletes is widespread. Because the majority of drugs with performance-enhancing effects are banned by the International Olympic Committee (IOC) and other sports organizations, athletes may use oral sports supplements containing steroid precursors, amino acids, creatine, and herbal stimulants to gain a competitive edge and circumvent antidoping policies. Many of these commonly used substances have little or no proven benefits for improving athletic performance, and safety data are lacking. In addition, because these supplements are inadequately regulated, athletes may unknowingly ingest and test positive for a banned substance because of adulteration or improper labeling of the supplement. Some commonly used and potentially harmful performance enhancers including anabolic steroids, steroid precursors, and creatine are the focus of this chapter (Table 70-1). Sympathomimetics, erythropoietin, human growth hormone, and amino acid or protein supplements also are used by athletes but are not discussed here.

ANABOLIC STEROIDS

Anabolic steroids (ASs) are a class of synthetic molecules that are structurally related to testosterone and exert anabolic (i.e., muscle building) properties. ASs are most commonly prescribed by clinicians to treat disease-related wasting and disorders of testosterone deficiency.

They are abused by athletes seeking greater physical strength, ability, or appearance. Unfortunately, these steroids are not purely anabolic and, in fact, possess androgenic properties as well. Their androgenic qualities influence a number of different organ systems including the reproductive, cardiovascular, hematologic, central nervous, and hepatobiliary systems. The effects are most pronounced in athletes who tend to take suprapharmacologic doses.

Testosterone was first isolated, synthesized, and characterized in Europe in 1935.¹ Modern use as athletic performance enhancers began with Russian power-lifters in the early 1950s and peaked in the 1970s with the athletic programs in Germany. ASs have been banned by the IOC since 1964, yet their use is still widespread. In 1990, the Anabolic Steroids Control Act was enacted, putting ASs on Schedule III of the Controlled Substance Act and making them illegal without a prescription.² Despite these restrictions, use among athletes and teenagers continues. The Monitoring the Future (MTF) study, which has tracked anabolic steroid use among 8th, 10th, and 12th graders in the United States since 1989, reported that use of these substances was between 2.2% and 2.8% in 2000.³ The majority of users were males. A 2001 National Collegiate Athletic Association (NCAA) study of substance use among college student-athletes revealed that anabolic steroid abuse had increased since 1997 and that the main reason for use was to improve athletic performance or appearance.⁴

Structure

All ASs currently available are structural analogs of testosterone. The core structure contains four fused rings with potential for modification in the A, B, or C rings as well as at carbon 17 (Fig. 70-1). Each structural modification imparts unique properties to the steroid derivative such as enhanced oral bioavailability, improved pharmacokinetics, or altered anabolic-to-androgenic activity. When testosterone is administered orally or by parenteral injection, the native molecule is rapidly degraded by the liver and does not achieve significant levels in the systemic circulation. For this reason, a number of formulations and structural derivatives have been prepared.

Testosterone is delivered as an injectable, transdermal patch, dermal gel, or micronized oral preparation. Wilson has presented an excellent review of the various formulations and structural properties,^{5,6} which are described below.

1. Esterification of the 17- β hydroxyl group increases the lipophilicity of the steroid molecule and slows its release into the circulation. The ester must

TABLE 70-1 Summary of Potential Adverse Effects of Common Performance Enhancers

ORGAN SYSTEM AND SPECIFIC HEALTH CONCERNS	ANABOLIC STEROIDS	STEROID HORMONE PRECURSORS	CREATINE
Cardiovascular	Hypertension, LVH, CHF, decreased HDL cholesterol	Decreased HDL	None known
Gastrointestinal/liver	Increased LFT, cholestatic jaundice, peliosis hepatis	None known	Diarrhea, gastromitestinal, pain, concern for suppression of hepatic creatine synthesis
Musculoskeletal	Increased muscle strength and mass	No different from placebo	Osmotic cell swelling, muscle cramping, rhabdomyolysis
Neurologic/psychiatric	Mood lability, euphoria, increased libido, withdrawal symptoms	None known	None known; rare reports of seizures
Reproductive/pregnancy/lactation	Amenorrhea, testicular atrophy, decreased or morphologically abnormal sperm, feminization in men, masculinization in women	Transient rise in testosterone or estradiol	Effects on testicular creatine production unknown
Hematologic	Polycythemia	None known	None known
Renal	None known	None known	Elevated serum and urinary creatinine; long-term effects on GFR unknown
Mutagenic/carcinogenic	Heptoma, hepatocellular carcinoma	None known	None known
Pediatric/adolescent	Precocious puberty, early closure of epiphyseal plates	None known	Theoretical concerns about effects on developing kidneys and immature musculature

CHF, congestive heart failure; GFR, glomerular filtration rate; HDL, high-density lipoprotein; LFT, liver function test; LVH, left ventricular hypertrophy.

**FIGURE 70-1** Core structure of anabolic steroids.

undergo hydrolysis before the steroid can act at its target receptor. Except for the undecenoate, these steroid esters are injectable.

- Alkylation of the 17- α position renders the steroid resistant to hepatic degradation. These derivatives are orally active.
- Alteration of the A, B, or C rings slows metabolism, increases or decreases affinity for the androgen receptor, or imparts resistance to aromatization.

The pharmacologic and toxicologic effects of the various steroid analogs can be predicted based on its chemical alteration. The 17- α alkylated androgens are more resistant to portal hepatic metabolism but are also more hepatotoxic. Fluoxymesterone, 19-nortestosterone, and 1-methyl-substituted steroids are not aromatized at the A ring to form estrogen-like compounds. Consequently, they lack the feminizing properties of testosterone. A final example is 7 α -methyl-19-nortestosterone, which is a poor substrate for 5 α -reductase and possesses minimal activity in prostate tissue.

Pharmacology

The biosynthesis of testosterone from cholesterol is a multistep process involving enzymes in both the adrenal glands and the testis or ovaries. Cholesterol undergoes side chain cleavage and A-ring oxidation to form pregnenolone, which has two potential pathways to testosterone (Fig. 70-2). The pathway shown in bold arrows represents the predominant pathway and includes dehydroepiandrosterone (DHEA) as an intermediate. Alternatively, progesterone can be converted to androstenedione via 17-hydroxyprogesterone. Androstenedione and testosterone are reversibly interconverted.

Testosterone can be metabolized to active and inactive metabolites by extraglandular tissue. It can be reduced at the 5- α position to dihydrotestosterone, which influences male sexual development and virilization. Testosterone is also a substrate for adipose tissue aromatase, which synthesizes estrogens. These estrogens are responsible for testosterone's feminizing properties. The major inactive urinary metabolites include etiocholanolone and androsterone, which exist as free steroids or water-soluble conjugates.

PHARMACOLOGIC AGENTS

A list of the most commonly abused ASs is shown in Box 70-1. They are all classified as class III agents by the DEA and are banned by the IOC.

Several different dosing regimens are utilized to enhance the anabolic effects, to minimize side effects,

FIGURE 70-2 Biosynthesis of androgens and estrogens.

and to avoid detection of steroids in urine and blood.⁸ “Stacking steroids” involves using two agents at once. This may include injectable forms taken with oral agents, or short-acting forms taken with long-acting agents. “Stacking the pyramid” is a regimen similar to “stacking steroids” except that doses of ASs are progressively escalated until halfway through the cycle at which point doses are then decreased to zero. Cycles last from 6 to 12 weeks. Another regimen termed *cycling* involves alternating between periods of use and nonuse. Periods vary between 6 and 14 weeks. It is not known whether continuous or intermittent regimens exert greater adverse effects on the body.

BOX 70-1

COMMONLY ABUSED ANABOLIC STEROIDS

Oral

Oxymetholone
Oxandrolone
Methandrostenolone
Stanozolol

Injectable

Nandrolone decanoate
Nandrolone phenpropionate
Testosterone cypionate
Boldenone undecylenate
Tetrahydrogestrinone

Toxicology

ANABOLIC EFFECTS

The anabolic properties of androgens in women and hypogonadal men are undisputed. East German sports programs reported impressive performances by their female athletes during the clandestine doping experiments of the 1970s and 1980s.¹ Testosterone replacement has also been shown to increase lean body mass in hypogonadal HIV patients.⁹

Despite these positive results in women and hypogonadal males, there was long-standing controversy regarding the anabolic potential of androgens in eugonadal males. Much of the debate arose because only slight and transient positive nitrogen balance was observed after modest doses of androgens were given. In addition, athletic performance did not improve when testosterone or other ASs were added to a training regimen. Critics argued that many of the studies were not standardized in terms of steroid dosing or training regimens, lacked proper controls, were unblinded, and relied on case studies or small study populations.¹⁰ When suprapharmacologic doses of steroids were used to assess upper-body weight-lifting tasks in highly trained athletes, a statistically significant increase in muscle mass and strength was seen relative to placebo.¹¹ Bhasin and

associates were able to demonstrate increases in fat-free mass and muscle size and strength in normal men on supraphysiologic doses of testosterone.¹²

VIRILIZING EFFECTS

All currently available ASs possess some androgenic properties. These virilizing properties are most apparent in women and children, whose testosterone levels increase several-fold from baseline. Elevations of up to 30-fold from normal have been reported in women self-administering testosterone and ASs.¹³ Masculinization is one of the first effects seen in female athletes given ASs.^{14,15} Deepening of the voice, clitoral hypertrophy, amenorrhea, hirsutism, and decreased body fat are reported in a majority of female athletes. In addition, approximately half these women experience acne, male pattern balding, and change in breast size. Deepening of the voice and clitoral hypertrophy are often irreversible after prolonged therapy. The other signs and symptoms may regress when the androgens are withdrawn.

Children taking ASs experience precocious puberty in the form of acne, early growth of pubic hair, penile enlargement, and frequent erections. ASs can also stunt the growth of children and adolescents. A 1956 study by Sobel and colleagues on the use of methyltestosterone as a growth stimulant in children noted profound discrepancy between height age and bone age.¹⁶ Keele and Worley conducted a double-blind, placebo-controlled study on the effects of oxymetholone on growth in children and found that 12 months of treatment caused a mean increase in height relative to placebo without significant differences in bone age.¹⁷ Thus, while short-term accelerated growth of bone is seen during early administration of ASs, long-term use leads to early closure of the epiphyseal plates and decreased stature compared with predicted height. Stunted growth is irreversible and is seen mainly with oxandrolone.

FEMINIZATION

Under physiologic conditions, a small percentage of naturally produced testosterone is metabolized to estradiol. The enzyme responsible for this reaction is aromatase and is found predominantly in adipose tissue. Male athletes administered parenteral testosterone esters in supraphysiologic doses have elevated plasma estradiol levels.¹⁸ Consequently, they can develop gynecomastia and increased fatty deposition. The occurrence of gynecomastia is unpredictable but is more commonly observed in children or in adult males taking high doses of androgen. Feminization in male athletes is a phenomenon observed with steroids susceptible to aromatization (i.e., C₁₉ steroids with a Δ^4 , 3-keto configuration). Poor substrates for aromatase such as 19-nortestosterone and fluoxymesterone do not cause these side effects. Treatment of gynecomastia includes antiestrogens such as tamoxifen and clomiphene.¹⁹

REPRODUCTIVE SYSTEM EFFECTS

High doses of ASs are known to interrupt the hypothalamic-pituitary-gonadal axis in healthy men and women. ASs suppress gonadotropin (leutinizing hormone

[LH] and follicle-stimulating hormone [FSH]) production, which normally acts on gonadal tissue to produce estrogen, progesterone, and testosterone. As mentioned above, women taking high-dose steroids frequently report irregular menses or amenorrhea. The hormonal perturbations resulting from ASs in healthy male athletes have been extensively studied.²⁰ Testicular atrophy, decreased sperm count, and increase in morphologically abnormal sperm paralleled reduction in serum FSH and LH.^{21,22} The resulting infertility often remains long after the androgens are stopped but is reversible. Treatment with recombinant human chorionic gonadotropin can expedite return of normal sperm count and morphology.²³

ERYTHROPOIESIS

Discrepancies in hemoglobin concentration between adult males and females appear to be related to differences in testosterone levels. Stimulation of erythropoiesis is a common effect of testosterone and other ASs. For this reason, ASs have had some therapeutic use in treating anemia. ASs in healthy athletes without anemia can cause profound polycythemia. Urhausen and coworkers²⁴ compared hemoglobin and hematocrit values in former and current male AS users and found significantly higher values in current users. Leukocyte and platelet counts were also increased. The average increase in hemoglobin concentration with pharmacologic doses of testosterone esters is 1 g/dL in men and 4.3 g/dL in women. Like many other effects of anabolic steroid use, erythropoiesis is reversible if the drug is discontinued.

HEPATOTOXICITY

ASs alkylated at the 17- α position are orally bioavailable and resist portal hepatic metabolism. These 17- α derivatives are also more hepatotoxic and are associated with elevated liver enzymes, peliosis hepatis, cholestatic jaundice, and hepatic neoplasms. Dickerman and colleagues observed that the incidence of hepatotoxicity may be overestimated if measured in terms of elevation in aspartate aminotransferase (AST) and alanine aminotransferase (ALT) in male resistance trainers.²⁵ Resistance training alone can cause elevations of AST and ALT, which are released from skeletal muscle. For this reason, the authors advocate measuring γ -glutamyl transferase (GGT) levels to assess specific hepatic damage along with creatine phosphokinase (CPK) levels to assess skeletal muscular damage. Despite these claims, Urhausen and coworkers have shown that plasma AST and ALT levels are higher in bodybuilders taking ASs than in bodybuilders not taking these drugs.²⁴ GGT and bilirubin in the two groups were not above the normal reference range. In fact, GGT was lower in current abusers. The authors also point out that AST/ALT ratios are less than 1, which is more consistent with a hepatic rather than a skeletal muscular source of AST and ALT. Transaminase concentrations normalized after cessation of steroid use.

Cholestatic Jaundice

Numerous reports of cholestatic jaundice suggest that its development is dependent on the dose and duration

of exposure to 17- α substituted steroids. This condition is more common when high doses are used or in the presence of preexisting liver disease.^{26,27} The doses and regimens of ASs used in the setting of sports enhancement likely pose potential risk of cholestatic liver disease. Jaundice, anorexia, malaise, and nausea develop in a minority of individuals. The liver is often cholestatic without frank inflammation. While some individuals have isolated elevations in AST, ALT, and bilirubin, rarely do they experience liver failure or necrosis as a result of 17- α steroid use. The cholestasis resolves when the drugs are discontinued.

Peliosis Hepatis

Peliosis hepatitis is a rare condition characterized by multiple small hemorrhagic cysts randomly distributed throughout the liver. Several cases associated with anabolic steroid use have been reported including one young athlete who was a long-term intermittent steroid user.²⁸ Fibrosis and portal hypertension as well as life-threatening hemorrhagic rupture of the cysts may occur. The cysts may recede when ASs are stopped.

Hepatic Adenomas and Carcinomas

Benign adenomas and malignant hepatocellular carcinoma have been reported in users of 17- α alkyl steroids.²⁹ Evidence for a strong cause-effect relationship comes from reports of hepatic adenoma regression upon discontinuation of the 17- α substituted steroid.³⁰ A more serious consequence of abuse of these androgens is hepatocellular carcinoma.³¹ Athletes who use higher doses of oral androgens for long periods of time are particularly susceptible. The average time interval between initiation of oral ASs and detection of hepatocellular carcinoma is approximately 6 years. These highly vascularized tumors also can rupture, causing serious bleeding. Interestingly, the hepatocellular carcinoma associated with 17- α alkylated steroid abuse tends not to metastasize and regresses after withdrawal of medication.³²

CARDIOVASCULAR EFFECTS

The cardiovascular effects of ASs are numerous and include alterations of serum lipid profiles, change in LV dimension, and increase in diastolic blood pressure. Studies examining serum cholesterol profiles in AS abusers have revealed a marked decline in high-density lipoprotein (HDL), which is not dose-dependent.³³ Serum low-density lipoprotein (LDL) and cholesterol effects were less consistent. While some studies have demonstrated statistically significant elevations of LDL levels, others have shown no LDL increases in AS users as compared with nonusers. Several case reports have described myocardial infarction and sudden cardiac death in young bodybuilders taking ASs.^{34,35}

ASs have been reported to increase blood pressure in athletes. Comparison of blood pressure in weight-lifting AS users and nonusers revealed that resting and exertional systolic and diastolic values were higher in AS users.³⁶ However, after adjusting for biceps size, the authors concluded that differences in blood pressure

may be an artifact of larger arm circumference in AS subjects. In a double-blind, crossover study of ASs in five body builders given nandrolone or placebo, diastolic blood pressures were higher during nandrolone treatment.³⁷ Values returned to baseline 6 weeks after cessation of AS use. Systolic blood pressures were not altered. Effects of ASs on blood pressure are thus not clear-cut.

Echocardiographic evaluations of LV size and function in elite body builders using ASs have yielded mixed results. Two studies showed increased LV wall and ventricular septal thickening associated with decreased ventricular compliance in weight lifters using versus not using ASs.^{38,39} Greater LV mass and septal thickness were demonstrated in the same users on-versus-off AS dosing cycles. De Piccoli and associates⁴⁰ assessed LV morphology and function in AS-abusing bodybuilders, non-AS-abusing body builders, and sedentary individuals and found that AS could induce LV enlargement and thickening, leading to decreased diastolic compliance. Echocardiographic findings in sedentary controls and nonusers were similar. In contrast, a study by Salke and colleagues⁴¹ concluded that weight lifting alone could cause myocardial hypertrophy and that AS does not potentiate this effect. In all of the above studies, there was no demonstrable impairment of LV function.

The risk of congestive heart failure may be increased in AS abusers because of the well-documented fluid-retaining properties of these androgens.⁴² Niemenen and associates⁴³ reported two cases of male steroid-abusing weight trainers who exhibited signs and symptoms of congestive heart failure. These patients had echocardiographic evidence of LV hypertrophy and diastolic dysfunction both of which reversed with cessation of AS use. In individuals with myocardial changes from weight training and AS use, the added effect of fluid retention may be the determinant in exacerbating congestive heart failure. Despite these reports, the occurrence of heart failure in a population of healthy young AS-abusing athletes is rare.

PSYCHOLOGICAL EFFECTS

Behavioral effects of ASs include direct psychoactive effects such as psychosis and aggression as well as withdrawal-related symptoms such as depression. Because androgens play an important role in the development of secondary sexual characteristics, it is no surprise that many abusers who take supraphysiologic doses report increased libido. Other effects include euphoria, increased energy, and greater confidence as well as aggression, irritability, and mood lability. A phenomenon known as "steroid rage" has been described and may be responsible for criminal acts carried out by AS abusers, who prior to taking these drugs, did not have criminal records.⁴⁴ Several examples of manic behavior are also reported. Pope and Katz⁴⁵ conducted a controlled study of 88 athletes using ASs and 68 control athletes and found that 23% of steroid users reported mania, hypomania, or depression versus 6% of controls. Another study comparing aggression and mood changes in AS-abusing and nonabusing male weight lifters found

that supraphysiologic testosterone concentrations were associated with aggressive tendencies.⁴⁶

Symptoms associated with withdrawal from steroids include depression, insomnia, anorexia, decreased libido, and fatigue. Kashkin and Kleber⁴⁷ compared the delayed depressive syndrome resulting from a fall in serum steroids to that observed in withdrawing cocaine-dependent individuals. Along with the above symptoms, the loss of physical prowess and muscular physique may have profound psychological effects on the steroid user. Dramatic changes in body image and performance often drive these athletes to resume use of ASs.

STERIOD PRECURSORS

Androstenedione and DHEA are two important steroid precursors that are widely used and readily available in health food stores and pharmacies and via the Internet. Under the 1994 Dietary Supplement and Health Education Act, these agents can be sold over-the-counter because they occur “naturally” in the body. However, use of these supplements is currently banned by the IOC and several other athletic associations. Despite these bans, androstenedione and DHEA sales are on the rise. Androstenedione became popular after major league baseball player Mark McGwire admitted to taking it during the 1998 baseball season when he broke the major league home run record. DHEA has been touted as a “fountain-of-youth” remedy and has also been embraced by athletes as a “natural” precursor to testosterone.

Structure and Pharmacology

Androstenedione and DHEA are androgen precursors, that is, intermediates in the synthesis pathway of testosterone from cholesterol (see Figure 70-2). Strictly speaking, they are *androgenic* steroids and have not been proven to be *anabolic* steroids, and therefore they remain available as over-the-counter supplements instead of Schedule III Controlled Substances.

Androstenedione is produced by the adrenal glands and gonads and can be converted to either estrone or testosterone. It is currently marketed as a “natural” alternative to ASs, with claims that it increases serum testosterone levels and enhances muscle growth when combined with resistance training. In healthy women, a 100-mg dose of androstenedione resulted in a six- to sevenfold increase in serum testosterone levels.⁴⁸ Variable results were reported in healthy males taking androstenedione 100 to 300 mg/day. Statistically significant increases in serum testosterone levels were achieved within the first week of treatment at 200 to 300 mg/day relative to placebo,⁴⁹ but levels returned to baseline at 12 weeks of treatment.⁵⁰ Estradiol levels were significantly elevated at all doses. In addition, statistically significant decreases in HDL cholesterol were observed at 2, 5, and 8 weeks after initiation of androstenedione along with resistance training. Investigators have failed to demonstrate skeletal muscle adaptation to resistance

training or favorable changes in lean body mass when androstenedione is taken at recommended doses.^{49,50}

DHEA is produced by the adrenal glands and is the most abundant steroid hormone in the blood. DHEA has been similarly studied to evaluate its role in altering serum testosterone levels and resistance training in healthy young males.⁵¹ While DHEA supplementation does produce a rise in serum androstenedione, it does not affect serum testosterone or estrogen levels. In addition, DHEA does not increase strength or lean body mass in men compared with placebo treatment. Interestingly, a dose of 1600 mg/day (recommended dose, 30 to 90 mg/day) has been shown to reduce serum LDL and body fat in five healthy men with no reported side effects.⁵² However, a similar evaluation of 1600 mg/day DHEA in eight healthy men did not demonstrate LDL or body fat alterations.⁵³

CREATINE

Oral creatine supplementation has become a popular practice among athletes of all ages, and creatine is probably the best-studied sports supplement. Surveys on creatine use report that 28% of collegiate athletes use this supplement regularly, and creatine use has been reported by athletes as young as 10 years of age.⁵⁴ Typical use of creatine involves a loading period of 20 g/day for 5 days, followed by a maintenance dose of 2 to 5 g/day,⁵⁵ although continued high-dose use is not uncommon.

Structure and Pharmacology

Creatine is a nitrogenous amino-acid derivative that is ingested at the rate of 1 to 2 g/day in diets that include fish and meat (Fig. 70-3). An equal amount of creatine is synthesized endogenously in the liver, kidney, and pancreas. Creatine is found in numerous body tissues including skeletal muscle, heart, brain, and testes. It is entirely excreted by the kidneys after conversion to creatinine, and creatine supplementation can cause a small dose-dependent rise in serum creatinine.⁵⁶ Creatine has a single physiologic role (i.e., reversible equilibrium with phosphocreatine in generation of ATP during skeletal muscle contraction under anaerobic conditions). This reaction generates adenosine triphosphate (ATP) for 10 to 20 seconds. Creatine supplementation is claimed to enhance athletic performance by raising phosphocreatine muscle stores and increasing the duration of burst-exercise capacity.

Limited human pharmacologic data suggest that creatine exhibits saturable kinetics.⁵⁷ Both the volume of distribution and clearance decrease with increasing oral dose, possibly owing to limitations in skeletal muscle

FIGURE 70-3 Chemical structure of creatinine.

uptake and storage of creatine. With loading doses of 20 g/day, maximal intramuscular creatine levels appear to be achieved in about 2 days.⁵⁸ Continued high-dose creatine intake may be of no benefit beyond this time. Creatine levels remain elevated for as long as 1 month after supplementation owing to slow turnover of creatine to creatinine.⁵⁹

A recent meta-analysis⁶⁰ of 96 published investigations concluded that creatine supplementation improves lean body mass and upper-body and repetitive-bout tasks lasting less than 30 seconds, such as stationary cycling sprints and weight lifting repetitions, but does not improve longer duration exercises such as running and swimming. Effect sizes were greater for loading than for maintenance creatine supplementation regimens, and there were no gender differences in effects of creatine. Creatine supplementation has also been demonstrated, in limited human studies, to improve the symptoms and slow the progression of certain neuromuscular diseases including muscular dystrophy, amyotrophic lateral sclerosis, and gyrate atrophy.⁵⁷

Toxicology

Concerns about the safety of creatine supplementation have arisen from anecdotal case reports of dehydration, muscle cramping, rhabdomyolysis, and acute renal failure, as well as theoretical concerns about long-term use and effects on children and adolescents. One case of interstitial nephritis has been described in a 20-year-old male creatine user.⁶¹ Creatine supplementation was also implicated in a case of relapsing nephrotic syndrome in a 25-year-old man.⁶² Acute quadriceps compartment syndrome and rhabdomyolysis, necessitating bilateral thigh fasciotomy, was reported in a 24-year-old previously healthy male taking creatine 25 g/day for 1 year.⁶³

Published studies indicate that short-term creatine use (<28 days) at recommended doses is not associated with significant adverse effects such as gastrointestinal, renal, or muscle dysfunction, although these were all performance studies involving fewer than 12 subjects.⁶⁴ Studies on side effects are limited, but one survey of NCAA Division I male baseball and football players who voluntarily took creatine revealed that of 52 athletes 16 (31%) reported having diarrhea, 13 (25%) experienced muscle cramps, and 7 (13%) complained of dehydration.⁶⁵ Rapid weight gain (within 24 hours of dosing) has been observed in several studies and is believed to be related to osmotic fluid retention in the muscle cell, which may account for reports of dehydration. Creatine has been shown to increase muscle compartment pressure both at rest and under exercise conditions.⁶⁶ No large-scale safety studies have been conducted on the long-term effects of chronic creatine supplementation.

Diagnosis

Adverse effects related to performance enhancers may go unrecognized because patients are reluctant to admit use of banned substances. Nonetheless, there are clinical signs and symptoms that suggest performance-enhancing

drug and supplement use that could potentially be confirmed by serum and urine testing.

Evidence of masculinization in females, feminization in males, or short stature in young athletes suggests anabolic steroid use. Infertility, polycythemia, and abnormal liver function tests in athletes and body builders are other clinical clues of steroid use.

A thorough review of steroid drug testing is beyond the scope of this chapter, but basic principles of AS detection may be relevant for toxicologic diagnosis.⁶⁷ Testing for AS abuse has been controversial since its institution by the IOC in the early 1980s. Currently, the most widely used method for detecting ASs involves quantitative measurement of the parent compound or its metabolite in urine by gas chromatography (GC-MS). For compounds that are not naturally present in the body, such as nandrolone, diagnosis is straightforward. The detection of nandrolone or its metabolite in the urine of athletes strongly suggests that they have taken these ASs.

Testing for testosterone is more complicated because it is produced physiologically. For this reason, a urinary ratio of testosterone (T) to its 17- α epimer epitestosterone (E) is determined. T and E are produced in the body in relatively equivalent amounts and do not interconvert. Among healthy subjects not using ASs, the urinary ratio of T to E is approximately 1:1. Individuals who take T show a rise in their urinary T-to-E ratio. The IOC considers a result greater than 6:1 to be indicative of exogenous T use.⁶⁸ False-negative results can be obtained by coadministering E or using a short-acting T preparation that leaves the body quickly enough that the ratio falls below 6:1.⁶⁹ Other methods for detecting T have also been developed that evaluate T-to-E ratio over time, T-to-LH ratio, and T metabolite to other T metabolite ratios. Because these tests are time consuming and expensive, they are rarely utilized.

Androstenedione and DHEA supplementation cannot be confirmed by drug testing because these substances are produced endogenously. Occasionally, these products contain trace steroid contaminants, such as 19-norandrostenedione, that cause positive urine test results for metabolites of banned steroids such as nandrolone.⁷⁰

Creatine can be measured in serum and urine, but such testing has little clinical utility. Creatine supplementation can increase serum creatinine in the absence of renal dysfunction owing to increased metabolic production and potential cross-reactivity of creatine with some creatinine assays.

Management

Treatment of adverse effects of performance-enhancing products is primarily supportive. Significant toxicity resulting from acute overdoses of oral steroids, androstenedione, DHEA, and creatine has not been described. No specific antidotes exist, and there is no role for enhanced elimination techniques in such cases. Because of reports of compartment syndrome and rhabdomyolysis with creatine, complaints of muscle pain or cramping by athletes warrant medical examination.

Rhabdomyolysis should be managed with aggressive hydration and alkalinization of the urine. Severe, persistent pain of the lower extremities may necessitate measurements of muscle compartment pressures.

Persons reporting long-term use of ASs may require evaluation of cardiac and hepatic function, including echocardiography and serum liver function tests. Athletes and body builders who report use of performance enhancers should be informed of the potential health risks associated with the use of such products, as well as the possibility of testing positive for banned substances.

TOXIC METALS AND MINERALS

71

Mercury: Heavy Metals and Inorganic Agents

CARL R. BAUM, MD

At a Glance...

- Mercury exists in three forms: elemental, inorganic, and organic. Each of these forms produces a unique profile of toxicity. However, interconversion among the three forms of mercury can occur in situ, producing overlap in the spectrum of clinical manifestations associated with each.
- Mercury is ubiquitous; blood concentrations in the general US population are typically 1-5 µg/L.
- Exposure to toxic amounts of mercury can occur from a number of sources including occupation, diet, polluted air, and complementary/alternative remedies.
- The primary target organs of mercury toxicity are the brain, lungs and kidney.
- Mercury exposure is assessed through its measurement in blood and/or urine.
- The primary treatment of mercury intoxication is to end exposure; having a relatively short elimination half-life, mercury is readily excreted in urine or bile. In rare cases, chelation therapy may be warranted to treat severe intoxication. Dimercaprol and succimer are the most effective chelating agents for mercury intoxication.

Mercury, a heavy metal, exists in the environment in three major forms: elemental, inorganic, and organic.¹ As with most toxic heavy metals, human poisonings have been associated with mercury for centuries. In the 1800s, there were many reports in which chronic occupational exposure to elemental mercury fumes caused a dementia-like syndrome among hat felters. This central nervous system toxicity led to the coining of the phrase “mad as a hatter.”¹⁻⁴ Individuals who attempt to vacuum spilled liquid mercury, or to extract gold or silver from alloys, risk acute inhalation exposure to the vaporized elemental mercury.⁵⁻⁸ The approved use of mercury-containing medicinals in the form of antisyphilitic agents, diuretics, cathartics, topical salves, teething compounds, and diaper powders has, fortunately, been eliminated in the United States. Historically, however, these compounds were responsible for numerous outbreaks of

mercurialism. The most widely known outbreaks were in children exposed to products containing calomel (mercurous chloride, an inorganic form). In the 1940s and 1950s, it became known that these products caused acrodynia, or so-called “pink disease.” The manifestations of acrodynia include pain and erythema of the palms and soles, irritability, insomnia, anorexia, diaphoresis, photophobia, and skin rash.⁹ Human exposure to methylmercury, the most common environmental form of organic mercury, has resulted in massive environmental disasters. One such massive exposure occurred in the 1950s in Japan, where effluent from an industrial plant contaminated Minamata Bay and led to more than 1000 deaths among area residents who consumed methylmercury-contaminated seafood.¹⁰ Other mass exposures have been associated with grain contaminated with methyl- and ethylmercury.^{11,12}

Sources of mercury are numerous. Mercury-containing minerals such as cinnabar (HgS) exist in the earth’s crust, and erosion, volcanic eruptions, and natural degassing release mercury into the environment. Mining (cinnabar is the major ore), smelting, and fossil fuel combustion represent non-natural sources. Independent of the initial source (natural or industrial), mercury undergoes extensive transformation once it is released into the environment.¹³ For example, aquatic microorganisms transform inorganic mercury via methylation into methylmercury, which accumulates in sea animals. Consumption of methylmercury-contaminated seafood is the major source of nonoccupational mercury exposure in humans. In addition, certain environmental conditions oxidize elemental mercury to divalent inorganic mercury; conversely, in vivo reduction reactions may convert inorganic mercury to the elemental form.^{1,13}

Mercury is used in the production of chloralkali (caustic soda), batteries, and measuring devices (thermometers, barometers, and sphygmomanometers) (Fig. 71-1), and it is used as a fungicide in the agricultural industry. Indoor latex paint once contained a mercury-containing antimildew agent, but federal law prohibited further production (but not sales) in the United States after

FIGURE 71-1 A Princo mercurial barometer. (Courtesy of Robert E. White Instruments, Inc., Boston, MA.)

August 1990.¹⁴ Various medicinal and antiseptic agents, as well as dental amalgams, contain mercury.¹³ Box 71-1 lists many sources and uses of mercury.

The occupational and environmental use of mercurial agents is regulated, and guidelines exist to limit exposure to these products. The Environmental Protection Agency includes mercury on its list of hazardous air pollutants and regulates its emission from industrial plants. Also, threshold limit values, permissible exposure limits, and short-term exposure limits have been established for various forms of mercury.¹³

PHARMACOLOGY

The chemical symbol for mercury, Hg, is derived from the Greek word *hydrargyros*, or “water silver.”¹³ This description is appropriate because mercury is the only metal that is liquid at room temperature. The three forms of mercury (elemental, inorganic, and organic) have different biologic and toxicologic properties. In general, however, mercury forms covalent bonds to sulfide groups; thus, it interferes with the function of sulfhydryl enzymes, disrupting many important metabolic cellular functions.¹⁵

Elemental Mercury

Elemental mercury (Hg^0) is liquid at room temperature. Commonly known as quicksilver, elemental mercury

BOX 71-1

MERCURY-CONTAINING PRODUCTS AND OTHER SOURCES OF MERCURY

Elemental	Inorganic	Organic
Barometers	Acetaldehyde production	Antiseptics

Thermometers	Vinyl chloride production	
Semiconductor cells	Wood preservatives	
Silver and gold production		

transforms at room temperature from the liquid to an easily inhaled vapor; consequently, the lung is the major target organ of acute exposure. Elemental mercury is lipid soluble and, once inhaled, passes rapidly through the alveoli into the bloodstream and red blood cells. Once absorbed, most of the elemental mercury is oxidized to the inorganic divalent, or mercuric, form (Hg^{2+}) through the action of catalase enzymes; after intense inhalation exposures, therefore, symptoms and signs of subacute or chronic inorganic mercurialism predominate.¹⁶ Although nonexcreted elemental mercury may accumulate to some degree in the kidney, it does not usually produce renal damage. The mercuric ion is not lipid soluble and does not readily cross the blood-brain barrier; however, a small but potentially significant amount of nonoxidized elemental mercury persists and penetrates readily into the central nervous system, where significant toxicity does occur. Most of the circulating mercuric ion is excreted in feces, urine, and, to a small degree, saliva. The intact gastrointestinal tract absorbs elemental mercury poorly, and ingestions of the metal from, for example, a thermometer are generally nontoxic.^{1,13}

Inorganic Mercury

Historically, inorganic forms of mercury in topical medicines, cathartic agents, and diuretics were important sources of human poisonings; however, most of these

agents have been banned in the United States. Of interest, mercury-containing creams and soaps (used for skin lightening), although banned in the United States, continue to be manufactured and distributed in some European countries and have been discovered in areas in which their use is banned.¹⁷ Currently, the occupational inhalation of elemental mercury with *in vivo* conversion to inorganic mercury is probably the most common source of inorganic mercury poisoning.¹⁸ Inorganic mercury exists primarily as a salt of divalent (mercuric) and monovalent (mercurous) forms. The bichloride (HgCl_2) form of inorganic mercury, corrosive sublimate, is one of the most common of these salts, and as its name suggests, is directly toxic to the mucosa.¹⁵ This corrosive property constitutes the major initial toxicity associated with acute exposure to inorganic mercury. The gastrointestinal tract absorbs approximately 2% to 15% of an ingested dose, which accumulates in the kidney and causes renal cell damage.¹ Cutaneous absorption of inorganic mercurials also occurs, and chronic exposure to topical inorganic mercurials may lead to significant toxicity.

Plasma proteins transport absorbed inorganic mercury (red blood cell:plasma ratio, 1:2.5) to the kidneys, where it undergoes glomerular filtration, tubular secretion and reabsorption, and eventual elimination.^{1,15} However, because renal excretion is inefficient, mercury accumulates unless it binds to a chelating agent. Although inorganic mercury's lipid solubility is poor, chronic exposure leads to gradual accumulation of the mercuric ions in the cerebellar and cerebral cortices of the brain, and to eventual central nervous system disease.¹⁹ Mercuric ions do not readily cross the placenta, and fetotoxicity, if it occurs, is rare.¹⁵

Organic Mercury

Organic mercurials are used extensively in agriculture as fungicides and seed dressings. Organic mercury exists in three major forms: aryl (phenylmercuric acetate), long-chain, and short-chain alkyl (methyl- and ethyl-) compounds. These forms are grouped according to absorption, distribution, and elimination into two classes: the aryl and long-chain organic mercurials, once absorbed, are converted rapidly to inorganic forms, and their toxicity is similar to that of inorganic mercury; the alkyl mercurials, methyl- and ethylmercury, are quite stable after absorption, with only a small amount of the parent compound converted to the mercuric form. Organic methylmercury is the most widely distributed and toxic form of organic mercury in the environment and is responsible for most of the mass toxic exposures. The gastrointestinal tract absorbs 90% to 95% of ingested alkyl forms, which rapidly penetrate red blood cells; this results in a large red blood cell:plasma ratio. Organic mercury binds avidly to and inactivates sulfhydryl-group enzymes.^{1,15} Because of its lipid solubility, alkyl mercury is distributed throughout the entire body, accumulating in the brain, kidney, liver, hair, and skin; toxic effects are evident primarily in the brain. Methylmercury also passes readily through the placenta and is of major

concern in pregnant women because of its profound fetotoxicity.¹⁰ Methylmercury is acetylated or conjugated to cysteine or glutathione in the liver, and is then excreted in the bile. The *N*-acetyl-homocysteine-methylmercury metabolite undergoes enterohepatic recirculation and is excreted ultimately in the feces (approximately 90%) and in the urine.²⁰

CLINICAL PRESENTATION

The manner in which patients present with mercury poisoning depends on the form of mercury, the duration and intensity of the exposure, and certain conditions of the patient. Inhalation of elemental mercury vapor and ingestion of inorganic mercurial compounds may lead to acute toxicity, while exposure to organic mercury generally causes chronic toxicity.

Elemental Mercury

Exposure to high concentrations of vaporized elemental mercury may cause acute pulmonary symptoms. Initial symptoms consist of fever, chills, shortness of breath, and a metallic taste in the mouth—all consistent with metal fume fever. Other symptoms and signs include stomatitis, lethargy, confusion, vomiting, and colitis. These clinical findings usually abate within 1 week; however, in some instances, they worsen and progress to pulmonary edema, respiratory failure, and death.⁵⁻⁷ Young children are particularly susceptible to the acute pulmonary effects of elemental mercury vapor. Following exposure, usually from the melting of metals or vacuuming of elemental mercury in the home, the child may develop severe pulmonary disease, including alveolar dilation, interstitial emphysema, and pneumatocele, pneumothorax, and pneumomediastinum formation. Small airway obstruction from cellular desquamation may occur, and pulmonary fibrosis, granuloma formation, and respiratory failure often ensue.^{6,7}

Elemental mercury-containing dental amalgams are another potential source of exposure. If appropriate guidelines for use and handling are not followed, dental workers may be exposed to toxic amounts of aerosolized elemental mercury.²¹ The effects of vaporized dental amalgam fillings within patients' mouths is a subject of controversy. Although chewing does release elemental mercury vapor, and urinary mercury levels of patients with mercury fillings are slightly higher than those in people without mercury fillings, to date no scientifically rigorous studies have identified clinical evidence of associated disease.²²

Ingestion of elemental mercury is usually of no concern because of poor gastrointestinal absorption. However, abnormal gastrointestinal function or anatomy (e.g., decreased gut motility or fistulous tracts) may allow elemental mercury into the bloodstream and the peritoneal space.²³ The common scenario of a child who has a small amount of elemental mercury from a broken thermometer in the mouth or rectum is of no concern unless direct trauma from the broken glass is evident.

After intentional intravenous injection (usually as a suicide attempt), elemental mercury may embolize to the lungs and cause symptoms and signs of acute pulmonary embolus, including shortness of breath, dyspnea, chest pain, hypoxemia, and death.²⁴ In addition, elemental mercury may be transformed to its inorganic form and subsequently lead to renal disease. Accidentally or intentionally injected inorganic mercury may be absorbed gradually, leading to systemic symptoms unless the mercury is surgically removed.²⁵

Intense acute or chronic exposure to elemental mercury fumes causes cutaneous and central nervous system dysfunction. The classic description is a triad of tremor, gingivitis, and erethism. Erethism is a constellation of findings that includes insomnia, shyness, memory loss, emotional lability, anorexia, and depression. Signs of oral toxicity include gingivitis, stomatitis, and loose dentition. Additional findings may include headaches, visual disturbances (constricted or tunnel vision), peripheral neuropathy with sensory or motor abnormalities (or both), anosmia, and ataxia.^{2,4,18} If the medical and occupational history is not thorough, chronic mercurialism may be misdiagnosed as parkinsonism, depression, or Alzheimer's disease. Inhalation exposures have also been misdiagnosed as pheochromocytoma and toxic shock syndrome.^{26,27}

Inorganic Mercury

Inorganic mercury poisoning occurs primarily via the oral route. Acute symptoms and signs of inorganic mercury poisoning are related to direct caustic effects, and depend to some degree on the concentration and type of salt (mercuric forms are more toxic than mercurous forms).²⁸ At high concentrations, symptoms are usually immediate and include pain, vomiting, and hematemesis. Necrosis of any portion of the gastrointestinal tract may occur with subsequent luminal pooling of body fluids, hypovolemia, electrolyte imbalance, acute tubular necrosis, and death. In those who survive the acute phase of toxicity, renal failure may develop. Home accidents involving the preservative in stool collection kits (mercuric chloride 4.5%) are not uncommon and should be considered in patients presenting with signs of corrosive gastrointestinal injury.^{29,30} Ingestion of disk batteries, many of which contain mercury, is relatively common among pediatric patients; although these batteries are very unlikely to break apart and spill inorganic mercury into the gastrointestinal tract, complications are usually related to local corrosive injury. Ingestion of button batteries with subsequent clinical signs of systemic toxicity is very rare.³¹

Prolonged inhalation exposure to elemental mercury in an occupational setting is the most likely cause of chronic inorganic mercury poisoning.¹⁸ Historically, the topical application of inorganic mercurial salves and the chronic ingestion of diuretics or cathartics were common sources of inorganic mercury poisoning, causing renal failure, dementia, and acrodynia. Acrodynia, which means "painful extremities" and is also known as "pink disease," presents as erythema and edema of the hands

and feet, skin rash, diaphoresis, tachycardia, hypertension, photophobia, irritability, and decreased proximal muscle tone.³² In addition, subtle neuropsychiatric disturbances have been reported in patients chronically exposed to inorganic mercury.³³ In the 1940s and 1950s, exposure to mercurous chloride was responsible for numerous cases of pediatric acrodynia.⁹ Fortunately, federal regulations that have limited or banned many inorganic mercurial compounds have rendered chronic poisoning rare outside the occupational setting. However, new cases have been associated with exposures to broken mercury-containing light bulbs and spilled elemental mercury.^{8,34,35} Of importance, acrodynia does not develop in everyone exposed to mercurial compounds; consequently, its presence is often a marker for a more widespread problem. In 1980, three cases of acrodynia led to the discovery that a commercial diaper service using a phenylmercuric fungicide had exposed up to 12,000 infants.³⁶

Organic Mercury

Ingestion of contaminated food products is the usual route of organic mercury exposure, although inhalation and dermal exposure may cause toxicity. The aryl and long-chain organic compounds may cause findings similar to those of chronic inorganic mercury. Depending on the amount ingested, symptoms of short-chain alkyl organic mercurial poisoning begin days to weeks after ingestion. This delay occurs primarily because organic mercury targets enzymes that must be depleted before clinical signs develop. The major symptoms and signs of alkyl mercury poisoning are neurologic, consisting of visual field constriction, ataxia, paresthesia, neurasthenia, hearing loss, dysarthria, mental deterioration, muscle tremor, movement disorders, and even death.¹⁵ Dermal exposure to these products may cause dermatitis or burns. Ingestion of methylmercury rarely, if ever, causes gastrointestinal symptoms; however, the ingestion of ethylmercury may induce vomiting, cramping, and diarrhea. Organic mercurials have been reported to cause thrombocytopenia and agranulocytosis.^{1,10} Symptoms of acute and chronic exposures to organic mercury are similar, with the central nervous system abnormalities predominating. Pathologic and magnetic resonance imaging findings include damage to the cerebral cortex—specifically the visual cortex (calcarine region), the motor and sensory centers (pre- and postcentral cortex), and the auditory center (temporal cortex)—and to the cerebellar cortex. Destruction and demyelination of the sensory nerve fibers and dorsal roots of the peripheral nervous system also occur.³⁷

Organic mercurials are extremely toxic to the fetus. Although all forms of mercury cross the placenta, organic mercury passes most readily. Maternal exposure may lead to spontaneous abortion or severe mental retardation of the child, with global developmental delay, cerebellar ataxia, tremor, nystagmus, dysmetria, limb deformities, and seizure disorders, as in Minamata disease.¹⁰

More recent studies have described cognitive deficits in a cohort of children born in the Faroe Islands (located

halfway between Iceland and Norway), where pilot whale meat is a staple of the diet. Mercury concentrations of cord blood and maternal hair served as indicators of prenatal exposure to methylmercury from whale meat. At 7 years of age, nearly 90% of members of the cohort underwent extensive neurodevelopmental examination, which revealed dysfunction most notably in language, attention, and memory.³⁸ In contrast, neurodevelopmental studies of children in the Republic of Seychelles (an island group in the Indian Ocean), where consumption of a variety of ocean fish is the only source of methylmercury, found no risk from prenatal exposure.³⁹

A chemistry professor at Dartmouth who spilled liquid dimethylmercury inadvertently onto her gloved hand presented to medical attention 5 months later with acute deterioration in balance, gait, and speech. Despite aggressive therapy, she became unresponsive within 3 weeks. Life support was eventually withdrawn, and she died 10 months after the exposure. Autopsy revealed diffuse disease of the cortices, and remarkable atrophy of the cerebellum.⁴⁰

Considerable debate has arisen over the vaccine preservative thimerosal, its active component ethylmercury, and their causal roles in neurodevelopmental disorders, such as autism, attention-deficit hyperactivity disorder, and speech and language delay. In an extensive review, the Institute of Medicine concluded that although the hypothesis, based primarily on analogies to methylmercury, is biologically plausible, there is inadequate evidence “to accept or reject a causal relationship between thimerosal exposure and neurodevelopmental disorders. . . .”⁴¹

DIAGNOSIS

A thorough occupational and environmental history may reveal exposure to a mercurial compound, particularly after an acute inhalation exposure to elemental mercury or an ingestion of inorganic mercury. The latter should be considered in the patient who presents after a suicide attempt with symptoms and signs of caustic ingestion. The diagnosis of chronic or subacute mercury poisoning may be more difficult. Because the major target organs of toxicity include the central nervous system, the kidneys, and skin and mucous membranes, any patient with an altered mental status and renal failure, with or without cutaneous findings, should be evaluated for mercury intoxication. The constellation of findings of acrodynia should also alert the physician to the possibility of exposure to mercurial compounds. Probably the most important tool in the diagnosis of chronic mercury poisoning is a very thorough occupational and environmental history.

If mercury poisoning is suspected, confirmatory laboratory evaluation is usually necessary, particularly in cases of chronic exposure. Measurement of urine mercury levels is generally considered the best method for determining whether exposure to inorganic or elemental mercury has occurred, and whether chelation therapy is effective. Concentrations of mercury in urine greater than 20 to 25 $\mu\text{g}/\text{L}$ should be considered elevated.

Although no absolute correlation exists between urinary mercury concentrations and symptoms, levels greater than 150 $\mu\text{g}/\text{L}$ have been associated with nonspecific symptoms after chronic exposure to mercury vapors; levels greater than 300 $\mu\text{g}/\text{L}$ are usually associated with overt symptoms. Urine levels are helpful in confirming exposure to elemental and inorganic mercury. However, because organic mercury is poorly excreted in urine, organic mercurial exposure should not be ruled out on the basis of urinary mercury determination.

Blood (not serum) mercury levels in the normal population are usually less than 5 $\mu\text{g}/\text{L}$. Mercury levels in the blood may accurately reflect inorganic mercury exposure if they are obtained soon after exposure. However, because of redistribution to other body tissues, these levels may become less accurate as the exposure becomes more remote. Following methylmercury exposure, however, blood levels may remain elevated and are relatively accurate in determining the body's burden of organic mercury.¹⁵

Mercury accumulates in hair, and levels in hair may be used to document exposure. However, environmental mercury contaminates hair easily; therefore, measurements may be inaccurate following aerosol or other extraneous exposures. Thus, hair analysis alone should never be used to confirm exposure to mercury.¹

For ingested, intravenous, or subcutaneous exposures to elemental mercury, radiographs may be necessary to document both the presence and the efficacy of removal of these compounds. X-ray fluorescence techniques have been used to estimate body burdens of mercury. However, these techniques remain experimental and are not used routinely.⁴²

TREATMENT

Initial treatment of the mercury-poisoned patient is the same as that for any intoxicated patient. Assessment and management of the patient's *airway, breathing, and circulation* (ABCs) are of primary importance. Prehospital or hospital providers should remove contaminated clothing and flush contaminated skin and eyes. All patients with signs of acute mercurialism should undergo continuous cardiac monitoring and pulse oximetry.

Acute inhalation exposure to elemental mercury may cause, as discussed earlier, symptoms of metal fume fever, pneumonitis, and respiratory failure. Humidified supplemental oxygen should be provided; endotracheal intubation may be necessary for those with signs of respiratory failure. There are no known aerosolized antidotes for acute inhalation exposures; therefore, respiratory support is the mainstay of treatment. Infants with severe respiratory compromise after inhalation of elemental mercury have survived with vigorous respiratory support, including the use of high-frequency ventilation when conventional mechanical ventilation has failed.⁷ Patients with acute inhalation exposure to mercury may develop systemic poisoning once transformation of elemental mercury to inorganic mercury has occurred;

thus, they may require chelation therapy (see below in this section).

Ingestion of caustic inorganic mercury requires rapid assessment and treatment to prevent circulatory collapse. Rapid vascular access should be established, and vigorous replacement of fluid losses should be instituted. Caustic injury to the oropharyngeal mucosa may cause severe local edema, and endotracheal intubation or tracheostomy may be required to prevent obstruction of the airway. Decontamination procedures should be instituted early to prevent further corrosive injury and systemic absorption. The induction of emesis is, as with any caustic ingestion, contraindicated. The role of antiemetics has not been studied specifically, but they may be of benefit. Gastric lavage is no longer recommended routinely and is contraindicated if gastric or esophageal perforation is a possibility. Anecdotal evidence indicates that lavage with milk or egg whites may help bind mercurial compounds; thus, their use may be considered, especially since there is no evidence that these materials cause harm. If perforation is suspected or radiopaque objects remain present, direct endoscopic removal should be considered. Activated charcoal does not bind appreciably to metallic compounds. (However, some evidence indicates that some binding may occur; therefore, it may be considered unless perforation is suspected.²³) Finally, whole bowel irrigation with polyethylene glycol may be administered until the rectal effluent is clear and the radiopaque material is absent. Extracorporeal methods of mercury removal are not recommended; however, hemodialysis may be necessary if renal failure ensues.

Initial laboratory tests should include serum chemistry assessments and a complete blood count. Type and cross-matching of blood should be performed if exposure to caustic inorganic mercury is suspected. Because elemental mercury is radiopaque, appropriate radiographs should be obtained. Blood and urine should be obtained for appropriate evaluation for the presence of mercury (see section on Diagnosis) and other toxins, as indicated.

Following initial management, chelation therapy should be instituted if systemic absorption is expected, if the patient is symptomatic, or if elevated mercury levels in the blood or urine are discovered. Effective chelating agents include oral D-penicillamine (D-PCN), parenteral dimercaprol (British antilewisite [BAL]) and its oral congeners meso-2,3-dimercaptosuccinic acid (DMSA) and sodium 2,3-dimercapto-1-propanesulfonate (DMPS). Each of these agents contains thiol groups that compete with endogenous sulfhydryl groups for mercury.^{15,43}

After the acute ingestion of caustic inorganic mercury, chelation is best limited to the use of BAL. BAL is administered intramuscularly at a dose of 2.5 to 5 mg/kg every 6 to 12 hours. Common side effects of BAL include transient hypertension, tachycardia, pain at the injection site, nausea and vomiting, headache, and diaphoresis. Hemolysis may be induced if the patient has glucose-6-phosphate dehydrogenase deficiency. BAL should not be used for the treatment of alkyl organic mercury poisoning because it may actually worsen neurotoxicity.⁴⁴

TABLE 71-1 Clinical Characteristics of Mercury Exposure

	ELEMENTAL	INORGANIC	ORGANIC
Major Route of Exposure	Inhalation	Inhalation (chronic), oral dermal	Oral
Clinical Effects			
CNS	Tremor	Erethism, tremor	Minamata disease
Pulmonary	+++	–	–
GI	+	+++	+
Renal	+	+++	+
Acrodynia	+	+	–
Treatment	BAL, DMSA	BAL, DMSA	DMSA

BAL, British antilewisite; DMSA, 2,3-dimercaptosuccinic acid; +, present; –, absent.

If the patient is able to tolerate oral medications, PCN or DMSA may be used instead of or in addition to BAL. D-PCN forms a complex with mercury that is excreted in the urine. Therefore, it should not be used if the patient has renal failure. It is administered four times a day at 250 mg per dose (20 to 30 mg/kg/day for children). One- to 2-week courses of D-PCN therapy are given until the 24-hour urine mercury level is within an acceptable range. Side effects of D-PCN therapy include gastrointestinal upset, rash, leukopenia, thrombocytopenia, proteinuria, and hematuria. If mercury remains in the gastrointestinal tract, D-PCN should not be administered because it may increase absorption.^{15,23}

DMSA is an oral, water-soluble congener of BAL. Its use in mercury-poisoned patients is increasing, and it seems to be more effective than D-PCN at increasing urinary mercury levels in chronically exposed patients. DMSA has a better side effect profile than those of D-PCN and BAL; its adverse effects are usually limited to mild transient elevations in hepatic transaminase levels and mild gastrointestinal upset. DMSA is administered at a dose of 10 mg/kg three times per day for the first 5 days of treatment, and two times per day for the next 14 days. Repeated administrations may be necessary, with a 2-week interval between treatments.⁴⁵ Table 71-1 summarizes the clinical effects and treatment for the three forms of mercury poisoning.

72 *Iron*

ERICA L. LIEBELT, MD

At a Glance...

- Acute iron poisoning is primarily a clinical diagnosis, supported by laboratory data.
- Gastrointestinal symptoms—vomiting, hematemesis, diarrhea, and abdominal pain—characterize the early signs of toxicity.
- Shock, metabolic acidosis, and decreased level of consciousness characterize serious systemic toxicity.
- Aggressive gastrointestinal decontamination measures, particularly whole bowel irrigation, may be necessary to decrease toxicity.
- Deferoxamine is the antidote for iron toxicity.

Acute iron poisoning continues to be a common and potentially lethal toxicologic problem, especially in the pediatric population. In 2002, there were more than 24,000 reported exposures to iron-containing products in children younger than 6 years of age; fortunately, most resulted in either minor or no adverse outcomes. However, in the 1990s, iron was the leading cause of unintentional poisoning deaths among children in the United States who ingested pharmaceutical preparations. Although there have been no reported deaths in the United States in the past 2 years, many factors account for this high incidence of exposures and past history of deaths. First, iron-containing compounds, such as multivitamins with iron or iron tablets, are readily available and widely used in households as nutritional supplements during childhood and adulthood, particularly during pregnancy. Second, many iron preparations are brightly colored, are sugar coated, and look like candy, making them attractive to curious young children. Finally, parents and the general public do not recognize the potential toxicity of a product that is regarded as promoting health.

Preventing iron exposures is necessary to decrease the morbidity and mortality associated with its toxicity. In 1997, the U.S. Food and Drug Administration (FDA) required warning labels on all iron-containing preparations and mandated unit-dose packaging for iron-containing dietary supplements and drug products that contained 30 mg or more of elemental iron per dosage unit. In October 2003, the mandate for unit-dose packaging was removed because of a court ruling, which stated that the FDA did not have the authority to require manufacturers of iron-containing dietary supplements and drug products to use unit-dose packaging for poison prevention purposes.¹ The ramifications of this ruling are yet to be seen.

PHARMACOLOGIC AGENTS

Three major categories of iron preparations are available, each with varying potential for toxicity based on their content of elemental iron (Table 72-1). Children's chewable multivitamins have a low concentration of elemental iron (10–18 mg per tablet packaged in bottles of 60–100 tablets) and are rarely associated with serious toxicity. Nonprescription iron products (adult multivitamins with iron and iron supplements) and prescription iron supplements (i.e., prenatal vitamins) contain substantially higher concentrations of iron in the form of ferrous salts. The toxicity of iron results from the amount of elemental iron ingested, which, in turn, depends on the type of iron preparation. Ferrous fumarate contains 33% elemental iron; ferrous sulfate, 20%; and ferrous gluconate, 12%. These iron products are responsible for the moderate and serious toxicity and fatal outcomes that are reported with exposures. Carbonyl iron is another formulation that has not been reported to cause the same corrosive injury to the gastrointestinal tract seen with iron salt formulations (50–66 mg/tablet or capsule).

PHARMACOLOGY AND PHARMACOKINETICS

The average healthy adult body contains 3 to 5 g of iron, of which 70% is present in the ferrous state (Fe^{2+}) in

TABLE 72-1 Elemental Iron Content in Different Preparations

IRON PREPARATION	ELEMENTAL IRON CONTENT (%)	TABLET SIZE (mg)	ELEMENTAL IRON CONTENT/ UNIT DOSE
Iron Supplements			
Ferrous fumarate	33	200	65 mg
Ferrous sulfate	20	300	60 mg
		325	65 mg
Ferrous gluconate	12	300	36 mg
Feosol Elixir			44 mg/5 mL
Multivitamins			
Adult multivitamins with iron			10–110 mg/tablet
Children's multivitamins with iron			10–18 mg/tablet

hemoglobin and myoglobin and 25% occurs in the ferric state (Fe^{3+}) in the form of ferritin and stored as hemosiderin. The remainder is found attached to transferrin or in heme and flavin enzymes. Dietary iron is absorbed in the ferrous form in the duodenum and upper jejunum. A transferrin-like protein facilitates the energy-dependent carrier-mediated transport across intestinal mucosal cells. This mucosal receptor-dependent process acts as a limiting barrier for normal iron absorption, thus regulating iron balance. Free iron is toxic to many cellular processes; however, the body has many protective mechanisms to prevent this toxicity. Once absorbed, iron is either stored within ferritin or prepared for release to transferrin, an iron-binding protein carrier. The constant sloughing of intestinal cells provides the main mechanism of physiologic iron excretion.

Plasma iron is bound to transferrin in the ferric state, with 30% to 40% of the iron-binding sites usually saturated. Transferrin is a protein carrier that transports either dietary or storage iron that is entering the plasma for redistribution and utilization. Total iron-binding capacity (TIBC) is a measurement of the total amount of iron that transferrin can bind and normally exceeds serum iron concentration by twofold to threefold.

Most iron is transported to the reticuloendothelial system and hepatocytes, where it is stored within the protein ferritin after ferrous ions are oxidized to the ferric state and complexed with apoferritin. With increasing iron storage, some of the ferritin is transformed into hemosiderin. The small percentage of iron not stored as ferritin is incorporated into iron-containing enzymes or proteins such as hemoglobin and cytochrome enzymes. Humans can eliminate only a small fixed amount of iron per day (1 mg in adult males and 1 to 2 mg in adult females) primarily through exfoliation of gastrointestinal (GI) mucosal cells or menstrual blood loss, which can increase up to only 2 mg/day when excess iron accumulation occurs.

PATHOPHYSIOLOGY

It is evident from the description of normal iron metabolism that the body is poorly equipped to handle excessive amounts of iron. Regulation of iron absorption does not occur in the presence of excessive iron ingestions. Iron may continue to be absorbed passively down a concentration gradient in overdose because of its oxidative and corrosive effects on the GI mucosa, leading to dysfunction of the regulatory balance seen in therapeutic settings. In acute iron poisoning, iron absorption may occur along the entire length of the small and large intestine rather than just the duodenum and upper jejunum. Furthermore, the normal protective mechanisms (transport and storage proteins) become saturated, resulting in more free circulating iron, the agent responsible for cellular toxicity.

Iron toxicity is manifested as both local and systemic effects. Excess free iron catalyzes redox reactions, producing secondary toxicity from lipid peroxidation

and free radical formation.^{2,3} Iron has effects on the GI and cardiovascular systems as well as on the central nervous system.

Gastrointestinal Tract

Iron has direct corrosive effects on the GI mucosa, resulting in ulceration, edema, bleeding, venous thrombosis, infarction, and perforation.⁴ Deposition of iron can be demonstrated histologically in mucosal collagen and basement membranes as well as vascular tissues supplying the small intestine. These effects can lead to severe fluid losses both by direct hemorrhage and the “third spacing” of fluids, both contributing to systemic hypovolemia. The severity of these local corrosive effects depends on the quantity of elemental iron ingested, the concentration of iron in the preparation, the duration of its contact with the mucosa, and the amount of mucosal protection provided by food in the stomach at the time of ingestion; greatest mucosal damage occurs on an empty stomach. Gastric scarring may follow severe iron ingestion, resulting in stenosis of the gastric outlet and small bowel.⁵

Cardiovascular System

Multiple cardiovascular manifestations of iron excess are evident on the heart and blood vessels.^{3,6-8} Both free iron and ferritin (whose release is stimulated by free iron) are potent vasodilators that can cause hypotension as a result of venodilation. Iron also directly injures blood vessels, resulting in postarteriolar dilation and decreased venous tone. Capillary membrane permeability increases from direct toxic effects of iron, resulting in diffusion of fluids from the vascular compartment into the interstitium, exacerbating hypovolemia and hypotension. Cardiac output is ultimately decreased as a result of decreased filling pressures from fluid losses, decreased systemic vascular resistance, and probably metabolic acidosis and its depression of myocardial contractility. Iron infiltrates myocardial cells and produces fatty degeneration, which can produce a cardiomyopathy.

Liver

Circulating free iron accumulates initially in the Kupffer cells of the reticuloendothelial system and then in the hepatocytes, localizing in the mitochondria, where its toxicity is exerted. The liver is probably the organ most susceptible to injury because it is the first organ to receive portal blood containing toxic amounts of iron; the liver also has the greatest capacity to sequester iron that is not bound to transferrin.⁹ Histopathologically, the demonstrated effects of excess iron in the liver include cloudy swelling of the hepatocytes, portal iron deposition, fatty metamorphosis, and massive periportal necrosis.¹⁰ Formation of reactive oxygen species in the hepatocytes is most likely responsible for the hepatocellular damage. Hepatocellular toxicity is manifested by elevated bilirubin concentrations 3 to 4 days after ingestion, hypoglycemia, hyperammonemia, coagulation

defects, and, ultimately, encephalopathy. Acute hepatic failure is rare except in massive iron overdoses.

Hematopoietic System

Several mechanisms are responsible for the coagulation disturbances often noted with iron intoxication. Free iron inhibits the thrombin-induced conversion of fibrinogen to fibrin, resulting in a direct and early effect on coagulation that precedes liver dysfunction.¹¹ The bleeding from this iron-induced coagulopathy may contribute to the early GI blood loss. In addition, experimental iron poisoning has been associated with decreased thrombin production, thrombocytopenia, hypoprothrombinemia, and synthetic disturbances at several stages in the coagulation cascade.¹² In the later stages of iron poisoning, impaired synthesis of clotting factors occurs as a result of hepatotoxicity.

Metabolic Acidosis

The metabolic acidosis of acute iron poisoning can be explained by a number of different mechanisms. Lactic acidosis may result from hypovolemia, hypotension, and anemia, producing tissue hypoperfusion that causes increased anaerobic metabolism. Iron also disrupts oxidative phosphorylation through interference of the electron transport system, promoting anaerobic metabolism. Lipid peroxidation, catalyzed by ferrous ions, alters the membrane permeability of the mitochondria, allowing greater intramitochondrial accumulation of iron.¹³ The in situ conversion of iron from the ferrous (Fe^{2+}) to ferric (Fe^{3+}) state releases hydrogen ions that contribute to the metabolic acidosis. A buildup of unused hydrogen ions generated from nonbound ferric ions contributes to marked acidosis. Finally, iron directly inhibits enzymatic processes of the Krebs cycle, with the resultant accumulation of organic acids. Thus, metabolic acidosis is multifactorial in etiology and must be aggressively managed from all aspects.

Central Nervous System

Neurologic manifestations from iron toxicity are probably a result of the systemic manifestations of hypoperfusion, metabolic acidosis, hepatic toxicity, and coagulopathy. Iron can produce cerebral edema by an unknown mechanism that manifests itself as lethargy, coma, and seizures.

TOXICOLOGY

Clinical Manifestations

The clinical presentation of acute iron toxicity has traditionally been divided into four stages, which were first described in 1964, and based on the pathophysiology of iron poisoning.¹⁴ Progression of signs and symptoms may occur rapidly depending on the severity of the ingestion; thus, this clinical staging should be

determined primarily by the patient's clinical manifestations and not solely by the time since the ingestion. Some authors have suggested that there are five clinical stages, distinguishing hepatic necrosis as a separate stage.¹⁵ Nevertheless, clinical stages usually overlap in severe poisonings.

STAGE I (30 MINUTES TO 6 HOURS AFTER INGESTION) OR GASTROINTESTINAL PHASE

This stage is characterized by the acute GI effects of iron toxicity: nausea, abdominal pain, vomiting, and diarrhea. Local corrosive effects of iron to the stomach and intestinal tract may result in hematemesis, hematochezia, and melena. The vomitus and stools may also be dark gray, green, or black owing to the presence of disintegrating iron tablets. Vomiting is the most sensitive indicator of serious ingestions. Most patients with mild to moderate iron toxicity do not progress beyond this stage, with symptoms resolving within 6 to 8 hours. In severe ingestions, cardiovascular toxicity may also appear at this stage as pallor, tachycardia, and hypotension. Central nervous system toxicity may include lethargy and coma. The presence of shock and lethargy on initial presentation are poor prognostic signs. If no GI symptoms develop within 6 hours of a presumed iron ingestion, it is unlikely that iron toxicity will develop. Ingestion of enteric-coated iron tablets is an exception to the 6-hour rule.

STAGE II (6 TO 24 HOURS AFTER INGESTION)

This second phase of iron poisoning is sometimes referred to as the latent or quiescent period and is characterized by a transient resolution of GI symptoms. However, there may be subclinical hypoperfusion and metabolic acidosis if adequate fluid resuscitation has not been performed in the initial stage. The abatement of GI symptoms is presumed to occur as circulating free iron is redistributed into the reticuloendothelial system. Some patients may be prematurely discharged from a health care facility despite potentially life-threatening ingestions because of the false reassurance of clinical improvement. Thus, clinical reassessment and observation should occur if GI symptoms have improved to determine whether the patient has truly recovered or may progress to further clinical deterioration. This phase may be transient or not appear at all in those with severe iron ingestions.

STAGE III (12 TO 48 HOURS AFTER INGESTION) OR SYSTEMIC TOXICITY

Life-threatening systemic symptoms predominate during this stage. Fortunately, only a small percentage of patients with iron ingestions progress to this phase. Some patients with severe ingestions will progress to this phase of multisystem failure without experiencing a "quiescent phase." Recurrence of GI hemorrhage, hematemesis, melena, and bowel perforation may be seen. Acute circulatory shock characterized by tachycardia, tachypnea, pallor, hypotension, and cyanosis may recur. Cardiogenic shock may occur several days later owing to direct effects of iron on the myocardium. Metabolic

acidosis and coagulopathy are present. However, the hallmark of this phase is progressive pulmonary dysfunction with a radiologic appearance of adult-type respiratory distress syndrome or shock lung. The etiology is multifactorial: iron generation of free radicals that disrupt alveolar membranes in addition to the hypotension and metabolic acidosis. Hepatotoxicity usually occurs within 48 hours but does not develop in all iron-poisoned patients. It is the second most common cause of death after shock. Renal and neurologic dysfunction all may occur during this time. Death from iron toxicity is common in this phase, typically from respiratory failure and shock; thus, aggressive supportive treatment in addition to antidotal treatment is mandatory for survival.

STAGE IV (4 TO 6 WEEKS AFTER INGESTION) OR BOWEL OBSTRUCTION

Patients with severe poisoning who survive, as well as those who do not develop systemic toxicity, may go on to have gastric outlet obstruction or pyloric stenosis as a result of GI scarring. Vomiting is the presenting symptom of these late sequelae.

Range of Toxicity

The minimum toxic dose and the lethal dose of iron are not well established. Ingestions of less than 20 mg/kg of elemental iron have little risk for toxicity and require no specific treatment, although ingestion of 20 mg/kg in an adult human volunteer study resulted in nausea, malaise, and diarrhea in all six subjects.¹⁶ Ingestions of greater than 60 mg/kg can be associated with serious toxicity and require immediate referral to a health care facility for evaluation. Death from iron toxicity has been reported with a wide range of doses, from 60 to 300 mg/kg. Ingestions of 20 to 60 mg/kg may or may not produce symptoms of serious toxicity and require other historical factors in making a decision regarding triage and referral. In a retrospective study of iron ingestions in children, 28% of 380 children who ingested 40 to 60 mg/kg of iron had symptoms of vomiting, diarrhea, and abdominal pain that resolved.¹⁷ A retrospective review of 199 acute iron exposures revealed that only a small percentage of patients who ingested between 40 and 60 mg/kg of iron developed clinical symptoms (vomiting, diarrhea, abdominal pain), and no one developed serious toxicity.¹⁸ No patient in this study who ingested between 20 and 60 mg/kg of elemental iron had a serum iron level of more than 385 µg/dL, and no one developed serious manifestations. Adult and adolescent overdoses should be considered as intentional and require immediate referral regardless of the dose assessment.

DIAGNOSIS

The relative infrequency of deaths associated with the large number of iron exposures suggests that a wide range of clinical toxicity exists in iron poisoning.

Evaluation, diagnosis, and subsequent management of the patient requires a knowledge of the pathophysiology and clinical presentation as well as the factors that can guide in predicting the severity of toxicity. Acute iron poisoning is a clinical diagnosis, supported by laboratory data. It is unlikely that a patient who does not have clinical signs and symptoms within 6 hours of reported ingestion will develop iron toxicity. There are many ancillary diagnostic tests that can help to confirm the diagnosis, although none of these should be used independently to determine disposition and treatment. It is important to accurately interpret and understand the limitations of these diagnostic tests in assessing a patient with suspected or known iron poisoning.

History

An important component of the history is the type of iron formulation and amount of elemental iron ingested because the likelihood of iron toxicity can be predicted based on this information. Ingestions of children's multivitamins with iron are rarely associated with significant clinical toxicity and have never been reported to cause death. The content of elemental iron is relatively small (10–18 mg/tablet), and thus an enormous number of pills must be ingested for toxicity to occur. On the other hand, pure iron preparations that contain ferrous salts (found in prenatal vitamins and nonprescription iron supplements) contain significantly more elemental iron per tablet. Very few tablets can produce toxicity when accidentally ingested by a small child.

Determining the estimated amount of elemental iron ingested on a milligram per kilogram basis can help predict iron toxicity, thereby directing the triage and management of patients with unintentional ingestions. The reliability of estimating the number of tablets ingested depends on an accurate history, which may not always be possible in every scenario, assuming the worst-case scenario in estimating total number of pills available. When determining the potential dose of iron ingested, it is important to calculate the amount of *elemental iron* present in the iron preparation by multiplying the milligram amount of the preparation times the percentage of elemental iron in that preparation. For example, each 325-mg tablet of ferrous sulfate contains 20% (65 mg) elemental iron. Thus, if a 12-kg child ingests 15 325-mg ferrous sulfate tablets, the dose ingested is 15 tablets × 65 mg per 12 kg body weight = 81 mg/kg of elemental iron.

Laboratory Testing

SERUM IRON CONCENTRATION

Serum iron concentrations cannot always be correlated with the severity or the clinical stage of iron intoxication because it is the intracellular iron, not the free circulating iron in the blood, that is responsible for systemic toxicity. The serum iron concentration is useful in confirming an ingestion and may be useful in predicting serious toxicity only if blood samples are

drawn at the appropriate time. The most valuable time to assess potential toxicity with an iron concentration is 4 to 6 hours after ingestion because this time reflects the peak absorption for most preparations, with the exception of slow-release iron. A serum iron measured after this time may be “normal” and inappropriately interpreted as “nontoxic” in the presence of a potentially toxic ingestion because of the intracellular distribution of iron. If the time of the ingestion is unknown, serial iron concentrations should be obtained to determine the peak iron concentration.

Serum iron concentrations less than 300 µg/dL (4–6 hours after ingestion) are associated with little to no toxicity, concentrations greater than 500 µg/dL are associated with definite serious toxicity, and concentrations greater than 1000 µg/dL have resulted in death. Iron concentrations between 300 and 500 µg/dL may be associated with mild, moderate, or no toxicity. Such concentrations must be used in conjunction with the patient’s history and symptom complex to assess toxicity and the need for further intervention.

Iron concentrations are occasionally difficult to obtain on an emergency basis at many health care facilities. Thus, many studies have attempted to identify clinical symptoms and other laboratory data that would predict toxic iron concentrations. Invariably, these studies have been limited by their retrospective design and have not resulted in consistent identifiers. In one study, a white blood cell count greater than 15,000/mm³ or a serum glucose concentration greater than 150 mg/dL had a high positive predictive value identifying the child with an iron concentration of more than 300 µg/dL.¹⁹ Both parameters had very low specificity; thus, their absence did not exclude a high iron concentration. Vomiting was the most sensitive indicator for an iron concentration greater than 300 µg/dL. A subsequent study concluded that neither white blood cell count nor glucose concentration was accurate in identifying significant iron toxicity.²⁰ In a retrospective study of 92 children with iron poisoning, a serum iron concentration exceeding 500 µg/dL was associated with one single variable: coma.²¹ Concurrent coma, radiopacities on abdominal radiographs, leukocytosis, and an elevated anion gap had a positive predictive value of 100%, and the absence of all the variables had a negative predictive value of 95% for a serum iron concentration higher than 500 µg/dL. These studies highlight the importance of inability to use a single laboratory test to predict iron toxicity.

A serum iron concentration should be obtained from every patient who has a history of ingesting more than 60 mg/kg elemental iron as well as anyone with significant clinical symptoms or an intentional overdose. Serial iron concentrations may be necessary if the time of ingestion is unknown. Serum iron concentrations may be falsely low in the presence of deferoxamine (DFO) because this chelator interferes with the standard colorimetric and radioimmunoassay methods for iron measurement.²² When a patient is receiving DFO therapy, iron concentrations should be measured by atomic absorption spectrophotometry.

TOTAL IRON-BINDING CAPACITY

In the past, a serum iron concentration that exceeded the TIBC was considered an indication for chelation therapy and was believed to be a necessary laboratory test in the evaluation of the patient with iron poisoning. This was based on the assumption that the binding of iron to plasma proteins prevents any toxicity—when a serum iron concentration is less than the TIBC, there is little risk for toxicity. However, clinical experience has shown this maxim is untrue. No data have shown that iron toxicity only occurs when the serum iron concentration exceeds the TIBC. Also, TIBC measurements may be unreliable in the presence of excess serum iron or deferoxamine.^{23,24} An *in vitro* study demonstrated that adding iron to pooled serum resulted in an artifactual rise in the TIBC.²⁵ This same study showed that TIBC determinations varied substantially among different laboratories. Another study demonstrated that even though the TIBC increased and remained above the serum iron concentration in patients with iron ingestions, symptoms of iron toxicity still occurred.¹⁶ Because of the unreliability of the measured TIBC, this measurement is neither a useful nor a clinically indicated laboratory test in the evaluation of iron poisoning.

OTHER LABORATORY TESTS

Other laboratory studies that should be obtained in a patient with a significant iron ingestion include an arterial blood gas analysis; complete blood cell count; electrolytes, blood urea nitrogen, creatinine, glucose, and coagulation studies; serum transaminase determinations; and blood sampling for type and crossmatch.

Other Diagnostic Testing

ABDOMINAL RADIOGRAPHS

Because certain iron-containing preparations are radiopaque, an abdominal radiograph can be useful in confirming an iron ingestion and in determining the quantity and location of undissolved iron tablets in the intestinal tract (Fig. 72-1). However, the radiopacity of these tablets depends on the type of formulation and content of elemental iron. Thus, many liquid iron preparations and chewable vitamins with iron (which have low concentrations of iron) are not visible.²⁶ Also, the usefulness of the radiograph in determining the presence of iron pills may be limited if it is obtained more than 2 hours after the ingestion because the iron preparations may have dissolved and may not appear radiopaque despite their remaining in the GI tract. Thus, negative radiographs, especially 2 or more hours after ingestion, do not exclude iron overdose. Serial abdominal radiographs may be useful in determining the efficacy of GI decontamination.

Differential Diagnosis

The differential diagnosis should include infectious and metabolic etiologies for the GI symptoms and acid–base abnormalities. Similar clinical presentations from other

FIGURE 72-1. Abdominal radiograph of a 20-month-old child with a history of ingesting prenatal iron tablets.

poisonings include salicylates, theophylline, colchicine, organophosphates, arsenic, mercury, paraquat, and mushrooms. Fortunately, with pediatric ingestions, the history or abdominal radiograph confirms the diagnosis most of the time.

MANAGEMENT

Gastric decontamination, laboratory studies, and an abdominal radiograph are indicated for significant iron ingestions and clinical toxicity. For those unintentional ingestions between 40 and 60 mg/kg of elemental iron, the reliability of the history, reliability of the caretaker, and presence of clinical symptoms should dictate whether further diagnostic studies are necessary. Unintentional ingestions of less than 40 mg/kg of elemental iron require observation only (Fig. 72-2). Initial management should focus on ensuring an adequate airway, ventilation, and circulation. Hypovolemia and metabolic acidosis should be aggressively managed with isotonic fluid and bicarbonate.

Gastrointestinal Decontamination

Of major importance in limiting the severity of iron poisoning is preventing its absorption by removing as much as possible from the GI tract. Decisions regarding the optimal method for GI decontamination in iron ingestions are complicated by many issues. Many patients have already vomited, reducing the need for further gastric evacuation. This issue is addressed by obtaining an abdominal radiograph. Also, many adult iron preparations are too large to be removed from the holes in a gastric lavage tube, limiting the value of lavage in this setting. Finally, iron is not adsorbed by charcoal, increasing the overall importance of gastric evacuation efforts.

Gastric lavage with a large-bore orogastric tube may be indicated for intentional overdoses of iron and unintentional ingestions of more than 60 mg/kg of iron in those who have not vomited or who have visible pills in the stomach on abdominal radiograph. Normal saline is recommended as the lavage fluid. After lavage, a repeat abdominal radiograph should be obtained to assess the efficacy of gastric evacuation and determine whether further decontamination measures are necessary.

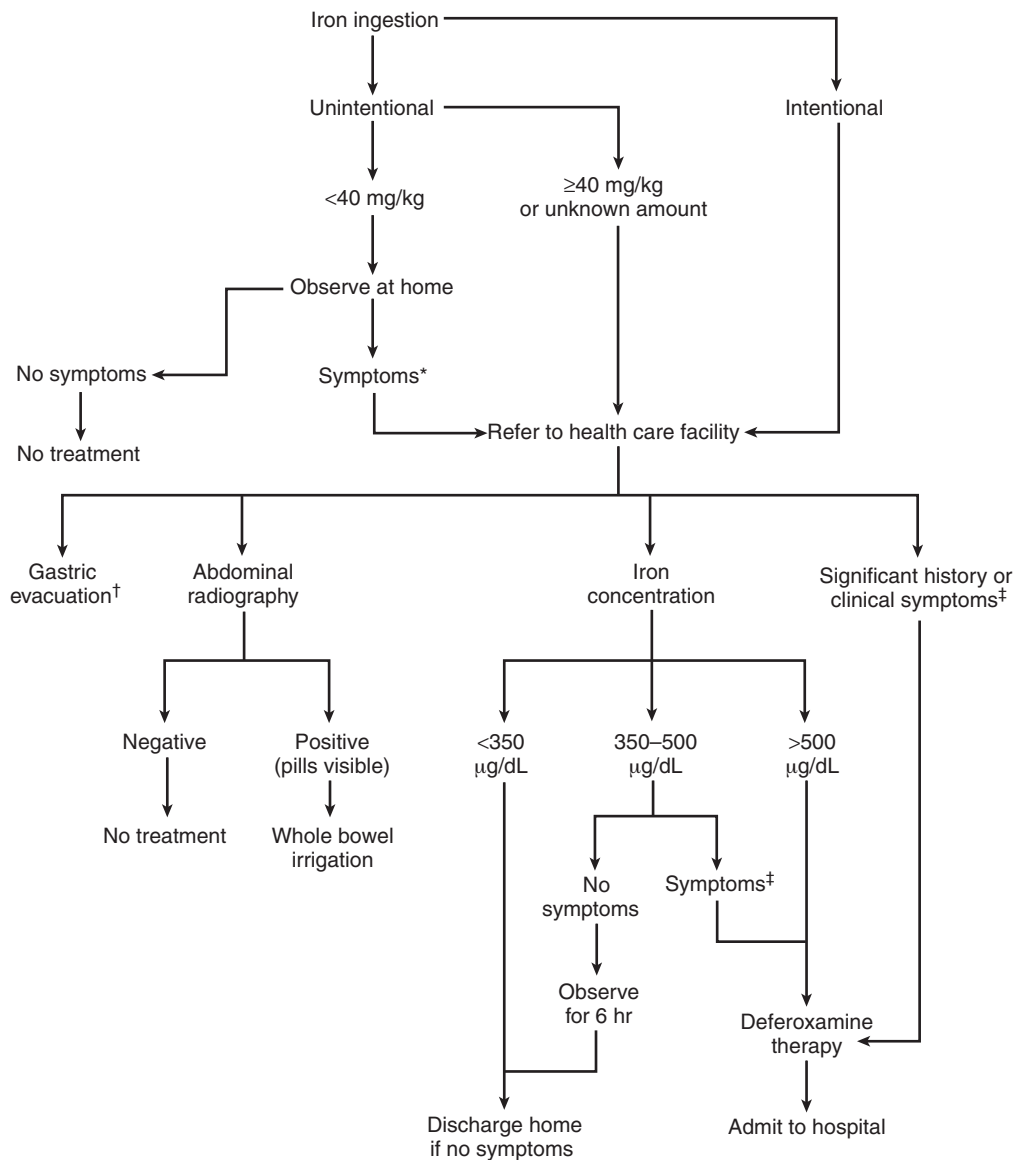

FIGURE 72-2 Algorithm for evaluation and management of iron poisoning.

*Persistent vomiting, diarrhea, hematemesis, abdominal pain, and lethargy.

†See text regarding indications for gastric lavage and whole bowel irrigation.

‡Persistent vomiting, lethargy, coma, hypotension, and metabolic acidosis.

The use of complexing agents in lavage fluid is an interesting historical issue in iron poisoning. Sodium bicarbonate and phosphate solutions have been used on the theoretical assumption that insoluble ferrous salts will be formed in the stomach, limiting iron's systemic absorption.²⁷ However, multiple human and *in vitro* studies have failed to demonstrate benefits from these solutions. Moreover, toxicity from administration of phosphate solutions (hyperphosphatemia, hypocalcemia, and hypernatremia) contraindicates their use.²⁸ Complexing iron in the GI tract using oral DFO as a lavage fluid has also been advocated. Although some human and animal studies have suggested benefit from enterally administered DFO, others have shown it does not substantially reduce the amount of iron available for absorption.^{29,30} Furthermore, some investigators have suggested that the iron–DFO complex ferrioxamine can be absorbed and contribute to increases in serum iron

concentrations; there is potential toxicity from the ferrioxamine compound as well.³¹ From a clinical standpoint, oral DFO is impractical because of the large volumes required in overdose to have any appreciable effect (100 mg of DFO will bind only 8 or 9 mg of iron). Thus, no agent has proven advantage over normal saline; these alternatives are therefore not recommended.

Other measures to decrease the GI absorption of iron have been studied. Animal studies have demonstrated a marked reduction of iron absorption after administration of oral magnesium hydroxide preparations such as milk of magnesia, in a dose five times the amount of elemental iron ingested.³² In addition, this solution may also provide a protective effect against the local corrosive effects of iron in the stomach and intestine. No human studies using magnesium hydroxide have been published. The use of an oral charcoal–DFO mixture has been shown in preliminary experimental studies to

effectively decrease the amount of GI iron absorption.³³ Further studies are needed with this combination before it can be routinely recommended for GI decontamination.

If iron tablets persist in the GI tract despite vomiting, or gastric lavage and serum iron concentrations continue to rise, whole bowel irrigation with a polyethylene glycol electrolyte solution such as Colyte or GoLYTELY should be initiated. Whole bowel irrigation is an effective method of GI decontamination, decreasing the passage time of iron through the GI tract and thereby reducing the time available for absorption.³⁴ Given the fact that iron preparations may not be completely removed by emesis or lavage, as well as the fact that iron is poorly adsorbed to charcoal, whole bowel irrigation is theoretically the most effective means of GI decontamination. Polyethylene glycol solutions should be administered at a rate of 2 L/hr in adolescents and adults, 1 L/hr in children, and 500 mL/hr in toddlers until the rectal effluent is clear and there is an absence of visible iron on abdominal radiograph. If vomiting occurs, administration rate should be reduced and then gradually increased to the desired rate.

Iron tablets may become embedded in the gastric wall, forming bezoars or pseudo-concentrations that are resistant to normal methods of decontamination. In such cases, endoscopy or surgical gastrotomy should be considered, especially when clinical toxicity persists.³⁵ Aggressive decontamination measures, in combination with supportive care and appropriate chelation therapy, should obviate the need for the surgical removal of iron tablets except in rare circumstances.

Antidote

Deferoxamine is a relatively selective chelator of iron produced by the organism *Streptomyces pilosus* and is the antidote of choice for serious iron poisonings. Guidelines for DFO's use, route of administration, duration of therapy, and dosing are not clearcut, although general recommendations can be gleaned from clinical experience and several studies^{30,31,36} (Box 72-1).

DFO combines with iron to form the iron-DFO complex known as ferrioxamine, which is then excreted through the kidneys. Ferrioxamine gives urine the classically described "vin rose" color, which actually is orange to reddish brown. DFO has a volume of distribution of 0.6 L/kg and a half-life of 10 to 30 minutes and is rapidly metabolized in the liver to inactive products. It binds iron in a 1:1 molar ratio, with 100 mg of DFO binding 9 mg of iron. Ferrioxamine has a volume of distribution of 0.2 L/kg. DFO binds circulating free iron in the ferric state. DFO also chelates ferric iron from ferritin and hemosiderin. DFO does not bind iron present in hemoglobin, myoglobin, transferrin, or cytochromes. However, there are other mechanisms that are probably responsible for DFO's protective effect; because it has a volume of distribution of 0.6 L/kg (indicating intracellular diffusion), it likely binds both cytosolic and intramitochondrial iron, preventing mitochondrial injury.

Indications for DFO chelation therapy are (1) peak serum iron concentration greater than or equal to

BOX 72-1

GUIDELINES FOR DEFEROXAMINE ADMINISTRATION, DISCONTINUATION, AND DOSING

Indications

1. Peak serum iron level ≥ 500 $\mu\text{g/dL}$, or
2. Significant clinical symptomatology: lethargy, coma, hypovolemia, metabolic acidosis, coagulopathy, or
3. Abdominal radiograph demonstrating significant number of pills despite attempts at gastrointestinal decontamination

Discontinuation*

1. Resolution of clinical symptoms
2. Absence of radiopaque pills (if present initially)
3. Return of normal urine color if vin rose-colored urine present initially

Dosing

1. Continuous intravenous infusion starting at 15 mg/kg per hour
2. May titrate dose according to severity of clinical symptomatology and development of hypotension (maximum infusion rate 30 mg/kg per hour)

*All three criteria should be present before deferoxamine is discontinued.

500 $\mu\text{g/dL}$; (2) significant clinical toxicity (i.e., severe GI symptoms, altered mental status, metabolic acidosis, hypoperfusion, cardiovascular instability); and (3) history of significant ingestion and an abdominal radiograph that demonstrates significant number of pills despite attempts at GI decontamination. Patients with peak iron concentrations between 350 and 500 $\mu\text{g/dL}$ must be evaluated for chelation therapy on an individual basis; the presence of significant clinical symptoms mandates treatment.

In the past, a positive DFO challenge test was proposed as an indication for chelation therapy, particularly in settings where iron concentration levels are not readily obtainable. This test was performed by administering an intramuscular dose of DFO and then observing urine for the vin rose color. The ability to detect this urine color change is subjective, is qualitative, and requires prechelation urine samples for comparison. Several studies had found this urine color change to be an insensitive marker for the presence of significantly elevated serum iron concentrations or serious iron poisoning.^{18,37} Thus, the absence of vin rose urine does not rule out severe iron toxicity. The DFO challenge test is therefore no longer recommended as a guide to determine the need for further chelation therapy.

Although DFO can be administered intravenously, intramuscularly, or subcutaneously, the preferred method for treatment of acute iron intoxication is a continuous intravenous infusion. Because of DFO's short half-life, the benefits of constant exposure to both the free circulating iron and the labile iron pool, this route is more advantageous. Intravenous administration of DFO has also been shown to be more efficient in removing iron than intramuscular administration.

DFO should be administered at a starting rate of 15 mg/kg/hr. There has been considerable debate about the maximum dose of DFO that should be administered. This results from concerns about DFO-induced hypotension and about its possible relationship to the development of adult respiratory distress syndrome.³⁸ Although the package insert states that the maximum dose should be 6 g/day, there have been numerous cases in which doses up to 35 to 45 mg/kg/hr or 16 to 20 g/day were administered to seriously ill patients without complications.³⁹ The limiting factor in DFO use is development of hypotension; dosing should be titrated according to patient response and the development of side effects. With severe intoxication, blood pressure support with fluid and vasopressors may be necessary to give high-dose DFO. Dosing of DFO is based on the amount of “free iron”; theoretically, then, higher doses should be administered in the first 24 hours. Some investigators have recommended intermittent boluses of DFO or an initial “loading dose” followed by a reduced infusion rate.⁴⁰ Adequate hydration before and during DFO therapy is necessary because acute administration of DFO may lower glomerular filtration rate.⁴¹

Duration of DFO therapy is variable, and published guidelines for discontinuing DFO therapy are vague, occasionally being misleading or unsupported by scientific data. Rational criteria for termination of DFO are (1) resolution of clinical signs and symptoms of systemic iron poisoning, specifically anion-gap acidosis and shock; (2) disappearance of radiopaque iron pills on repeat abdominal radiographs; and (3) return of normal urine color if vin rose urine was initially present. Some investigators had advocated use of a urine iron-to-creatinine ratio to determine the end point of chelation; however, this measurement needs further clinical validation and is unavailable in most clinical settings.⁴²

Potential adverse effects from DFO administration in acute iron poisoning are hypotension, rash, and *Yersinia enterocolitica* sepsis. Although the mechanism of hypotension is unknown, it may be caused by histamine release and is related to the rate of DFO infusion. The maximum rate of administration before hypotension develops is reported to be 45 mg/kg/hr; human reports have demonstrated infusion rates up to 35 mg/kg/hr without hypotension.⁴³ *Yersinia enterocolitica* sepsis has been reported in patients receiving DFO therapy.^{44,45} DFO acts as a siderophore, supplying iron to the bacteria and thereby increasing its virulence. Any patient presenting with fever, nausea, diarrhea, or pulmonary symptoms during or after DFO therapy needs an assessment of infection, including blood and stool cultures for this pathogen.

Continuous DFO infusion for greater than 24 hours has been associated with the development of adult respiratory distress syndrome.³⁸ However, the validity of this association remains controversial because iron poisoning itself has been reported to cause similar pulmonary sequelae. The mechanism of action for this adverse effect is postulated to be production of free radicals in the lungs after prolonged exposure to DFO. However, iron can also generate free radicals that are

capable of producing alveolar damage. The possibility of producing the adult respiratory distress syndrome in a patient with serious iron intoxication should not limit the use of DFO. Aggressive supportive therapy, careful monitoring, and appropriate discontinuation of DFO therapy should prevent this complication. One author has suggested administering the initial 24 hours of continuous deferoxamine infusion, followed by alternating 12 hours of DFO infusion with a 12-hour hiatus to allow for excretion of ferrioxamine.

The same guidelines for DFO administration should be applied to the pregnant patient without concern for adverse fetal effects from the DFO. Animal and human studies have demonstrated that neither toxic amounts of iron nor DFO cross the placenta.^{46,47} Fetal death results from maternal death, not from the effects of iron or DFO on the fetus.

A new oral iron chelator, 1,2-dimethyl-3-hydroxypyrid-4-one (L1, deferiprone) is being investigated for treatment in chronically iron-overloaded patients.⁴⁸ Oral deferiprone recently was shown to be effective in reducing mortality in a rodent model of acute iron poisoning.⁴⁹ Its safety and efficacy in human iron overdose has not been studied.

Elimination Enhancement

Extracorporeal methods for enhancing the elimination of iron have been studied, although their potential effectiveness is quite limited because they only remove free circulating iron and must be initiated before significant intracellular transport of iron has occurred. Exchange transfusion is theoretically useful in removing a larger burden of free and bound iron from the blood, although there are no data to support its routine use.⁵⁰ Because the volume of distribution of ferrioxamine is low (0.2 L/kg), hemodialysis is effective in removing it should the patient develop renal failure.⁵¹ Continuous arteriovenous hemofiltration has been investigated in experimental iron poisoning for removing ferrioxamine.⁵² None of these therapies has been shown to decrease morbidity or mortality of iron intoxication.

Disposition

Unintentional ingestions of less than 20 mg/kg elemental iron may be observed at home. Unintentional exposures in patients who develop no signs and symptoms after 6 hours and have no iron seen on abdominal radiograph may be discharged from the emergency department. Patients who intentionally ingest iron may be cleared medically if the above criteria are met and other medical evaluation for co-ingestants does not necessitate intervention. Patients who develop significant clinical toxicity, including severe GI symptoms, metabolic acidosis, decreased level of consciousness, hemodynamic instability, or serum iron concentrations higher than 500 µg/dL, should be monitored and treated in an intensive care unit.

At a Glance...

- Lead is a potent biologic toxin that possesses no physiologic benefit.
- Anthropogenic activity has placed enormous amounts of lead in the environment, resulting in almost universal exposure in humans.
- The major organ systems affected by lead are the brain, kidneys, bone marrow, skeleton, and reproductive tract.
- Lead is particularly harmful to young children, producing permanent effects to the brain and kidneys.
- Adults with lead poisoning can develop effects including emotional lability, memory difficulties, loss of libido, difficulty concentrating, and peripheral neuropathy.
- Treatment of lead poisoning in children consists of termination of exposure and nutritional supplementation; chelation therapy may also be necessary.
- Treatment of lead poisoning in adults consists of termination of exposure; chelation therapy is typically reserved for those with blood lead levels greater than 60 to 100 µg/dL.

Lead was once prized as one of the most valuable elements on earth. Because it has a number of highly desirable properties (low melting point, malleability, durability, low cost, octane-boosting), lead is ubiquitous in the environment. Both industrial and developing nations have found beneficial uses for lead. However, lead is also a potent toxin. In the past century, an explosion of scientific data has demonstrated the toxic effects of lead on the human body. This has been highlighted by the growing body of evidence that even small amounts of lead can produce permanent harm, particularly in young children. Lead poisoning (plumbism) is now considered one of the most common diseases of environmental origin.¹

This chapter reviews the toxicology of lead poisoning. Because of unique differences in the epidemiology, clinical toxicity, and treatment strategies of lead poisoning in adults compared with children, the chapter is later subdivided into lead poisoning in adults and then children.

HISTORY

Lead has been mined for thousands of years; the earliest recorded lead mine reportedly existed in Turkey in 6500 BC.^{2,3} Evidence of high lead use can be found in the skeletons of ancient Egyptians. By the Greek Bronze Age, lead was widely used in the manufacture of brass and cosmetics. Also, because lead geologically coexisted with silver, the mining of silver resulted in a marked increase in lead exposure. It is estimated that as long as 2200 years

ago, 25,000 tons of lead were produced annually.² Reflecting the increased use of lead over time, contemporary skeletons have bone lead concentrations 500 times higher than skeletons from ancient societies.^{2,4}

The fall of the Roman Empire is thought to have resulted from lead intoxication.^{3,5} During this era, lead-induced gout was endemic. Romans used lead in their plumbing (the word *plumbing* is derived from the traditional use of lead in water conduits), in their cooking utensils, and in the vessels that concentrated grape juice for wine. Lead was popular in wine because it enhanced color, wetness, and bouquet. The lead content of wine in the Roman era may have been as high as 15 to 30 mg/L. In fact, well into the 20th century, wines contained added lead. Lead poisoning was described at the same time that the metal became popular. Hippocrates wrote descriptions of lead colic. Similar descriptions have been recorded throughout history by Benjamin Franklin and others.

Initial interest in the illnesses caused by lead poisoning has been attributed to an 1839 publication by Tanquerel des Planches in which he described the clinical course of workers, primarily painters, who developed lead colic.⁴ In 1860, corresponding with the industrialization of Europe, epidemiologists described widespread reproductive toxicity in those with lead-related occupations as well as their spouses. In the 20th century, these occurrences, which were also being identified in the United States, led to regulations that protected workers from occupational exposure to lead. At an extreme, laws were passed to exclude women from lead-related occupations; the U.S. Supreme Court later reversed such laws.⁴

The increasing desire to reduce exposure to lead also resulted in legislation to protect not only workers but also the public at large from the hazards of lead exposure. Establishment of the Environmental Protection Agency (EPA) and passage of important laws including the Clean Air Act, the Clean Water Act, the Lead Poisoning Prevention Act, and the Housing and Community Development Act (Title X) all have served to dramatically reduce nonoccupational exposure to lead.

EPIDEMIOLOGY

Population Rates

The blood lead level of Americans has been monitored through the periodic conductance of the National Health and Nutrition Examination Survey (NHANES). The results of the most recent surveillance indicate that mean blood lead level has declined more than 80% since the performance of NHANES II (1976–1980), from 12.8 µg/dL to a current level of about 2 µg/dL.^{6,8} In

males, blood lead levels begin to rise in adolescence, continuing through most of adulthood, reflecting occupational exposure.⁹ In both elderly men and women, blood lead levels rise again, representing remobilization of lead as bone resorption occurs.

No particular blood lead level clearly defines lead poisoning in adults. In the past, the reference range for blood lead in adults was up to 60 $\mu\text{g}/\text{dL}$. The normal range is now considered to be less than 40 $\mu\text{g}/\text{dL}$. However, many clinicians continue to believe that lead poisoning in adults is defined only by the presence of clinical symptoms, not by any particular blood lead level. The increasing evidence of subclinical effects at low blood levels in adults argues for defining lead intoxication as a blood lead level of greater than 25 $\mu\text{g}/\text{dL}$.

Sources

Lead can be found throughout the environment. Exposure to lead therefore usually occurs from a number of sources (Fig. 73-1). Many of these sources are highly age dependent. For example, most (but not all) lead-based occupations expose adults but not children to excess lead. Although lead exposure can occur after a single event—for example, after inhalation of lead fumes during welding—it is usually chronic.

OCCUPATIONAL

In adults, the most significant exposures to lead usually occur in the workplace. The list of occupations associated with lead exposure is large (Box 73-1). Occupation-specific tasks including demolition, radiator repair, home remodeling, burning, blasting, firearm instruction (indoor and outdoor), grinding, and sanding all can result in frank lead poisoning.¹⁰⁻¹²

Occupational lead standards were introduced by the Occupational Safety and Health Administration (OSHA) in 1978 and have not been significantly revised.¹³ Under these guidelines, the permissible exposure limit for lead is 50 $\mu\text{g}/\text{m}^3$ for an 8-hour time-weighted average. Employers are responsible for maintaining proper working conditions, as well as for environmental and medical monitoring.¹³ Workers with blood lead levels of 60 $\mu\text{g}/\text{dL}$ or greater must be removed from the workplace; those with blood lead levels of 50 $\mu\text{g}/\text{dL}$ or greater on three occasions at 1-month intervals in the prior 3 months must also be removed from work. Those with blood lead levels of 40 $\mu\text{g}/\text{dL}$ or greater must undergo medical evaluation.¹¹ Employers are responsible for paying the salaries of employees who are removed from work for lead-related reasons.¹³ Because of the reproductive effects of lead at lower lead levels, recommendations have been made that the permissible blood lead level in workers be reduced to 10 $\mu\text{g}/\text{dL}$.¹

LEAD PAINT

Lead has been added to paint for centuries in order to make pigments more vivid, colors more stable, and the paint more durable. For the years that these beneficial properties were exploited, the addition of lead to paint was an industry standard. It is because of its durability under adverse weather conditions that lead-based paint became most popular in the northeastern United States. Interestingly, in Canada, which has even harsher climatic conditions, lead was banned from residential paint early in the 20th century. In the United States, however, lead was added to paint until 1978, when, in an effort to reduce lead exposure, particularly among young children, lead was effectively banned (restricted to a concentration of no more than 0.06%) from use in

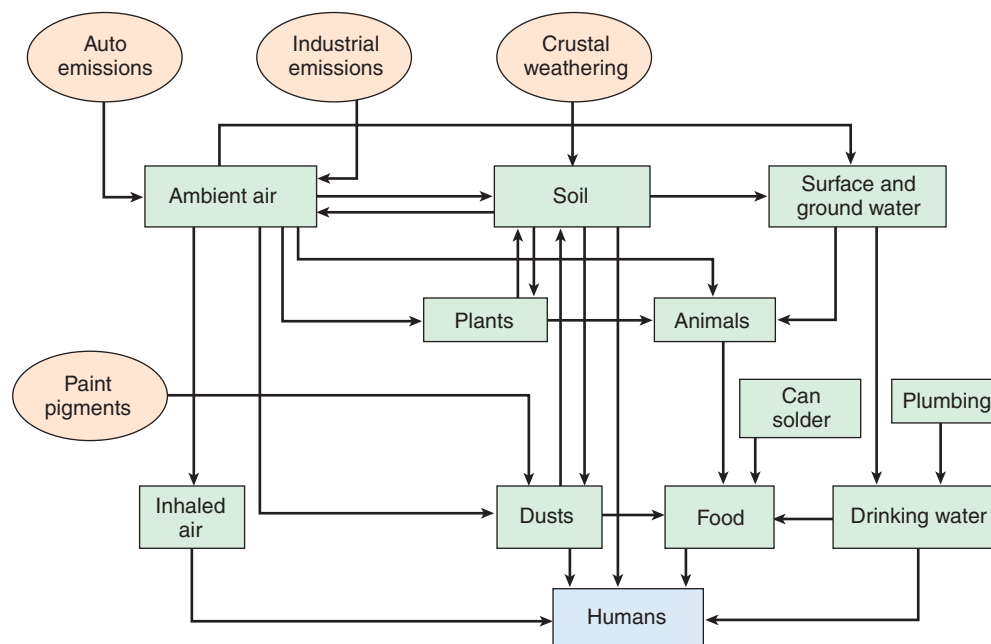

FIGURE 73-1 Sources and pathways of lead from environment to humans. (From U.S. Environmental Protection Agency: Air Quality Criteria for Lead. EPA-600/08_83/028aF-dF. Research Triangle Park, NC, Author, 1986.)

residential paint. Lead-containing paint is still used in nonresidential settings.¹¹ As a result of its extensive application, lead paint can be found in more than 38 million housing units in the United States.¹⁴

The presence of lead-based paint in homes has led to several problems. First, the natural decay of paint results in both chipping and the creation of lead dust. Also, when lead-containing homes undergo renovation of any type (e.g., scraping, demolition, window or wall removal), lead is released into the environment.¹⁵ Certain types of renovation, particularly paint removal with a heat gun, are extremely hazardous, resulting in the creation of highly toxic lead fumes.¹⁶ Even when homes are undergoing deleading in an effort to reduce lead hazards, improper techniques can result in lead poisoning in all family members.¹⁷ The EPA has established guidelines for safe levels of lead in household dust as follows: maximum lead concentration in uncarpeted floors, 40 $\mu\text{g}/\text{ft}^2$; interior window wells, 250 $\mu\text{g}/\text{ft}^2$; and window wells, 400 $\mu\text{g}/\text{ft}^2$ (www.epa.gov).

AIR

Industrial and automobile emissions are historically a major source of lead exposure. In the United States, leaded gasoline released more than 30 million tons of lead into the air before it was banned.⁴ The extent of airborne lead's contribution to lead levels is seen in the

effect of its removal from gasoline; when lead was phased out of gasoline in the 1970s, the mean blood lead of all Americans promptly declined by 35%. In the United States, the phase-out of leaded gasoline was completed in December 1995.

WATER

Water has become an increasingly important source of lead exposure, particularly as the contributions of paint, dust, food, and air diminish. Lead has contaminated many bodies of water as it has settled from the atmosphere. The increasing acidity of fresh water, due to acid rain, increases the solubility of waterborne lead. Soft water presents more of a lead hazard than hard water.¹⁸

Regulation of lead in public water supplies is the responsibility of the EPA. In a 1991 revision of the Clean Water Act, the maximum contaminant level of lead in water, which had been 50 parts per billion (ppb, $\mu\text{g}/\text{L}$), was replaced by an action level of 15 ppb. Under these new regulations, water suppliers must implement measures to reduce the level of lead in water if a significant number of homes are found to have elevated levels of lead.

Plumbing is an important cause of lead contamination in residential water. When public plumbing systems became widespread in the early 20th century, lead pipes served as the primary conduits directing water from public water sources into the home. In the 1950s, the use of lead pipes declined considerably. However, old public water systems continue to have extensive networks of lead pipe plumbing. Lead pipes have been largely replaced by copper or polyvinylchloride (PVC) pipes. The use of lead-based solder to join copper pipe joints was permitted until 1986. Therefore, homes with copper plumbing can be assumed to have lead in their water circuit. Because of the continued presence of lead pipes and copper pipes with lead solder joints, many cities in the United States have a high prevalence of lead-contaminated water.

Bottled water, which is under the regulation and oversight of the U.S. Food and Drug Administration, must have a lead content of no more than 5 ppb.

SOIL

Lead in soil can result either from its natural occurrence or contamination. The latter is responsible for most surface water lead in the United States. For example, studies of soil surrounding lead-emitting industries (e.g., smelters) have revealed soil lead concentrations higher than 60,000 parts per million (ppm, mg/L). In homes, lead contamination of soil occurs as painted exterior surfaces deteriorate.

Lead in soil is an important vector for human exposure. The EPA, in conjunction with the U.S. Department of Housing and Urban Development, has sought to reduce lead exposure through the development of guidelines on safe levels in soil. Under these standards, a safe concentration of lead in soil is considered to be less than 400 ppm.

HOBBIES

Certain household hobbies can result in lead exposure. These include any work that involves the use of solder

(which, when volatilized, produces highly absorbable lead fumes), the manufacture of fishing weights, and various aspects of artisanship. In the latter category, ceramic glazes occasionally contain lead. Although the use of lead glaze has been markedly reduced, it still occurs.

FOLK AND ALTERNATIVE MEDICINES

As discussed in Chapter 68, lead is sometimes found in alternative medicines, including Ayurvedic and folk remedies.¹⁹⁻²³ Dolomite, clamshell powder, and other calcium supplements may contain lead, particularly if their source is pulverized bone.²⁰⁻²⁸

FOOD

Food can be another source of chronic lead exposure. Lead enters the food chain through various routes. Vegetables, particularly homegrown vegetables that are grown in lead-contaminated soil, can introduce lead into the diet. Storage cans (“tin cans”) were previously manufactured with a lead-solder seam. This seam, coming into direct contact with food, could readily release lead, particularly into acidic foods. In some studies, the solder seam raised the lead content of food as much as 4000-fold. The use of lead solder for the seam was banned in November 1991.⁸ However, its widespread use has left many lead-containing cans still available.⁸ Also, cans brought from other areas of the world are likely to contain lead.

Kitchenware can also be a source of lead. Previous reports have identified frank lead poisoning from the use of lead-containing vessels. These include samovars (heating urns), plates, bowls, cups, pots, and containers made of pewter.²⁹

OTHER

Lead exposure can result from various types of substance abuse. First, the age-old practice of “moonshining”—that is, making illicit ethanol—has long been associated with lead poisoning from the use of lead-containing vessels such as discarded automobile radiators.^{30,31} Lead poisoning can be caused by sniffing leaded gasoline; this is one of the few causes of organic lead exposure. Finally, the synthesis of methamphetamine may involve lead acetate. Sporadic reports have described lead intoxication from the injection of lead-contaminated methamphetamine.

Lead absorption from retained bullets can occur in those with gunshot wounds.^{32,33} However, the kinetics of lead absorption from soft tissue have not been well characterized. For example, in animal models, lead appears to be poorly absorbed from muscle and fat; lead absorption from pleura and synovial fluid is most efficient.³⁴ Data from armed conflicts since the Civil War have documented lead poisoning in troops.³⁴

TOXICOKINETICS

Lead is variably absorbed after ingestion. Its absorption is active, mediated by the same mucosal transport

proteins that mediate calcium transport.³⁵ However, absorption is dependent on several factors, including the form of lead, particle size, gastrointestinal (GI) transit time, nutritional status, and chronologic age. Lead absorption is inversely proportional to size; the smaller the particle, the more complete the absorption. This is why exposure to lead dust results in higher lead concentrations than ingestion of an equal amount of lead from a paint chip.

Nutritional status is being increasingly shown to influence the extent of lead absorption. For example, iron deficiency results in increased lead absorption, probably because these atoms are linked to the same transport system.^{35,36} Iron deficiency also alters lead distribution within the body.³⁷ The prevalence of lead intoxication in childhood results, in part, from the relatively high incidence of iron deficiency in this population. Similarly, calcium deficiency is associated with increased lead absorption. High fat intake and inadequate calories have also been associated with enhanced lead absorption. Lead absorption is increased when the stomach is empty; small frequent meals reduce absorption, probably through lead binding by dietary phytates and other complexing agents.³⁵ Finally, lead absorption is inversely proportional to chronologic age. As a general rule, 30% to 50% of ingested lead is absorbed from the gut of a child, compared with less than 10% in an adult.^{11,35} This may be related to a higher density of intestinal transport proteins during periods of rapid growth.³⁵ Lead is also readily absorbed after inhalation of dust or fumes. Generally speaking, lead particles must be less than 0.5 μm to be absorbed from the respiratory tract.³⁸ Although inorganic lead is not absorbed through intact skin, organic lead compounds are.¹¹

After absorption, lead circulates in blood, having a half-life of about 30 days in adults.³⁹ However, half-life is related to the duration of exposure. Those with short-term exposure experience more rapid disappearance of lead from blood than those with long-term exposure.⁴⁰ In the blood, 95% of lead is attached to (or within) the erythrocyte; thus, it is *blood lead* and not serum lead levels that are measured. The volume of distribution of lead is unclear but is presumed to be large; only 1% to 5% of the body's lead burden is in the circulation.¹ Lead readily crosses the placenta; fetal blood lead levels are typically 30% to 35% higher than maternal blood levels.^{11,41-43}

The distribution kinetics of lead follows a three-compartment model. From blood, lead diffuses into soft tissues, including the liver, kidneys, bone marrow, and brain. This compartment is the primary site of lead's cellular toxicity. After a period that corresponds to a half-life of 1 to 2 months, lead diffuses from these tissues into bone. In bone, lead is incorporated into the hydroxyapatite lattice.¹¹ Lead is similarly incorporated into teeth. Once it is a part of bone, lead is presumed to be inert and nontoxic; however, this issue has been revisited as it becomes clear that conditions associated with bone mobilization (e.g., zero gravity, complete bed rest, medications, advancing years, and thyrotoxicosis) can also result in mobilization of lead.⁴⁴ Several researchers have described recurrent lead intoxication in children

with a prior history of lead intoxication when they suffer conditions producing bone mobilization.^{45,46} Concerns have been expressed that pregnancy, another state of bone resorption, can result in increased lead mobilization with the potential for fetal exposure to excess lead.⁴⁷⁻⁴⁹

Because of lead's incorporation into bone, most lead is retained in the body with very little elimination (in the absence of chelation); only about 30 µg/day is excreted by the kidneys.¹¹ Therefore, declining blood lead levels in those with lead poisoning not undergoing chelation represent only lead's distribution into soft tissues, not its excretion. In occupational monitoring, urinary lead excretion of less than 50 µg/g of creatinine is within normal limits. Lead's overall half-life is about 10,000 days (20–30 years).^{1,3,50}

MECHANISMS OF TOXICITY

The cellular mechanisms of lead's toxicity are multiple and involve many different physiologic actions. Lead is particularly toxic to enzymes, particularly zinc-dependent enzymes. The blood lead levels at which adverse health effects occur are variable (Table 73-1).

Organs most sensitive to lead's toxicity are the kidneys, hematopoietic system, and nervous system. In the kidneys, lead interferes with the heme-containing hydroxylase enzyme, which converts 25-vitamin D to 1,25-vitamin D, an effect that is reversible.^{11,51} In addition, a toxic action affects the renal tubules, producing a tubulopathy characterized by selective proteinuria. At blood levels as low as 40 µg/dL, lead produces dense intranuclear inclusion bodies in renal

tubules.¹ More advanced stages of lead nephropathy are associated with interstitial fibrosis, as well as tubular atrophy, with relative sparing of the glomeruli.¹

Lead has a high affinity for sulfhydryl groups, particularly those of metalloenzymes. Such enzymes include those in the heme synthetic pathway, particularly δ-aminolevulinic acid dehydratase, coproporphyrinogen oxidase, and ferrochelatase.⁴⁰ δ-Aminolevulinic acid dehydratase activity is inhibited at blood lead levels as low as 5 µg/dL.^{40,52} This results in accumulation of δ-aminolevulinic acid, a putative neurotoxin.^{43,53} Inhibition of ferrochelatase, which is responsible for incorporating iron into the porphyrin core, leads to elevated levels of erythrocyte protoporphyrin (EP).

Lead also affects neurotransmitter production.⁴⁸ This may be related to its ability to inhibit calmodulin, pyruvate kinase, and other enzymes essential to neuronal function. Many of lead's neurotoxic effects appear to result from its inhibition of cellular functions requiring zinc and calcium (which are also divalent cations).^{53,54} Lead interferes with normal calcium metabolism, causing intracellular calcium buildup; it binds to most calcium-activated proteins with 100,000 times greater affinity.⁴

LEAD POISONING IN ADULTS

Clinical Manifestations

Acute lead intoxication in adults is rare but can occur after high-dose respiratory exposure, such as use of a heating gun, acetylene torching of lead-coated metal, or organic lead exposure.¹¹ Acute intoxication can produce

TABLE 73-1 Significant Health Effects of Lead at Lowest Observed Blood Lead (PbB) Levels in Adults

LOWEST OBSERVED EFFECT PbB (µg/dL)	HEME SYNTHESIS AND HEMATOLOGIC EFFECTS	NEUROLOGIC EFFECTS	EFFECTS ON THE KIDNEYS	REPRODUCTIVE FUNCTION EFFECTS	CARDIOVASCULAR EFFECTS
100–120		Encephalopathic signs and symptoms	Chronic nephropathy		
80	Frank anemia				
60				Female reproductive effects	
50	Reduced hemoglobin production	↑ Subencephalopathic neurologic symptoms		Altered testicular function	
40	Increased urinary ALA and elevated coproporphyrins	↓ Peripheral nerve dysfunction (slowed nerve conduction)			
30					Elevated blood pressure (white males, ages 40–49)
25–30	Erythrocyte protoporphyrin elevation in males				
15–20	Erythrocyte protoporphyrin elevation in females				
<10	ALA-D inhibition				

ALA-D, δ-aminolevulinic acid dehydratase.

encephalopathy, severe GI upset, and renal failure. More commonly, lead intoxication results from long-term exposure.

Central nervous system (CNS) manifestations predominate in lead-poisoned adults. Signs and symptoms include fatigue, irritability, lethargy, insomnia, headache, difficulty concentrating, memory loss, and tremor.^{11,55} Other symptoms include myalgias, vomiting, constipation, and loss of libido.¹¹ Severe lead intoxication can result in an encephalopathy characterized by depressed consciousness, seizures, and coma, in association with cerebral edema. Life-threatening neurotoxicity usually develops with blood lead levels exceeding 150 µg/dL. Another CNS effect of lead poisoning is an abnormal auditory brainstem evoked potential.^{11,56}

Lead is also toxic to the peripheral nervous system, producing an axonopathy that results in motor disturbances.^{13,56} The distinctive pattern of lead-induced peripheral neuropathy affects the upper extremities more than the lower extremities, the extensors more than the flexors, and the dominant more than the non-dominant arm. Painter's wristdrop is a once-endemic syndrome of upper extremity paresis found in painters who regularly used or removed lead-based paint. The initial segmental demyelination eventually leads to injury of both the axon and cell body.³ Nerve conduction studies have shown that ulnar nerve conduction is disturbed at lead levels as low as 30 µg/dL.^{1,11,50,56}

The kidneys are a third major site of lead's clinical toxicity. After lead exposure, lead concentrations are highest in the kidneys, particularly in the proximal tubules. As a result, lead, like cadmium, produces a renal injury characterized by excretion of β_2 -microglobulin and *N*-acetylglucosidase.^{57,58} These proteins have been suggested as early markers of subacute lead-induced renal injury. Finally, chronic exposure to lead can result in hypertension; animal models suggest that hypertension results from disturbances in vasomotor tone.^{3,58-60}

Lead's effect on the hematopoietic system is one of its most described toxicities and has been used as a measure of its lead-induced physiologic dysfunction. *Basophilic stippling of erythrocytes, the precipitation of nuclear material, is a hallmark of severe lead exposure.* In fact, before laboratory techniques were available for measuring blood lead levels, the degree of basophilic stippling served as a diagnostic tool. Lead is also a potent suppressor of heme synthesis, producing anemia once lead levels exceed 50 µg/dL; the anemia can be either normochromic or hypochromic.¹

Lead's effects on reproduction are profound and multiple. For example, because of lead's diffusibility across the placenta, pregnant women with lead intoxication invariably have lead-poisoned offspring.⁴⁹ Also, because pregnancy is a condition associated with bone mobilization, women with a past history of lead poisoning may have elevated lead levels during pregnancy. Other reproductive effects of lead poisoning in women include a higher rate of spontaneous abortion and stillbirth.^{3,4,49} Lead is one of the few toxins in which paternal exposure is also associated with adverse reproductive outcomes.^{1,61}

Lead-poisoned men have decreased sperm counts and a higher number of abnormal sperm; these effects can appear at blood lead levels as low as 40 µg/dL.^{11,13,62}

Other complications of lead intoxication include hypertension, GI disturbances, mild liver function abnormalities, gingival lead lines (blue discolorations of the gingiva), muscle and joint aches, and gouty arthritis.^{3,11,63}

Assessment

The diagnostic evaluation of lead intoxication focuses on identification and quantification of those disturbances that can be readily diagnosed. The most important test is measurement of blood lead level. Because of lead's 30-day half-life and large volume of distribution, blood lead level is a relatively poor measure of total body burden; however, because blood is easy to obtain and provides useful information after recent exposure, blood lead determination remains valuable. Blood lead levels can currently be measured by a number of techniques, including atomic absorption spectrometry, anodic strip voltammetry, thermal-ionization mass spectrometry, and inductively coupled plasma-mass spectrometry (ICP-MS).⁴ All of these, when performed with appropriate quality control measures, are extremely accurate.

Because blood lead levels can be a poor representation of body lead burden, better methods of assessing lead exposure are being sought. With lead ultimately deposited in bone, and the skeleton serving as the primary in situ reservoir, diagnostic tools that measure lead in the skeleton are being developed. One of the most promising of these is x-ray fluorescence (XRF).⁶⁴⁻⁶⁶ XRF works by emitting x-rays at bone in order to activate electrons in valence shells, a process that produces energy that can be measured. L-line XRF stimulates electrons in the L electron shell, whereas K-line XRF acts only at electrons in the K shell. The latter technique appears to have greater accuracy in assessing total bone lead concentration. Studies are demonstrating that XRF analysis of bone assesses body lead burden far more accurately than does blood lead determination. For example, Hu and colleagues showed that among carpenters with long-term lead exposure, lead burden as assessed by XRF correlated more closely with lead suppression of heme synthesis than did blood lead level.⁶⁶ Although promising, XRF has been difficult to develop in children because they have relatively little bone calcification and because lead incorporation into bone appears to occur at less predictable rates; however, the procedure has been used in several pediatric studies. XRF has the potential to replace blood lead measurement as a method of assessing lead exposure.

EP measurement remains important in the evaluation of lead exposure. Because it is not only the quantity of lead in blood that is important but also the effect of that lead burden on body function, EP measurement serves to provide information on lead's organ toxicity. EP is easily measured through hematofluorometry.²⁷ As a general rule, adults with lead poisoning have less EP disturbance than children. It is also notable that rises in

EP lag behind lead exposure by several days; therefore, if measured shortly after exposure, EP levels may not yet be abnormal.

Other laboratory tests useful in the evaluation of lead exposure include abdominal radiographs, renal function tests, complete blood count, and δ -aminolevulinic acid dehydratase activity. Abdominal radiographs are useful only if acute lead ingestion is suspected. Blood urea nitrogen and serum creatinine levels should be measured, and a urinalysis should be performed. Although investigators have suggested that *N*-acetylglucosidase can be used as a marker of lead-induced renal injury, the clinical utility of this test has not yet been proved. A complete blood count (CBC) serves to identify either preexisting iron deficiency anemia or lead suppression of hematopoiesis; also, basophilic stippling can be identified on blood smear.

Methods of assessing nervous system function after lead intoxication include measurement of auditory brainstem evoked potentials and nerve conduction velocity.⁶⁷ Lumbar puncture should not be performed in patients with altered mental status from suspected lead poisoning because the underlying cerebral edema can lead to herniation.

Treatment

Treatment of adult lead poisoning begins with cessation of further exposure. For those exposed in the workplace, OSHA standards must be implemented, if the business falls under OSHA regulations. Even for non-occupationally exposed adults (e.g., artisans or family members with lead poisoning due to home renovation), the primary intervention is prevention of further exposure.

CHELATION THERAPY

Parenteral Agents

Chelators are agents that form stable ligands with metal, effecting enhanced renal or biliary excretion of the drug–chelate complex. Many chelators have been discovered during the past century. However, it was only after the mid-20th century that chelation therapy flourished. More than five lead chelators have been identified.

The most important lead chelator developed is *dimercaprol*. This agent was created in England during World War II after the search for an antidote to the deadly arsenic-containing gas lewisite. The resulting antidote was an arsenic chelator termed *British antilewisite* (BAL). Since its creation, BAL has proved to be one of the most potent heavy-metal chelators.⁶⁸ In addition to lead, BAL chelates mercury, arsenic, and gold. BAL forms a stable dithiol bond with lead; the resulting complex is eliminated in both bile and urine.

BAL has a significant adverse effect profile; as many as half of those who receive this drug develop an adverse reaction. Part of this results from BAL's required preparation in a peanut oil vehicle; having such an excipient, the drug can only be administered intra-

muscularly. BAL has oxidant properties that can produce hemolysis in those with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Other adverse effects include hypotension, rash, vomiting, and a metallic taste in the mouth.⁶⁹ Toxic reactions occur when BAL is administered to those taking oral iron supplements.

BAL should be administered to any patient with encephalopathy or a whole blood lead level greater than 100 $\mu\text{g}/\text{dL}$.⁹ The dose is 4 to 6 mg/kg per dose (maximum 300 mg per dose). Because of its vehicle, BAL should not be administered to patients with a history of peanut allergy.⁶⁹

Another effective lead chelator is calcium disodium ethylene diamine tetraacetic acid (CaNa₂EDTA, *calcium edetate*). Developed in the 1950s, this chelator became an important intervention in the treatment of childhood lead intoxication. Like BAL, EDTA forms a stable bond with the lead atom. The resulting complex is excreted in urine. EDTA can be administered intravenously or intramuscularly; it is not administered orally, both because this route is less effective and because evidence suggests that oral EDTA can enhance GI absorption of ingested lead. EDTA has a very short half-life (about 65 minutes). As a result, it is ideally administered by continuous intravenous infusion. Alternative administration strategies include intramuscular or intravenous administration two to three times daily. The dose of EDTA given to adults is 1 to 2 g daily.

As with BAL, adverse effects of EDTA limit its use. EDTA chelates nutrients, particularly zinc, in addition to lead. Therefore, in order to avoid zinc deficiency, courses of EDTA are limited to 5 days, followed by at least a 48-hour hiatus for nutritional recovery. EDTA courses are also limited to minimize its nephrotoxicity (manifested by proteinuria, hematuria, or glycosuria).⁶⁹ A limitation of EDTA is its relative ineffectiveness with blood lead levels less than 30 to 35 $\mu\text{g}/\text{dL}$, which narrows its range of utility.

Oral Chelators

Oral chelators have been developed to permit outpatient therapy for those with significant lead intoxication. These include succimer and *D*-penicillamine. They are discussed in the section on childhood lead poisoning.

INDICATIONS

Because adults, compared with children, are considered relatively resistant to the toxic effects of lead, indications for chelation therapy are controversial. In occupational medicine practice, treatment of lead poisoning is typically reserved for symptomatic adults, independent of blood lead level. Therefore, chelation therapy is often withheld until blood lead levels exceed 70 $\mu\text{g}/\text{dL}$, the range at which adults typically develop overt signs of lead intoxication. In such patients, hospitalization for EDTA chelation is recommended. Experience with childhood lead poisoning has demonstrated that EDTA chelation can exacerbate CNS toxicity when it is used as sole therapy in those with blood lead levels greater than 70 to 100 $\mu\text{g}/\text{dL}$; this CNS toxicity probably represents EDTA

promotion of lead penetration into the brain. To prevent this, dual therapy with EDTA and BAL should be considered for adults with blood lead levels greater than 100 $\mu\text{g}/\text{dL}$. BAL can be discontinued once the blood lead level has fallen below the range of 70 to 80 $\mu\text{g}/\text{dL}$.

As the subclinical toxicity of lead becomes more appreciated, a growing opinion is that in adults, chelation therapy should be provided before overt clinical symptoms appear in order to prevent long-term sequelae, such as renal injury, as well as to reduce overall lead burden. Therefore, clinically asymptomatic adults can be considered candidates for chelation therapy even at lead levels of 25 to 40 $\mu\text{g}/\text{dL}$. Pregnant lead-poisoned women, unless their plumbism is severe, should not undergo chelation because of the possibility that the chelating agent will enhance lead movement across the placenta and be teratogenic.¹³

CHILDHOOD LEAD POISONING

History

The history of childhood lead intoxication is comparatively brief. Childhood lead poisoning was first reported in Brisbane, Australia, in 1899, when, after extensive epidemiologic investigation, A. J. Turner and J. L. Gibson associated the poisoning of young children with the ingestion of paint in their homes. Through the 20th century, increasing reports described catastrophic illness in children related to their ingestion of lead paint. Clinical features included basophilic stippling, abdominal pain, irritability, and often coma, seizures, and death. In 1943, Byers and Lord published a seminal article indicating that although childhood lead poisoning had been thought of as an illness that, among survivors, produced no obvious sequelae, many children suffered cognitive disturbances or frank mental retardation. Since that paper, many additional studies have reported that lead poisoning in children can lead to subnormal intelligence, hyperactivity, aggression, and school failure.^{4,70}

In the 1950s and 1960s, many areas of the United States were found to have endemic rates of lead poisoning. These so-called lead belts were synonymous with large inner-city slums.⁴⁰ This observation led to public outcries until, in 1959, the U.S. Public Health Service recommended that blood lead levels of 60 to 80 $\mu\text{g}/\text{dL}$ be considered evidence of increased lead absorption in children; levels below this were not thought to have any clinical effect.⁴⁰ In 1970, the Surgeon General reduced the level of concern to 40 $\mu\text{g}/\text{dL}$ and for the first time shifted the focus from case finding to prevention through mass screening for childhood lead poisoning. Mass screening was facilitated through passage of the 1971 Lead-Based Paint Poisoning Prevention Act.⁴⁰ In 1975, the Centers for Disease Control (CDC) began to establish classifications and risk categories for childhood lead poisoning. The blood lead level of concern was reduced to 30 $\mu\text{g}/\text{dL}$ in 1975, to 25 $\mu\text{g}/\text{dL}$ in 1985, and to 10 $\mu\text{g}/\text{dL}$ in 1991.

According to the 1991 CDC guidelines, the redefinition of childhood lead intoxication as a blood lead of 10 $\mu\text{g}/\text{dL}$ or greater was based on increasing scientific data indicating that toxic effects of lead were demonstrable at this level.^{40,71} Subsequent studies have suggested that neurodevelopmental harm can be demonstrated in children with blood lead levels below 10 $\mu\text{g}/\text{dL}$.^{72,73} The 1991 CDC guidelines also moved from a single definition of lead poisoning to a tiered approach that recommended interventions based on a range of lead levels.⁷¹

The most important preventive legislative action to occur was the banning of lead from residential paint in 1978. However, with decades of use, the problem of lead poisoning from exposure to paint and dust continues.

Epidemiology

Childhood lead poisoning is currently defined as a blood lead level of 10 $\mu\text{g}/\text{dL}$ or greater. The new classification of lead poisoning establishes degrees of lead exposure as a means of prioritizing interventions (Table 73-2).

Data from NHANES on the epidemiology of childhood lead poisoning indicate that the average lead level of American children is 2 $\mu\text{g}/\text{dL}$, which is 80% less than mean blood lead levels in 1976. This blood lead level represents “background” exposure, the sum of different environmental sources. An estimated 450,000 U.S. children have lead poisoning.⁷⁴ Childhood lead intoxication is more prevalent in minority groups and among those living in the Northeast. The peak onset of lead poisoning in children is the second year of life, although de novo lead poisoning can appear in later childhood years.⁷⁵ Refugee children and those adopted from foreign countries can have prevalence rates of lead poisoning as high as 10% to 15%.^{76,77}

As with exposure to lead in adults, childhood lead exposure can result from many sources, including lead paint or dust, air, soil, water, and food.^{4,40,71} However, there are significant differences in the etiology of frank lead poisoning according to age. For example, in children, lead paint and dust are the primary source of lead poisoning (in contrast to vocational or avocational exposure in adults). Also, children can develop congenital lead intoxication.^{41,78}

Lead paint remains the most common cause of lead poisoning in children.⁷¹ The singular importance of paint results from several factors: (1) lead-containing paint chips are relatively sweet; (2) the small size and color of paint chips make them attractive to curious young children; (3) containing up to 50% lead by weight, paint chips are a high-dose source of lead, capable of producing fatal degrees of exposure^{79,80}; (4) pica, or repeated ingestion of nonfood objects, is most prevalent in early childhood, and in infants, hand-to-mouth activity is a completely normal developmental process; (5) children are more likely to have their hands dirtied by dust from the window well, the floor, or outdoor soil⁸¹; (6) household renovation of homes with lead generally results in greater contamination of the environment, a particular risk factor for lead poisoning in infancy⁸²; and (7) even household deleading can

**TABLE 73-2** Interpretation of Blood Lead Test Results and Recommended Follow-up for Children

CLASS	BLOOD LEAD CONCENTRATION ($\mu\text{g}/\text{dL}$)	COMMENT
I	≤ 9	A child in class I is not considered to be lead poisoned.
IIA	10–14	Many children (or a large proportion of children) with blood lead levels in this range should trigger community-wide childhood lead poisoning prevention activities. Children in this range may need to be rescreened more frequently.
IIB	15–19	A child in class IIB should receive nutritional and educational interventions and more frequent screening. If the blood lead level persists in this range, environmental investigation and intervention should be done.
III	20–44	A child in class III should receive environmental evaluation and remediation and a medical evaluation. Such a child may need pharmacologic treatment of lead poisoning.
IV	45–69	A child in class IV needs both medical and environmental interventions, including chelation therapy.
V	≥ 70	A child with class V lead poisoning poses a medical emergency. Medical and environmental management must begin immediately.

From the Centers for Disease Control and Prevention: Preventing Lead Poisoning in Children. Atlanta, Author, 1991.

result in greater exposure to lead if not performed properly. Children who live with an adult who has a lead-related occupation are at greater risk for lead intoxication as a result of dust importation by the adult.⁸³

Exposure to lead in water has greater impact on young children because of their relatively small size, their greater daily water consumption, and the greater proportion of dietary lead absorbed by a child's gut. Lead poisoning from lead-contaminated water has been reported by several researchers.^{82,84} In all these cases, water was being used to prepare infant formula. Water can become highly contaminated if warmed or boiled in a vessel that contains lead.^{85,86}

Although soil has not been clearly associated with the development of lead poisoning, it clearly contributes to background lead levels in children. Also, in areas with highly contaminated soil (e.g., homes near smelter), children tend to have higher blood lead levels.⁸⁷ In a study of the impact of soil lead abatement on blood lead levels in children, Weitzman and colleagues⁸⁸ showed that elimination of lead in soil could effect a reduction in blood lead of about 1 $\mu\text{g}/\text{dL}$, an amount insufficient to justify large-scale soil abatement measures.

Other potential causes of lead poisoning in children include administration of folk remedies (e.g., greta, azarcon, or Paylooh), congenital exposure, and ingestion of foreign bodies.^{4,42,71,89} A reported case of fatal childhood lead intoxication (blood lead level, 283 $\mu\text{g}/\text{dL}$) occurred after a child ingested a lead curtain weight, which was retained in the GI tract for several weeks.⁹⁰ Finally, lead intoxication has been reported in newborns who receive a blood transfusion from lead-poisoned donors.^{91,92}

All children are not at equal risk for lead intoxication; rather, it is the unique relationship between the individual child and his or her environment that results in lead exposure. This explains the common phenom-

enon of one child's developing lead poisoning while living in a house that contains lead, although other children in the same environment do not have increased lead exposure. The most important risk factor is generally the oral habits of the child, particularly the presence of pica. Another risk factor for childhood lead poisoning is developmental delay. Children with significant delays—for example, those with autism—are more likely to develop lead poisoning.^{71,93-95} Moreover, the pattern of lead poisoning in these children has atypical features, including its appearance at an older age and the tendency for recurrent exposure, despite environmental hazard reduction.⁹⁶ Finally, for reasons that are not clearly explained, childhood lead poisoning is more prevalent in summer than winter.

Toxicokinetics

The kinetics of lead in children have not been extensively analyzed but are thought, with some exception, to parallel the kinetics in adults.⁴ However, certain differences have been well characterized. For example, the extent of lead absorption is greater in children than in adults (30% to 50% versus 10%). Also, nutritional factors have a greater role in the development of childhood plumbism. Inadequate intake of iron, calcium, and total calories, all of which are more prevalent in children, are associated with higher blood lead levels.^{35,96} After its absorption, lead is distributed through soft tissues before its deposition into bone. The half-life of lead in the soft tissues of children may be longer, probably because children have less bone available for lead incorporation. As with adults, the estimated body elimination half-life of lead is 20 years.

Lead toxicokinetics in the pregnant and lactating woman have significant effects on children.⁹⁷ During both pregnancy and lactation, women mobilize skeletal

calcium.^{47,98-100} In the process, lead is mobilized as well. Because lead freely crosses the placenta, the fetus invariably receives some amount of maternal lead, presumably in association with the degree of skeletal lead in the mother, reflecting her lifelong exposure. Maternal bone lead has been correlated with fetal neurotoxicity.¹⁰¹ Lead is also mobilized with calcium during lactation.¹⁰²⁻¹⁰⁵ However, several studies indicate that the amount of lead excreted into breast milk is negligible unless maternal blood lead level is greater than 40 to 50 µg/dL.^{106,107}

Clinical Toxicity

Although the mechanisms of toxicity for lead poisoning in childhood are similar to those in adults, clinical manifestations are different. Also, the lead level at which these toxic manifestations appear is lower in children (Table 73-3). Children, for example, are more susceptible to all of lead's neurotoxic effects.

Lead encephalopathy in children has presenting features that are comparable to the disease in adults. However, encephalopathy appears in children at blood lead levels as low as 50 to 60 µg/dL.^{40,108} Prominent features are irritability, anorexia, apathy, listlessness, abdominal pain, obtundation, and, if untreated, cerebral edema, seizures, and death.^{108,109}

The CNS effects of lead have caused the greatest concern about childhood plumbism.^{40,71,110} Exposure to lead during critical periods of neurodevelopment can produce permanent changes in cerebral architecture. The mechanisms of these changes have been described by Goldstein, Silbergeld, and others^{53,111}; During the first 2 years of life, synaptic density and complexity are markedly increased such that by the third year of life, neuronal arborization exceeds the normal adult pattern

almost twofold.^{111,112} The enzymes that have an important role in mediating this process, including protein kinase C and calmodulin, are inhibited at very low concentrations of lead. Another critical factor in normal dendritic arborization is the activity of neural cell adhesions molecules; these proteins are also impaired by lead. The consequences of childhood lead exposure are thus reduced synaptogenesis and imprecise synaptic "pruning." Functional changes, including decreased neurotransmitter synthesis, also occur.^{53,111,112} The hippocampus is thought to be the primary anatomic site for these effects, this being an area with a high zinc content.⁴⁸ Severe lead exposure can disturb the integrity of the already immature, permeable blood-brain barrier of a child.^{40,113}

The clinical consequences of lead neurotoxicity are vast. At an extreme, children with severe lead intoxication can be left with profound cognitive disturbances (mental retardation). Estimates from several population-based studies are that children can lose about 5 points (95% confidence intervals ranging from 2 to 14) in intelligence quotient (IQ) for every 10 µg/dL elevation in their blood lead level.^{13,69,114-116} Although a loss of 5 IQ points is arguably insignificant in any child, the potential left shift of the normal distribution of IQ among children would result in greater numbers of children with low IQ and a reduction in the number of children with superior IQ.³⁸ It is this principle that has, in part, maintained public health momentum to reduce blood lead levels in children to the lowest range possible. Other adverse developmental outcomes in lead-poisoned children include aggression, hyperactivity, school failure, and antisocial behaviors.¹¹⁷⁻¹²³ Childhood lead poisoning has been associated with juvenile delinquency and even homicidal tendencies.^{124,125} Another

TABLE 73-3 Health Effects of Lead at Lowest Observed Blood Lead (PbB) Levels in Children

LOWEST OBSERVED EFFECT PbB (µg/dL)	NEUROLOGIC EFFECTS	HEME SYNTHESIS EFFECTS	OTHER EFFECTS
<10 (postnatal)	Deficits in neurobehavioral development		
10–15 (prenatal and postnatal)	Deficits in neurobehavioral development; electrophysiologic changes	ALA-D inhibition	Reduced gestational age and weight at birth; reduced size up to age 7–8 yr
15–20		Erythrocyte protoporphyrin elevation	Impaired vitamin D metabolism; pyrimidine-5'-nucleotidase inhibition
<25	Lower IQ, slower reaction time (studied cross-sectionally)		
30	Slowed nerve conduction velocity		
40		Reduced hemoglobin; elevated EP and ALA-U	
70	Peripheral neuropathies	Frank anemia	
80–100	Encephalopathy		Colic, other gastrointestinal effects; kidney effects

relatively common consequence of lead poisoning is the development of a learning disability in which overall IQ is normal by standardized testing but the child demonstrates discrete learning weaknesses such as impairment in memory, auditory processing, and visual-motor integration.^{70,115,126-128} Attentional weaknesses can give the appearance of attention-deficit hyperactivity disorder (ADHD).¹²⁹ These effects, which have been demonstrated in children with blood lead levels as low as 6 $\mu\text{g}/\text{dL}$, can persist through the preadolescent and adolescent years.^{72,73,119,121,122,130,131} Recent data suggest that there is the potential for some reversibility in lead neurotoxicity, challenging assumptions that all neurodevelopmental effects of lead poisoning are reversible.^{132,133} Some researchers believe that there is no clear evidence that lead poisoning causes learning problems in children.^{134,135}

Peripheral neuropathy can occur in children with lead intoxication¹³⁶; children with sickle cell disease may be at higher risk for this complication.^{136,137} Children can develop subclinical peripheral neuropathy at lead levels as low as 30 $\mu\text{g}/\text{dL}$.¹³⁷ Hearing is also significantly depressed by low levels of lead exposure^{138,139} (Fig. 73-2). Motor disturbances, including reduced scores on bilateral coordination, upper limb speed, and dexterity tests, may also occur.^{140,141}

Renal toxicity due to childhood lead poisoning includes impairment of vitamin D activation^{51,140,141}; this appears to be a reversible effect. A 50-year follow-up of lead-poisoned children suggests that they have a sevenfold greater risk for adult hypertension.

FIGURE 73-2 Fraction of children with hearing worse than a reference group stratified by quintiles of blood lead concentration, after adjustment for covariates. (From Schwartz J, Otto D: Lead and minor hearing impairment. *Arch Environ Health* 1991;46:300-305.)

Hematopoietic effects of lead poisoning in children include suppression of erythropoiesis with resulting anemia. Children are more sensitive to lead suppression of heme synthesis, as evidenced by their higher EP concentrations. However, the anemia that accompanies lead poisoning is sometimes cause rather than effect because iron deficiency results in greater lead absorption.⁷¹

Lead can disturb bone development, leading to the formation of growth arrest, or “lead lines.” Lead lines are best identified at the metaphyses of long bones, particularly the distal radius and proximal fibula. These lines generally appear 3 to 6 weeks after a period of significant lead exposure and generally correlate with a peak blood lead level of greater than 45 to 50 $\mu\text{g}/\text{dL}$.¹⁴² Childhood lead poisoning has also been associated with the development of dental caries.^{143,144}

Diagnosis

Assessment of children with known or suspected lead intoxication requires a careful physical evaluation that includes investigation of clinically overt signs and symptoms such as irritability and abdominal pain. The laboratory evaluation is an important adjunct. All children with lead intoxication should receive a venous blood lead and EP level, a CBC, measurement of blood urea nitrogen and creatinine, urinalysis, and measures of iron status (serum iron with total iron-binding capacity, serum ferritin, or reticulocyte hemoglobin). The need for radiographs should be individualized. If recent ingestion of lead-containing material is suspected, an abdominal radiograph should be obtained. Radiographs of the long bones can be useful as an assessment of timing and magnitude of exposure.⁷¹ In children with blood lead level less than 45 to 50 $\mu\text{g}/\text{dL}$, long bone radiographs are usually valueless. As a general rule, long bone films never alter clinical management.

Newer means of assessing lead burden are being explored. For example, the research use of deciduous teeth has the potential to be clinically valuable. Also, XRF in children may ultimately prove to have the same value that is being found in the assessment of adult lead intoxication.^{122,145}

Treatment

Treatment of lead intoxication in children focuses on three components, in descending order of importance: environmental inspection/hazard reduction, nutritional supplementation, and, if necessary, chelation therapy.^{71,146}

Whenever a child is found to have lead poisoning, its etiology must be identified. Unless the source is clearly known, a complete environmental inspection is necessary. This inspection is guided by data obtained from an environmental history, including previous lead tests of the child, the age and condition of the child’s housing, recent renovations, water intake, use of kitchenware that may contain lead, time spent elsewhere (including daycare, school, and relatives’ homes), occupations of adult family members, oral habits of the child, and

siblings or playmates with lead intoxication. The results of the history should guide inspection of areas that may include the home interior and exterior, water, and alternate housing.^{71,146} Inspections for lead are generally performed using either a sodium sulfide test (the reaction between this solution and lead produces gray-black lead sulfide) or XRF. The latter test is best able to detect lead paint that is covered by a nonlead surface. Interior home inspection should include dust wipings, especially when there are children younger than 1 year, who are more likely to have dust-laden hands because of their crawling. Household lead hazards, if found, should be reduced or fully abated (i.e., delead). In one study, deleading alone was shown to reduce blood lead levels by as much as 30%.¹⁴⁷ On the other hand, deleading has the potential to result in greater lead exposure if not conducted properly.¹⁴⁸ Therefore, it is important that work be done with minimal environmental contamination, with the family living elsewhere and with final inspection before reoccupancy. Methods of reducing without removing household lead hazards include use of trisodium phosphate detergent and the application of encapsulants, which are chemical polymers that effectively (albeit temporarily) cover lead surfaces.

Nutritional supplementation focuses on eliminating iron and calcium deficiency, both of which result in greater absorption of ingested lead.^{35,71,149,150} Because there are no consistently accurate measures of iron status in children,^{35,71} iron supplementation should be empirically initiated; iron sulfate elixir or drops can be prescribed in a dose of 3 to 6 mg/kg per day for a period of 4 to 6 weeks. Although evidence in animal models suggests that iron supplementation promotes the elimination of lead from the body, in human subjects, its only proven effect is reduction of further lead absorption.^{35,71} Calcium deficiency is uncommon in children who have a varied diet with regular milk intake. If there is any question about calcium intake, however, the diet should be enhanced with calcium-rich foods (e.g., yogurt, cheese, milk) or calcium supplementation should be prescribed.^{35,71} The combination of environmental abatement and nutritional supplementation is often sufficient to produce prompt reductions in blood lead level. However, the diminution in blood lead level may not be sufficient or may not occur rapidly enough to reduce the risk for multisystem injury. In these cases, chelation therapy is warranted.

Chelation Therapy

Chelation therapy for lead intoxication was initially developed to reduce the mortality associated with childhood lead poisoning. Increasing emphasis is being placed on its use to prevent morbidity as well. Therefore, although the same agents are available for both adults and children with lead intoxication, the greater focus, particularly the development of oral chelators, has been directed to pediatric treatment.

Increasing options in both parenteral and oral chelation therapy have brought into question the indications for hospitalization of lead-poisoned children. Decisions

for hospitalization should be individualized. However, the goals of hospitalization are at least threefold: (1) to provide environmental protection so that the child has no further lead exposure, (2) to provide close monitoring for evidence of clinical toxicity, and (3) to provide aggressive chelation therapy.⁶⁰ With these principles, hospitalization should be considered for all children who are younger than 6 years and who have a blood lead level exceeding 45 to 55 $\mu\text{g}/\text{dL}$. Children who are hospitalized for lead intoxication should never be returned to the environment in which their lead poisoning occurred unless hazard reduction measures have been completed.

PARENTERAL CHELATING AGENTS

Parenteral agents for lead intoxication in childhood are BAL and EDTA. However, both of these agents are used in different fashions in the pediatric population. For example, because of the risk for CNS deterioration or death when EDTA alone is given to children with severe lead intoxication,¹⁵¹ dual therapy with both BAL and EDTA should be instituted for children with blood lead levels of 70 $\mu\text{g}/\text{dL}$ or greater.⁶⁹ EDTA is begun about 4 hours after the first dose of BAL. BAL is given every 6 to 8 hours until the blood lead level is less than 70 $\mu\text{g}/\text{dL}$. Adverse reactions and cautions are the same in children as in adults, although children appear to have a higher prevalence of febrile reactions.⁶⁹ BAL should be used cautiously in those with G6PD deficiency, and oral iron therapy must be discontinued. Peanut allergy is a contraindication to the use of BAL.⁶⁹

EDTA is given in a daily dose of 35 to 50 mg/kg per day (1000 to 1500 mg/m²). Although the agent can be given intramuscularly, intravenous administration is preferred because intramuscular EDTA is extremely painful and because brisk urine output, necessary to prevent EDTA nephrotoxicity, is better achieved with intravenous hydration. Because of EDTA's short half-life, continuous intravenous infusion is preferred; however, administration every 8 to 12 hours is an acceptable alternative. The duration of therapy is 3 to 5 days, depending on the blood lead level.⁶⁹ Thereafter, therapy is discontinued. A "rebound" blood lead level measurement should be obtained 2 to 3 days after the EDTA is discontinued for those in whom an immediate second course of EDTA chelation is anticipated. For others, a 2- to 3-week rebound level is obtained. Some degree of rebound, which represents redistribution of lead from soft tissues into blood, always occurs after chelation. Additional courses of EDTA may be necessary, depending on the degree of rebound. It is not uncommon for children with blood lead levels of 60 $\mu\text{g}/\text{dL}$ or greater to require two or more courses of EDTA.⁶⁹

Because not every child with lead intoxication has a gratifying response to EDTA chelation, particularly children with blood levels less than 45 $\mu\text{g}/\text{dL}$, the EDTA mobilization test was once a widely used method of identifying children who will benefit from chelation therapy.^{152,153} To perform the test, a child is given a single dose of EDTA followed by an 8-hour collection of urine, which is analyzed for total lead excretion. A positive mobilization test is considered a ratio of greater than 0.6

between the dose of EDTA administered (in milligrams) and the quantity of urine excreted (in micrograms). The lead mobilization test, although valuable, has shortcomings.^{69,154} First, it is difficult to collect 8 hours of urine in small children in the absence of catheterization, which is traumatic. Spilled or lost urine makes test interpretation difficult if not impossible.¹⁵⁵ The performance of the test is labor intensive and requires an 8- to 10-hour health care visit (or brief hospitalization).¹⁵⁶ Finally, there is little likelihood of a positive mobilization test result in children with blood lead levels less than 25 to 35 $\mu\text{g}/\text{dL}$.¹⁵³ Collectively, these factors have made the mobilization test relatively useless.⁶⁹

ORAL CHELATING AGENTS

Numerous oral chelating agents have been used or are in current use for the treatment of lead poisoning. The two most commonly used agents are D-penicillamine and succimer.

D-Penicillamine was fortuitously discovered in 1953 by Walshe¹⁵⁷ and, because of its copper-chelating ability, was quickly used in the treatment of Wilson's disease. Its efficacy at chelating lead initially resulted in suggestions that penicillamine be used to treat lead-exposed workers without their removal from work.

D-Penicillamine has unique, incompletely understood chelating properties.¹⁵¹ For example, it does not appear to be capable of forming stable bonds with the lead atom. Nonetheless, it does enhance urinary lead excretion, possibly by forming a heterocyclic ring (sulfur and nitrogen atoms binding the lead).¹⁵⁸ Like BAL, penicillamine is capable of chelating other metals, including arsenic and mercury.

The efficacy of D-penicillamine in childhood lead intoxication has been demonstrated in studies by Sachs, Vitale, Marcus, Shannon, and others.^{151,159-164} Data from these studies have shown that penicillamine can reduce blood levels, even in children with blood lead levels of 20 to 35 $\mu\text{g}/\text{dL}$. Blood lead levels as low as 3 $\mu\text{g}/\text{dL}$ can be achieved using this drug.¹⁶³ D-Penicillamine can be considered for children with blood lead levels in the range of 2 to 35 $\mu\text{g}/\text{dL}$.⁶⁹

D-Penicillamine is given in a dose of about 15 mg/kg daily.¹⁵⁹ Its use is initiated after baseline CBC. Available only in capsules or tablets of 125 and 250 mg, the tablets must usually be crushed or the capsules opened and placed in food or drink. Having an unpleasant odor and taste, penicillamine must often be concealed in juice or food. Because iron may decrease D-penicillamine absorption by as much as 65%, iron supplementation should be discontinued during penicillamine therapy.¹⁵⁸ The agent is given twice a day at home by the parents. During treatment, children must be monitored every 2 to 4 weeks for evidence of adverse effects. Monitoring laboratory tests include CBC, urinalysis, blood lead, and EP determinations. Typical courses of D-penicillamine therapy are 2 to 3 months in length.

Penicillamine has an overall adverse effect rate of 5% to 10%, a rate that has led to considerable reluctance to use it. The most common adverse effect is GI upset.

More serious effects occur in about 7% of children and include rash white blood cell count depression. The occurrence of adverse effects should prompt discontinuation of therapy.¹⁵⁹ In all reported experience with D-penicillamine use for childhood lead poisoning in otherwise healthy children, these effects have been mild and reversible.

Succimer is an oral chelating agent that was discovered in the 1950s; in 1991, it became the first oral chelating agent ever approved for the treatment of lead intoxication.^{158,165-167} An oral congener of BAL, succimer has, interestingly, not been approved for adult lead intoxication, in part because of the ever-present risk for its abuse by workers, employers, or physicians.¹⁶⁸

Succimer has been approved for use in children with blood lead levels exceeding 45 $\mu\text{g}/\text{dL}$. However, studies have demonstrated that its safety and efficacy extend to children with blood lead levels between 25 and 45 $\mu\text{g}/\text{dL}$.^{167,169,170}; it is therefore a therapeutic option for these patients. Although there is no clearly defined upper limit of lead level for which succimer can be used, it is prudent to use conventional, dual parenteral therapy (EDTA and BAL) in children with blood lead levels of 70 $\mu\text{g}/\text{dL}$ or greater.

Succimer is available in 100-mg capsules. The current treatment protocol is administration of 10 mg/kg per dose. For the first 5 days of succimer therapy, it is given three times daily. For the next 14 days, treatment is twice a day. A complete course of DMSA chelation is therefore 19 days. An alternative regimen is 10 mg/kg/dose, given twice a day for 28 days. Adverse effects associated with succimer, which occur in about 5% of patients, include rash and minor elevations in hepatic transaminases; monitoring should include periodic liver function testing.^{158,162} Succimer, unlike BAL, does not produce hemolysis in those with G6PD deficiency. Also, succimer can be administered concomitantly with iron therapy. Mean reductions in blood lead with succimer are as great as 70% to 80%.^{158,165,166} However, in contrast to penicillamine, succimer discontinuation is followed by a robust rebound in blood lead level, appearing 2 to 4 weeks after completion of therapy. It is not unusual to experience rebound lead values that approximate the pretreatment value. As a result, multiple courses of succimer are usually necessary to produce enduring reductions in blood lead levels. Because lead rebounds can be confused with reexposure to lead, it is important to monitor EP levels. Lead reexposure is associated with increases in EP values; lead rebound is not.

Additional agents that have been used for the treatment of lead intoxication are dimercaptopropane-sulfonate (DMPS) and trientine.^{171,172} Neither of these agents has moved beyond the investigational stage.

INDICATIONS AND GOALS FOR CHELATION THERAPY

The indications for initiating chelation therapy in children are controversial. For children with blood lead levels of 10 to 20 $\mu\text{g}/\text{dL}$ (the majority of lead-poisoned children in the United States), chelation therapy is not

recommended, primarily because it is difficult to identify a single source of lead to abate and because for lead levels in this range, the risk for adverse effects from chelation therapy may outweigh the potential benefits.⁷¹ Instead, education, hazard reduction (if a lead source is found), and nutritional supplementation are provided. For those children with blood lead levels of 20 µg/dL or greater, consultation with a lead specialist is recommended.⁷¹ Among these children, chelation therapy should be considered. The decision to begin therapy should be based on (1) evidence that the blood lead level is not declining despite environmental abatement and nutritional supplementation, (2) the age of the child (evidence strongly suggests that the most neurodevelopmentally vulnerable age is the first 24 months of life¹³¹), (3) evidence of biochemical disturbances (i.e., an elevated EP level), (4) the assumption that reducing lead burden does reverse some toxicity (e.g., renal and hematopoietic) and may reverse neurodevelopmental disturbances,^{53,132,173} and (5) the desire to reduce lead burden to prevent its deposition in bone, where recrudescence later in life could occur. In initiating chelation therapy, the goals of treatment must also be established. Although this is also an area of some controversy, it is rational to have a goal of reducing blood lead level to the range of 10 to 15 mg/dL, if not lower. This requires long-term treatment strategies and frequent monitoring.

In children with more serious lead poisoning (blood lead > 30 to 35 µg/dL), formal cognitive or neuropsychological testing should be performed to identify neurodevelopmental weaknesses and initiate remedial programs as soon as possible. Because these weaknesses are generally not identifiable with gross developmental assessment (e.g., the Denver Developmental Screening Test) and may not be evident in the first few years of life, formal testing is recommended after the ages of 4 to 6 years of age, with close neurodevelopmental monitoring through adolescence.¹⁷⁴

Prevention

Prevention of childhood lead poisoning has led to both primary and secondary prevention strategies.^{71,110,175} Primary prevention consists of environmental inspection and abatement before a child develops lead intoxication. Because the cost of identifying and abating all homes (or other sources) with lead is prohibitive, primary prevention efforts have been difficult to implement. However, federal and state legislation that includes lead notification before home renting or purchase is being passed to ensure safe housing. Other primary preventive measures, including lead removal from soil, were attempted in a pilot study by Weitzman and colleagues, with little success.⁸⁸

Prevention has focused primarily on secondary efforts. Under this philosophy, because lead poisoning is asymptomatic in its early phases, the goal is to identify children who have developed lead poisoning, in order to prevent their lead levels from rising further and to protect their siblings and playmates from lead exposure.

Secondary prevention forms the basis of routine lead screening in children.

Secondary prevention through screening initially consisted of capillary (fingerstick) measurement of EP levels. This test was used both because EP level rises with lead intoxication and because capillary lead tests are easily contaminated by lead on the fingertip, leading to a high rate of false-positive results. When the definition of lead poisoning was reduced to 10 µg/dL in 1991, EP screening had to be abandoned because EP does not consistently rise until blood lead level exceeds 30 to 35 µg/dL.¹⁷⁶ Therefore, with a desire to identify all children who have blood lead levels of 10 µg/dL or greater, the current recommendation is to measure blood lead only. Although capillary lead testing can produce false-positive results, making it less useful, it is an acceptable means of screening children if performed properly.^{177,178}

Another strategy for secondary prevention is universal lead screening. Because lead intoxication is present throughout the United States and there are no completely reliable means of case finding, recommendations have been that all children receive periodic lead screening, regardless of where they live or their socioeconomic status. This recommendation has been strongly criticized because it is costly and because, in many areas, its yield is extremely low.¹⁷⁷ Opponents believe that lead screening in areas that have a low incidence of lead poisoning are a financial waste.¹⁷⁹ Targeted screening—that is, screening of children thought to be at risk for lead exposure—may be a more cost-effective strategy.^{180,181} Selective screening, if used, should target siblings and close playmates of lead-poisoned children. Lead poisoning in domestic pets may signal lead intoxication in the child.¹⁸² Other children at risk for exposure include those with developmental delays, those with a history of foreign body ingestion or insertion, and those with a history of physical abuse.^{71,183-185} Risk assessment questions have been created by the CDC and other researchers to use in identifying children at risk for lead exposure.^{186,187}

74 *Arsenic and Arsine*

DAVID C. PIGOTT, MD ■ ERICA L. LIEBELT, MD

At a Glance...

- Acute inorganic arsenic toxicity is characterized by severe gastroenteritis, cardiovascular instability, seizures, acute respiratory distress syndrome, and renal failure.
- Survivors of acute inorganic arsenic toxicity develop peripheral neuropathy and Mees' lines.
- Chronic inorganic arsenic toxicity is characterized by sensorimotor peripheral neuropathy, pancytopenia, palmar and plantar hyperkeratoses, liver disease, and cancers.
- Seafood can contain large amounts of organic arsenic, a relatively nontoxic form.
- Laboratory diagnosis utilizing measurement of urinary arsenic concentrations supports the diagnosis; speciation to distinguish inorganic from organic arsenics is useful in identifying the type and source of arsenic.
- Treatment of arsenic toxicity may include the use of chelating agents—BAL, DMSA, or DMPS.
- Clinical signs and symptoms of arsine poisoning are abdominal pain, hematuria, and bronze-pigmented skin.
- Acute massive hemolytic anemia and renal failure characterize severe arsine toxicity.
- Treatment of severe arsine intoxication includes exchange transfusion.

ARSENIC

Introduction

Arsenic is a metalloid that exists in multiple forms—gaseous (arsine), organic, and inorganic (arsenite and arsenate). The name *arsenic*, which is derived from the Greek word *arsenikon*, meaning potent, has become synonymous with poison. The gaseous form, arsine, is the most toxic of arsenic species. Of the remaining forms, inorganic arsenate (pentavalent arsenic) and arsenite (trivalent arsenic) are the most toxic, while organoarsenical compounds (“fish arsenic”) are generally considered to have little toxicity.

Arsenic has had various medicinal and industrial uses throughout history, which have led to the recognition of both its acute and chronic toxicities (Box 74-1). It also has been a popular homicidal or suicidal agent, the result of its availability, low cost, and tasteless and odorless characteristics. For similar reasons, arsenic has been included on lists of possible chemical substances that could be used as chemical warfare agents by terrorists.

History

Arsenic and arsenic poisoning have been recurring themes in history and literature for centuries. Aristotle

referred to sandarach (arsenic trisulfide) in the 4th century BC. The first isolation of a free form of arsenic is generally credited to Albertus Magnus (c. 1206–1280), the famed theologian, philosopher, and scientist. The longtime use of arsenic and arsenical compounds in common household items has likewise been well documented. An arsenic-based pigment known as Paris green or Scheele's green was developed around 1775 by Carl Scheele, a Swedish chemist. It was used in paints, wallpaper, and fabrics (and also as an insecticide) until the end of the 19th century, when its toxic effects became known. Its bright green color was derived from a combination of copper arsenate and copper acetate.

The use of arsenical compounds for poisoning has also had a long and storied career. From the Borgias of the Middle Ages, who were rumored to have treated their unfortunate guests to arsenic-laced wine, to Napoleon, whose death has been argued by some to be the result of repeated arsenic poisoning, arsenic has long been the poison of choice for those bent on toxicologic malfeasance.

Famous epidemics of arsenic poisoning include the “Staffordshire Beer Epidemic” at the turn of the last century, the poisoning of a cohort of Japanese infants with arsenic-laced formula in 1955, and chronic arsenic poisoning in Singapore from a contaminated herbal preparation in 1972 and 1973. Millions of victims in India and Bangladesh have been chronically exposed to toxic levels of arsenic from their water supply and are suffering from arsenicalism.¹⁻³ This epidemic has been called the largest mass poisoning in recorded history. Recently, several incidents of mass arsenic poisoning have been reported, with the perpetrators adding arsenic to communal food or drink at public gatherings.⁴

Uses/Sources

Arsenic is an element that occurs naturally in the earth's crust. Environmental sources of arsenic include underground aquifers and volcanoes. Water coursing along geologic belts of arsenic (as in the Bangladesh epidemic) can become highly contaminated. The major source of environmental arsenic for the general population in the United States is food. In marine environments, inorganic arsenic can be made organic by microorganisms. The shellfish that ingest these microorganisms contain the highest concentrations of this nontoxic arsenic species in the form of organic arsenic or arsenobetaine. Other dietary sources of arsenic (usually inorganic) include grains, meats, and drinking water. The World Health Organization (WHO) guideline value for arsenic in drinking water is 0.01 mg/L.⁵ In 2002, the U.S. Environmental Protection Agency (EPA)'s rule for new standards for arsenic in drinking water became effective,

BOX 74-1 SOURCES OF ARSENIC**Inorganic Arsenic****Pesticides**

Insecticides
Herbicides
Fungicides/algicides
Wood preservatives (chromium-copper-arsenate)

Occupation/Sites/Industries

Smelting/mining of nonferrous ores (copper and gold)

Etching
Lead plating
Microchip processing

decreasing the maximum contaminant level (MCL) from 50 ppb to 10 ppb in public water systems.⁶ Water systems must meet this standard by January 2006. This change is estimated to prevent between 19 and 31 cases of bladder cancer and 19 to 25 cases of lung cancer each year as well as numerous cases of skin cancers and heart disease. However, it is still projected to lead to a cancer mortality rate as high as 1 per 100,000 people.

For centuries arsenic has been used for medicinal purposes. In the 1800s, Fowler's solution (1% potassium arsenite) was used to treat a variety of infectious and malignant diseases. In the past it was also used as a treatment for syphilis. It is still prescribed for African sleeping sickness (melarsoprol). In 2000, arsenic trioxide (Trisenox) was U.S. Food and Drug Administration (FDA)-approved as a chemotherapeutic agent for acute promyelocytic leukemia.

Industrial sources and uses of arsenic are numerous. It has been used in agriculture as an insecticide,

herbicide, defoliant, fungicide, and growth regulator. It has also been used as rat and ant poison. Arsenic is used in metallurgy for hardening alloys of copper and lead, as a dopant in semiconductor production, and in the manufacturing of pigments for paints, ceramics, and some types of glass.

Until recently, the most common use of arsenic in industry was as a wood preservative in combination with copper and chromium (copper chromium arsenate, or CCA). CCA protects wood from rotting due to insects and fungi, greatly extending the wood's life span. It has been used to pressure-treat the lumber used for decks, picnic tables, and playground and other outdoor equipment since the 1930s. Burning and sanding of arsenic-treated wood has resulted in clinical toxicity.^{7,8} In 2003, the EPA finalized an agreement to phase out use of CCA-treated lumber in residential settings; as of January 2004, pressure-treated wood containing CCA could no longer be sold in the United States for home use. However, industrial uses of treated lumber such as for guardrails and utility poles are still allowed.

In 2002, arsenic exposures (including arsenic-based pesticides) represented 1621 of the over 2 million total poison exposures reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System.⁹ Of these exposures, 519 were reported in children younger than 6 years of age. Of these 1621 exposures, 1290 were unintentional. Nine patients developed life-threatening symptoms; one death was reported. These data almost certainly underrepresent the total number exposures in this country, particularly those resulting from occupational and environmental sources.

Pharmacology

Arsenic compounds exist primarily in two chemical states: trivalent (As^{3+} , arsenite, the most toxic and carcinogenic) and pentavalent (As^{5+} , arsenate). The basis of toxicity for trivalent arsenic stems largely from its affinity for sulfur, particularly sulfhydryl group-containing cellular enzymes.¹⁰ Pentavalent arsenic compounds are less toxic but can uncouple oxidative phosphorylation via a process known as "arsenolysis." Organoarsenical compounds have no well-defined toxicity. However, organoarsenate toxicity has been reported in animals exposed to monosodium methyl arsenate, a common herbicide.¹¹

Trivalent arsenic inhibits the conversion of dihydrolipoate to lipoate in the pyruvate dehydrogenase reaction, resulting in decreased production of acetyl coenzyme A, an essential cofactor in the ATP-generating Krebs cycle (Fig. 74-1). Through its affinity for sulfhydryl groups, trivalent arsenic interferes with multiple other cellular enzymes. It blocks the production of glutathione, an important endogenous antioxidant, thereby subjecting cells to greater risk of oxidative damage.^{12,13}

The toxicity of pentavalent arsenic largely results from its *in vivo* conversion to trivalent arsenic. In addition, pentavalent arsenic has a molecular structure similar to that of inorganic phosphate; it therefore can substitute for phosphate in glycolysis and cellular respiration

FIGURE 74-1 Pathophysiological effects of trivalent arsenic, As(III). Trivalent arsenic interferes with the transformation of dihydroliipoate to lipoate, thereby inhibiting the formation of acetyl coenzyme A, an essential cofactor in the ATP-generating Krebs cycle.

processes. High-energy phosphate bonds are not made, leading to uncoupling of oxidative phosphorylation. Finally, adenosine diphosphate (ADP) binds to pentavalent arsenic, leading to the production of ADP-arsenate rather than the usual high-energy ATP molecule (Fig. 74-2).¹²

Pharmacokinetics and Toxicokinetics

The gastrointestinal (GI) absorption of most trivalent and pentavalent arsenic compounds dissolved in water exceeds 90%. Poorly soluble compounds, such as arsenic trioxide, are less well absorbed. The volume of distribution is 0.21 L/kg, with 90% being eliminated from the blood within 2 hours. For the remaining arsenic, a more gradual decline occurs, with a half-life of about 30 hours. Metabolism of arsenic is achieved primarily through its methylation. Pentavalent arsenic compounds are converted to the more toxic trivalent arsenic prior to their methylation. Trivalent arsenic undergoes methylation to monomethylarsenate and dimethylarsenate.^{12,13}

FIGURE 74-2 Pathophysiological effects of pentavalent arsenic, As(V), termed *arsenolysis*. Pentavalent arsenic can substitute for inorganic phosphate in the formation of ATP, instead creating the unstable byproduct ADP-arsenate and thereby decoupling oxidative phosphorylation, an essential process in cellular respiration.

Urinary arsenic excretion is rapid, with 46% to 69% of arsenic eliminated with 4 to 5 days. However, continued excretion can occur for weeks to months.^{14,15}

Dermal absorption is minimal unless arsenic is present in a lipid-soluble form or skin integrity is damaged; however, absorption can occur through the mucous membranes. The potentially fatal human dose of arsenic trioxide (arsenite) following an acute exposure is estimated to be between 1 and 4 mg/kg.

Special Population: Children

In the past several years, arsenic has been increasingly scrutinized as a poisonous substance because of concerns about the potential health risks to children who play on arsenic-treated playground equipment. When exposed to outdoor elements, especially acidic rainwater, the arsenic in CCA can leach out of the wood. Several studies have documented significantly higher concentrations of arsenic in the soil immediately under pressure-treated wood compared with control samples.^{16,17} In many samples, the concentrations were several-fold higher than state limits and EPA regulatory guidelines. Because of their normal hand-to-mouth activity, children can be exposed to high concentrations of arsenic from contaminated surfaces or soil over their lifetime, increasing their risk for cancer and chronic toxicity. Children's susceptibility to the toxic effects of arsenic may also be increased owing to differences in GI absorption; metabolism; higher body surface area, resulting in greater absorption per pound of body weight; higher respiratory rate; and different breathing zones. As mentioned above, commencing January 2004, the EPA no longer allows pressure-treated wood containing CCA to be used for residential applications. However, several thousand tons of existing lumber will remain on porch decks and playground equipment, and children will continue to be exposed.

Clinical Toxicology

Arsenic can affect nearly every major organ system and is also a well-known carcinogen.¹⁸ Trivalent arsenic compounds are known to cause tracheal and bronchogenic carcinomas, hepatic angiosarcomas, and various skin cancers, such as intraepidermal carcinomas, squamous cell carcinomas, and basal cell carcinomas.¹⁹ An increased risk of myelogenous leukemia has also been demonstrated after arsenic exposure.²⁰ Bladder, renal, lung, and liver cancers have all been associated with chronic internal exposure to arsenic-containing solutions or arsenic-contaminated drinking water.^{19,21}

The toxic effects of arsenic depend largely on the degree and duration of exposure. A single large exposure can produce rapid and even fatal effects; a smaller chronic dose of arsenic leads to delayed or gradual effects that occur over months to years (Table 74-1).

Acute arsenic toxicity usually follows ingestion, but significant toxicity can also be seen following inhalation or dermal exposure. Initial symptoms affect the GI tract, causing oral irritation and burning in the oropharynx

TABLE 74-1 Acute vs. Chronic Arsenic Toxicity

SYSTEM	ACUTE TOXICITY	CHRONIC TOXICITY
Central nervous	Confusion, delirium, encephalopathy, seizures	Encephalopathy, headache, seizures, psychosis, personality changes
Peripheral nervous	Peripheral neuropathy appears early	Sensorimotor neuropathy develops/persists
Cardiovascular	Hypotension, conduction delays (prolonged QT), dysrhythmias (bradycardia, ventricular fibrillation, torsades de pointes)	Prolonged QT _c and conduction delays
Gastrointestinal	Nausea, vomiting, intense thirst, watery or bloody diarrhea, abdominal pain, acute hepatitis	May be absent, stomatitis, cirrhosis, portal hypertension
Pulmonary	Cough, dyspnea, chest pain, pulmonary edema	Cough
Hematologic	Hemolytic anemia	Anemia, leukopenia, pancytopenia
Renal	Acute tubular necrosis, acute renal failure	
Otolaryngologic	Mucous membrane irritation, metallic taste	Laryngitis
Dermatologic	Mees' lines, transverse lines in hair	Hypo- or hyperpigmentation, hyperkeratosis (palms and soles), skin cancers, facial/peripheral edema, alopecia
Other		Multiple cancers, blackfoot disease

and esophagus, followed by nausea, vomiting, and severe diarrhea. This diarrhea has been described as analogous to the “rice water” stools associated with cholera. Hemorrhagic gastroenteritis may occur, or necrosis of the GI mucosa leading to perforation. Increased vascular permeability and endothelial damage with “third spacing” of interstitial fluid are characteristic; adequate volume resuscitation of patients suffering from acute arsenic exposure is essential but may not prevent a fatal outcome.

Central nervous system (CNS) symptoms may also occur, including seizures or acute encephalopathy. Encephalopathic symptoms may include headache, confusion, decreased memory, personality change, irritability, hallucinations, and delirium. Development of peripheral neuropathy due to axonal degeneration, as in other heavy metal exposures, can occur relatively rapidly after acute arsenic ingestion.²² Sensory symptoms predominate early in the course, with patients complaining of “pins and needles” primarily in the lower extremities. Progression of the neuropathy is characterized by numbness and tingling to absent sensation of pain, touch, temperature, and deep tendon reflexes in a stocking-glove distribution. Motor weakness may develop and sometimes progress to an ascending flaccid paralysis similar to Guillain-Barré syndrome. The peripheral neuropathy usually occurs within 1 to 3 weeks following exposure, but in one series, nine patients developed maximal neuropathy within 24 hours.²³

Cardiac dysrhythmias such as torsades de pointes and ventricular fibrillation have been described, as well as sudden bradycardia leading to cardiac arrest.²⁴ Prolongation of the QT interval has also been well reported. Multisystem organ dysfunction is described, with hepatic involvement leading to acute hepatitis and renal failure.²⁵ Fetal demise is a documented complication of acute maternal arsenic poisoning.²⁶

Less severe presentations of acute arsenic poisoning may result in persistent GI symptoms requiring hospitalization and intravenous fluid replacement. A garlicky breath odor may be present. Dermatologic

findings are not characteristic early in the clinical course of acute arsenic toxicity. However, transverse lines across the finger and toenails (Mees' lines) appear after 1 to 2 weeks and are one of the most characteristic signs of acute arsenic poisoning. Mees' lines do not appear after chronic arsenic exposure.

In chronic arsenic toxicity, the fulminant presentations associated with a single acute arsenic ingestion are not seen. Rather, the gradual development of skin pigmentation changes, palmar and plantar hyperkeratoses, GI symptoms, anemia, and liver disease are common.²⁷

Skin findings, such as hyperpigmentation and hyperkeratoses, are often among the first symptoms of chronic arsenic toxicity. Later, the development of skin cancers such as Bowen's disease (intraepithelial squamous cell carcinoma) is seen.²⁷ Hepatomegaly is a common finding in patients with chronic arsenic exposure.²⁸ Other hepatic abnormalities including cirrhosis and noncirrhotic portal hypertension have been linked to chronic arsenic exposure. Increased incidence of diabetes mellitus in arsenic-exposed populations has also been described, the result of arsenic's endocrine-disrupting effects.²⁹ GI volume losses as seen in acute arsenicalism are less common.

Arsenic has a deleterious effect on both red and white blood cell populations, leading to anemia, aplastic anemia, and agranulocytosis. Arsenic's adverse effect on white blood cell levels was first documented with the use of Fowler's solution on leukemia patients in the late 1800s; recently, arsenic trioxide (Trisenox, Cephalon, Inc., Frazer, PA) has surfaced as a potential therapy for patients with acute promyelocytic leukemia.^{30,31}

Chronic encephalopathy, headache, and peripheral sensorimotor neuropathy can be seen with long-standing arsenic exposure because arsenic is primarily a peripheral neurotoxin.³² Overt CNS toxicity, however, is rare. Chronic cough may develop. A syndrome of lower extremity vascular insufficiency (blackfoot disease) has been documented in Taiwanese populations exposed to elevated arsenic levels in well water.³³

Diagnosis

The diagnosis of acute or chronic arsenic poisoning is made primarily on the basis of history and clinical presentation. In cases of homicide or environmental exposure, the patient or health care provider may not even know that arsenic poisoning has occurred. Medical history taking should address the patient's home heating methods (burning of arsenic-treated wood in stoves or fireplaces); drinking water source; gardening, farming or forestry activities; use of folk, herbal, or homeopathic remedies; location of residence in relation to agricultural or industrial activities; diet; and occupational history. Physical examination may provide the characteristics as described above. The utility of laboratory diagnostic studies depends on whether the exposure is acute, chronic, or remote, with residual clinical effects such as cancers.

LABORATORY TESTING

Arsenic Levels

To interpret blood and urine tests accurately, it is important to understand the pharmacology of arsenic, particularly its metabolism and clearance, as well as sources of organic arsenic. The most useful test for confirming excessive arsenic exposure is a 24-hour urine collection and analysis. An elevated arsenic level confirms the diagnosis of arsenic exposure but not the type of arsenic; a low level does not exclude the diagnosis of arsenic toxicity. Normal urine levels of arsenic in an unexposed person should be less than 25 μg per 24 hours or 10 to 30 $\mu\text{g}/\text{L}$ of urine.³⁴ In infants and children, a 6- to 8-hour timed urine specimen can be substituted for a full 24-hour collection. Urinary levels of inorganic arsenic, both trivalent and pentavalent, peak within 10 hours and normalize as soon as 20 to 30 hours after ingestion. Levels of urinary methylarsonic acid and dimethylarsinic acid peak within 40 to 50 hours after ingestion and normalize approximately 6 to 20 days after ingestion.³⁵

In an emergency, a single urine void or "spot" urine may be collected as a substitute for a 24-hour collection. In these specimens, arsenic should be measured per gram of creatinine. Because creatinine excretion is so variable in children, a "spot" urine is completely unreliable. In one study, initial spot urine arsenic levels ranged from 192,000 to 198,450 $\mu\text{g}/\text{L}$ in patients with symptoms of acute toxicity.³⁶ Because urinary excretion of arsenic is intermittent, definitive diagnosis relies on finding a concentration of greater than 50 $\mu\text{g}/\text{L}$ arsenic, 100 $\mu\text{g}/\text{g}$ of creatinine, or a total of greater than 100 μg arsenic in a 24-hour urine collection, again taken in the context of the patient's history and clinical presentation. Urinary arsenic excretion varies inversely with the postexposure time period, but low-level excretion may continue for months after exposure. In one study of patients with arsenic-induced peripheral neuropathy, for 4 to 8 weeks' duration, patients had total 24-hour urinary arsenic measurements of 100 to 400 μg .³⁷

When seafood is ingested, urinary arsenic levels may transiently increase to 200 to 1700 $\mu\text{g}/\text{L}$.³⁸ Therefore, laboratory arsenic speciation into organic arsenobetaine

(predominant arsenic in seafood) versus inorganic levels is needed to determine the actual type and source of the exposure. Alternatively, patients can abstain from fish consumption for 1 week prior to testing; in this instance, all arsenic excreted can be presumed to be inorganic. All urine should be collected in metal-free containers. Most hospital laboratories do not routinely measure heavy metals; thus, it is important that specimens from acutely ill patients be sent to a reference laboratory.

A serum arsenic level is highly variable. It will usually be elevated in a recent acute exposure but is rapidly cleared after several hours. Serum levels of arsenic in unexposed persons are less than 3 $\mu\text{g}/\text{dL}$.³⁹ If there is a significant delay between ingestion and presentation, diagnosis of arsenic poisoning based on serum concentrations may be erroneous. Concentrations are often normal in cases of chronic toxicity.

Analysis of arsenic in hair or nails generally is not useful. Although arsenic may begin to accumulate in these areas within hours of exposure, these samples may also be contaminated by environmental deposition of arsenic. Analyzing pubic hair may be useful. Laboratories offering hair and nail analysis have demonstrated inconsistent results and fail to establish appropriate normal reference ranges.⁴⁰ However, such testing may be helpful to confirm exposure in populations.

Other Laboratory Studies

Because inorganic arsenic is radiopaque, an abdominal radiograph may demonstrate the material in the GI tract after an acute ingestion.⁴¹ The rapid absorption of arsenic may limit the usefulness of this test after several hours.

Other laboratory tests to include in the evaluation are a complete blood count with peripheral smear, seeking the presence of anemia, leukopenia, thrombocytopenia, and/or basophilic stippling⁴²; a chemistry panel that identifies renal insufficiency; liver function tests for elevated aminotransferases and bilirubin; and an electrocardiogram for prolongation of the QT_c interval and torsades de pointes. Urinalysis may show proteinuria, hematuria, and pyuria. Cerebrospinal fluid analysis in patients with CNS findings due to arsenic may be normal or exhibit mild protein elevation.³⁷ This is in contrast to patients with Guillain-Barré syndrome, who typically have an elevated protein concentration after the first week of the illness.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for inorganic arsenic toxicity depends on the particular symptom or combination of symptoms being manifested. Infectious gastroenteritis may mimic acute inorganic arsenic poisoning initially; however, the more prolonged course of clinical symptoms and persistent need for intravenous fluids with arsenic toxicity is atypical for most viral and bacterial enteric illnesses and should alert the health care provider to consider arsenic toxicity. Other toxic agents may present with acute GI symptoms (Box 74-2). Guillain-Barré syndrome and arsenic toxicity may present with very similar peripheral neuropathies,

BOX 74-2

Thallium
Lead

although the former is not associated with persistent GI symptoms. Peripheral neuropathies associated with diabetes, alcohol, thallium, and chronic lead poisoning should also be considered.

Management

SUPPORTIVE MEASURES

Acute arsenic toxicity can be life threatening and necessitates aggressive supportive therapy (Table 74-2). Hypotension should be treated with crystalloid fluids initially and may require blood products if GI hemorrhage is ongoing. Vasopressor and inotropic therapy may be necessary if fluids alone do not provide hemodynamic stability. All patients should be placed on a cardiac monitor and evaluated for cardiac dysrhythmias or conduction abnormalities. Ventricular tachycardia and fibrillation can be treated with lidocaine and/or

amiodarone, and defibrillation.^{24,43} Torsades de pointes can be treated with isoproterenol, magnesium, and/or overdrive pacing.

Patients with evidence of chronic arsenic toxicity should be removed from the arsenic source. If homicidal intent is suspected for hospitalized patients, visitors should be monitored closely and outside food forbidden.

GASTROINTESTINAL DECONTAMINATION

If radiopaque material is seen on abdominal radiograph, gastric lavage may be useful. However, its efficacy is likely to be limited because of rapid GI absorption of arsenic. Although arsenic poorly adsorbs to activated charcoal, it should be administered when there is suspicion for co-ingestants. Whole-bowel irrigation may be necessary to decontaminate the GI tract of any radiopaque material remaining after gastric lavage.⁴⁴ Continuous nasogastric suction may be important in removing arsenic resecreted in gastric or biliary secretions.⁴⁵ One study reported detectable arsenic in gastric aspirates of three patients 5 to 7 days following ingestion.⁴⁶

ANTIDOTES

Chelating agents are the antidotes for severe arsenic poisoning. Chelation therapy should be initiated as soon as possible if acute inorganic arsenic toxicity is suspected; organic arsenic exposure does not require chelation. For cases of suspected chronic toxicity, therapy can wait until laboratory verification of the diagnosis is made unless the patient's clinical status is deteriorating. Four chelating agents are available in the United States, each with their own efficacy and safety profile.

British antilewisite (BAL), or 2,3-dimercaptopropanol, has been the standard therapy for acute inorganic toxicity. BAL was developed during World War II because of concern that lewisite, a toxic dichlorovinyl arsenic-

TABLE 74-2 Treatment

TOXIN	SUPPORTIVE CARE	GI DECONTAMINATION	CHELATION THERAPY	TRANSFUSION	HEMODIALYSIS
Inorganic arsenic	Intravenous crystalloids Monitor for hypotension, dysrhythmias, seizures	Orogastric lavage (if radiopaque material is seen on abdominal radiograph) Whole-bowel irrigation until radiopaque material is gone Continuous nasogastric suction to interrupt enterogastric recirculation	BAL: 3 to 5 mg/kg IM every 4 hours <i>or</i> DMPS: 3 to 5 mg/kg IV (maximum, 250 mg) every 4 hours; 4 to 8 mg/kg PO every 6 to 8 hours DMSA: 10 mg/kg/dose PO tid for 5 days, then bid		Hemodialysis for renal failure
Arsine	Oxygen Intravenous crystalloids Red blood cell transfusion Monitor for hyperkalemia, oliguria/anuria, and dysrhythmias			Exchange transfusion for severe hemolysis/anemia	Hemodialysis for acute renal failure

containing vesicant, would be used as a chemical weapon. BAL was used clinically for the treatment of arsenical dermatitis caused by diphenylamine chlorasine and organoarsenical antisyphilitic agents.

BAL is a lipid-soluble dithiol chelator formulated in peanut oil; it can be administered only as a deep intramuscular injection. It binds to arsenic to form a BAL-thioarsenite compound that is readily eliminated by the kidneys. Case series have demonstrated that BAL is efficacious and can reduce mortality of acute toxicity if given early (i.e., within 6 hours of exposure). In one study of 15 patients with encephalopathy, all but one patient improved clinically within 24 hours of BAL initiation.⁴⁷ Some reports suggest that neuropathy can be prevented if BAL therapy is instituted within hours of ingestion, whereas others have found that BAL is not effective in treating the neuropathy.^{23,37,48} In these studies, however, treatment was not instituted in many patients until 4 to 6 weeks after ingestion.

Dosing for BAL is 3 to 5 mg/kg every 4 hours until the 24-hour urinary arsenic excretion is less than 50 µg/L or until another chelating agent is substituted. In some animal models, BAL appears to worsen arsenic toxicity by enhancing its redistribution in the brain.⁴⁹ Because BAL is lipid soluble, it may be more efficacious than DMSA and DMPS (see below), both of which are water soluble, in removing tissue arsenic.⁵⁰ Potential adverse effects of BAL include tachycardia, elevated temperature and blood pressure, nausea, vomiting, headache, burning sensation of the lips, and seizures. BAL can be administered parenterally to critically ill patients.

DMPS, or 2,3-dimercaptopropanol-sulfonic acid (Unithiol, Dimaval), is a water-soluble analog of BAL used in the treatment of mercury, arsenic, and lead poisoning. DMPS was first developed in the former Soviet Union in the 1950s but was not available outside that country until 1978, when it was approved in Germany for use in mercury and lead poisoning. Although not approved by the FDA, DMPS can be obtained for compassionate use through an Investigational New Drug (IND) Application Process from Heyl, a German pharmaceutical company. As of 2005, it is no longer distributed in the United States in bulk quantities for compounding.

Animal studies demonstrate that DMPS is equal to or better than DMSA and BAL in reducing toxic effects of arsenic.⁵¹⁻⁵³ It has also been associated with a reduction in tissue levels of arsenic in experimental animals and increased excretion of arsenic in human studies.^{54,55} One randomized clinical trial found that DMPS significantly improved clinical scores and urinary excretion of arsenic compared with placebo in 21 patients with chronic arsenicalism.⁵⁶ An additional case report found that DMPS administration was associated with recovery from severe arsenic-induced peripheral neuropathy.⁵⁷

DMPS can be administered by oral, intramuscular, or intravenous routes. The intravenous route should be reserved for those patients with a compromised cardiovascular or GI status (GI erosions) that would impair oral absorption. For severe acute toxicity, 3 to 5 mg/kg (maximum dose 250 mg) are given every 4 hours by slow intravenous infusion over 20 minutes. Once the patient

has been stabilized, oral DMPS, 4 to 8 mg/kg every 6 to 8 hours, is administered. Most of the reported adverse reactions to DMPS are allergic and include skin reactions (rash, urticaria), mucous membrane reactions, and elevated body temperature. Rapid intravenous administration may be associated with vasodilatation and transient hypotension. Although DMPS increases the urinary excretion of copper and zinc, this effect should not be clinically significant in patients without preexisting deficiency of these trace elements.

DMSA, 2,3-dimercaptosuccinic acid, is an oral analog of BAL and approved by the FDA for treatment of lead poisoning in children. Animal studies demonstrate that DMSA is equal or superior to BAL in urinary and fecal elimination of arsenic as well as decreasing concentration of arsenic in liver, kidneys, spleen, and brain.^{58,59} DMSA has been used successfully to chelate arsenic in humans.⁶⁰ The dimercaptan-arsenic complex is water soluble, resulting in significant excretion of arsenic. The optimal dosing is unknown, and some clinicians follow the treatment guidelines established for lead (see Chapter 73). If urinary concentrations of arsenic remain elevated, prolonged therapy may be necessary. DMSA may be substituted for BAL once GI injury has resolved and gut motility has returned in acutely ill patients. For patients with chronic toxicity, DMSA may be the treatment of choice if DMPS is not available.

D-Penicillamine is an oral monothiol chelator originally developed as a chelator for copper but useful for other heavy metal poisonings. It has been used as a chelating agent for arsenic poisoning, although little experimental evidence validates its efficacy.^{61,62} Animal models comparing D-penicillamine, BAL, DMSA, and DMPS found D-penicillamine ineffective in treating arsenic toxicity.⁶³ It should be used only when BAL, DMPS, and DMSA are unavailable. The recommended dose is 25 mg/kg dose (maximum, 1 g/24 hr) every 6 hours until the urinary arsenic is less than 50 µg/L/24 hours. Adverse effects include rashes, leukopenia, thrombocytopenia, and nephrotoxicity.

EXTRACORPOREAL ELIMINATION

Hemodialysis has been reported to eliminate arsenic at clearance rates ranging from 76 to 87 mL/min with or without concomitant BAL therapy.⁶⁴⁻⁶⁶ It may be an effective adjunctive therapy in patients with renal insufficiency and should be instituted for patients with renal failure.

DISPOSITION

Patients exhibiting symptoms of acute arsenic toxicity should be admitted to the hospital for supportive care and chelation therapy. Patients with cardiovascular instability and significant symptoms should be managed in an intensive care unit. Appropriate law enforcement should be notified if homicidal intent is suspected. It is imperative that the source of arsenic exposure be identified by public health officials so that reexposure does not recur after discharge. If the exposure was suspected to be occupational, a workplace evaluation should be undertaken along with notification of the

proper authorities. Long-term follow-up including physical therapy and rehabilitation may be necessary for patients with neurologic sequelae. Neurologic injury may be permanent.

ARSINE

Introduction

Arsine (arsenous hydride, or AsH_3) was identified in 1775 and its toxic properties discovered in the early 1800s when a German chemist died after inhaling the gas in his laboratory. It is the most toxic form of arsenic. Arsine is a colorless, odorless, nonirritating gas that is denser than air and has an odor of garlic. Arsine is produced when acids come into contact with arsenic residues or when water acts on metallic arsenide compounds. It is used as a dopant gas in the semiconductor industry. Occupational exposure may occur for workers involved in galvanizing, soldering, etching, lead plating, and computer microchip processing (see Box 74-1).

Pathophysiology

Arsine poisoning is characterized by rapid and fulminant hemolysis of red blood cells. Several mechanisms of red blood cell toxicity have been proposed.⁶⁷ Hemoglobin fixes arsine in a nonvolatile form within the red blood cell.⁶⁸ It has been suggested that the arsenic dihydride and elemental arsenic resulting from oxidation of arsine are the hemolytic agents. The inhibition of catalase by arsenic or arsenic compounds with the formation of hydrogen peroxide has also been proposed as a mechanism of hemolysis. Others have postulated that arsine depletes erythrocyte glutathione stores, resulting in cell membrane instability, thereby causing hemolysis.⁶⁹ Explanations of the mechanisms by which very low levels of arsine gas induce severe hemolysis remain speculative.

Many theories have been advanced to explain arsine nephrotoxicity.⁶⁷ Deposition of erythrocyte breakdown products in the renal tubules may result in renal failure. Necrotic renal tubules containing hemoglobin casts are characteristically observed in tissue specimens obtained at autopsy in cases of fatal arsine poisoning. Further impairment results from a decrease in renal perfusion that is inversely proportionate to the degree of hemolysis. However, severe tubular damage has been described in arsine poisoning in the absence of extensive hemoglobinuria. Thus, it is unlikely that the nephrotoxic effects of arsine are entirely due to the lysis of red blood cells and blockage of renal tubules by products of red blood cell breakdown. Limited experimental evidence suggests a direct toxic effect of arsine on the kidneys, perhaps by inhibition of renal tubular-cell respiration.⁷⁰

Cardiac effects, presenting as conduction disturbances, are most likely related to hyperkalemia as a result of massive hemolysis. Arsine may also exert direct toxicity on myocardial tissue.

Toxicokinetics

Arsine concentrations of 3 to 10 ppm for several hours have produced minimal symptoms, whereas exposure to 16 to 300 ppm for 30 to 60 minutes is dangerous.⁷¹ Inhalation of an airborne concentration of 150 ppm or greater may cause death within 30 minutes after exposure, while lengthy exposure to 10 to 50 ppm may still cause death owing to hemolytic anemia and renal failure. The U.S. Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) of arsine in an 8-hour time-weighted average is 0.05 ppm. The odor threshold of arsine is 10-fold greater than this limit. Following arsine absorption, the compound is oxidized to elemental trivalent arsenic and arsenous oxide, compounds known to be human carcinogens.

Toxicology

CLINICAL MANIFESTATIONS

The interval between arsine exposure and the onset of symptoms is variable, depending on concentration of the gas and duration of exposure. There usually is a delay of 2 to 24 hours. Clinical symptoms may include headache, malaise, weakness, dizziness, dyspnea, nausea, vomiting, abdominal and flank pain, and thirst. Excretion of dark-red urine frequently develops 4 to 6 hours after exposure. Bronzing of the skin that looks like jaundice may be observed 24 to 48 hours later. A unique triad of symptoms—abdominal pain, hematuria, and jaundice—has long characterized the clinical features of arsine poisoning.

Physical examination may reveal fever, tachycardia, tachypnea, and the peculiar bronze tinting of the skin and mucous membranes that is more often described as jaundice. Abdominal tenderness and rigidity, enlargement and tenderness of the liver, and costovertebral tenderness have been observed. A garlic odor may be present on the patient's breath or in the patient's sweat.

Acute renal failure may develop secondary to kidney damage by mechanisms described above. Oliguria or anuria may manifest before 72 hours. Renal failure is the usual cause of death in cases of lethal arsine poisoning. Pulmonary edema and congestive heart failure may occasionally occur. Electrocardiographic abnormalities have been noted. Delayed neurologic sequelae such as peripheral polyneuropathy and encephalopathy have been described.

Diagnosis

LABORATORY TESTS

The most characteristic laboratory finding of arsine poisoning is a Coombs' test–negative hemolytic anemia. Hemoglobin concentrations of less than 10 g/dL are not unusual. Reticulocytosis and leukocytosis are also observed. The peripheral blood smear may show red-cell fragments, ghost cells, anisocytosis, poikilocytosis, and basophilic stippling. It has been reported that unstained preparations of white cells demonstrate a blue-green cast to the nuclei.⁷² The red-cell fragility test is normal.

Serum bilirubin and lactate dehydrogenase are usually elevated.

Urinalysis may reveal hemoglobinuria and sometimes tubular casts containing erythrocytes and hemoglobin. Serum potassium usually is elevated because of hemolysis and decreasing renal function. Electrocardiographic findings may include high-peaked T waves, nonspecific ST-T wave changes, and various degrees of heart block. Chronic exposure to arsine gas may result in anemia, mild elevation in total bilirubin, and high concentration of urinary arsenic.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of arsine poisoning includes poisoning by other agents that cause hemolytic anemia, that is, potassium chlorate and stibine (antimony dihydride); infectious diseases such as leptospirosis and malaria; and the rare hematologic disorder paroxysmal nocturnal hemoglobinuria. Lead poisoning may mimic chronic low-level arsine exposure, since both may produce anemia and basophilic stippling.

Treatment

Decontamination must include removal from the environment where arsine exposure occurred, removal of clothing, and skin irrigation. Oxygen, intravenous crystalloids, and cardiac monitoring are included in the initial stabilization. The goal of further treatment for arsine toxicity is stopping the ongoing hemolysis and monitoring for renal failure.

ELIMINATION

Exchange transfusion is the only therapy that will remove the arsine-hemoglobin complexes and restore the red cell population without fluid overload.⁷³ It may be indicated when plasma free hemoglobin levels are greater than 1.5 g/dL or when exposure to high levels of arsine is suspected. Simple transfusion of packed red blood cells, however, may be adequate treatment for mild hemolysis. Hemodialysis is required for acute renal failure. Supportive care includes monitoring for hyperkalemia, urine output, and cardiac dysrhythmias. The role of urine alkalization and forced diuresis with sodium bicarbonate to minimize precipitation of hemoglobin and prevent kidney damage is controversial.

ANTIDOTES

The role of chelation therapy in acute arsine poisoning is unestablished. BAL therapy does not prevent or reduce hemolysis even when administered soon after exposure.⁷⁴ One published case of chronic arsine exposure reports that D-penicillamine was associated with resolution of clinical symptoms.⁷⁵ Unlike in acute inorganic arsenic poisoning, chelation therapy should not be used routinely for acute arsine poisoning.

DISPOSITION

Asymptomatic patients should receive basic decontamination and be observed for 4 to 6 hours. Because of the rapid and significant toxicity after exposure to arsine

gas, any patient with mild symptoms or a history of significant exposure should be admitted for observation and supportive care for a minimum of 24 to 48 hours. Patient with evidence of hemolysis should be admitted to an intensive care unit because of the potential for rapid and fulminant progression of hemolysis and the probable need for exchange transfusion.

Patients should have outpatient follow-up to monitor renal function and anemia. In addition, counseling and monitoring for the possible development of late-onset peripheral neuropathy and encephalopathy should be initiated.

ALAN H. HALL, MD ■ MICHAEL W. SHANNON, MD, MPH

At a Glance...

- Aluminum was responsible for dialysis-associated encephalopathy, which has largely disappeared due to elimination of aluminum from dialysate solutions.
- Ingested antimony may result in a cholera-like illness. Inhalation of stibine (SbH₃) gas may result in massive intravascular hemolysis.
- Soluble barium compounds may cause significant gastrointestinal symptoms and potentially fatal hypokalemia.
- Beryllium, an irritant in acute respiratory exposures, causes a systemic granulomatous disease that has a radiological appearance similar to that of sarcoidosis.
- Long-term exposure to bismuth salts may cause encephalopathy with characteristic EEG changes.
- Cadmium is responsible for a potentially fatal pneumopathy when inhaled as the oxide. In the 1940s in Japan, it was responsible for *itai-itai* disease, characterized by leg and low back pain, chest pain, and difficulty walking with severe, diffuse osteopenia and physical deformities.
- In its hexavalent form, chromium is a bronchial and nasal carcinogen. Chromium is also extremely irritant, causing nasal perforation, “chrome holes” in the skin, and pulmonary irritation with sometimes delayed pulmonary edema. It is toxic to numerous organs.
- Cobalt is cardiotoxic and has been responsible for beer-drinker’s cardiomyopathy due to its former use as a foaming agent in beer.
- Copper, an essential nutrient, has been associated with eye disease and cirrhosis of the liver in overdose.
- Gold, used in rheumatic disease, causes significant toxicity in skin and kidneys due to the formation of immune complexes.
- Magnesium is an essential nutrient. In overdose, central nervous system depression with lethargy, coma, neuromuscular paralysis, hypotonia, hyporeflexia, and ECG changes may be observed.
- Manganese is one of several metals (including zinc and copper) that are responsible acutely for metal fume fever. When chronically inhaled, it may cause a Parkinson-like syndrome.
- Nickel comes in numerous forms. It is a frequent cause of skin allergy. Like hexavalent chromium, nickel carbonyl is a nasal and lung carcinogen. Nickel carbonyl is a gas encountered in the petroleum industry and may be rapidly fatal.
- Acute selenium poisoning may result from ingestion of gun bluing solution. Death may ensue rapidly, associated with metabolic acidosis, ARDS, and myocardial depression.
- Colloidal silver has been widely promoted as an alternative medicine. It has no proven benefits and may cause argyria, a permanent pigmentation of skin, nails, and mucous membranes.
- Thallium is an extremely toxic metal employed as a pesticide. Toxic ingestion produces a practically pathognomic clinical triad of gastroenteritis, polyneuropathy, and alopecia.
- Trialkyltins are responsible for sometimes severe gastrointestinal, CNS, and renal toxicity.
- When ingested, zinc may cause significant local GI effects.
- Metal fume fever (most often occurring during welding) may result from inhalation of zinc, copper, magnesium, cadmium, manganese, and antimony. It is a self-limited illness with no demonstrated long-term sequelae.
- Chelators are available for treatment of some of the toxic metals.

SPECIFIC AGENTS**Aluminum**

Aluminum is the most abundant metal in the earth’s crust. It has no known human function. Exposure occurs from contaminated drinking water and aluminum cans, containers, and cooking utensils. Dermal exposure occurs from aluminum-containing deodorants. Aluminum silicate and magnesium aluminum silicate are generally safe as ingredients in topical cosmetic products; they are not significantly toxic, but may cause mild eye irritation.¹ Magnesium aluminum silicate application to human skin for 1 week did not cause adverse effects.¹ Some aluminum-containing cosmetic products cause dermal hypersensitivity reactions. Two patients developed multiple pruritic nodules that contained aluminum and persisted for several years after immunization with

vaccines adsorbed on aluminum hydroxide.² Workers who mine and process aluminum silicate have developed pulmonary fibrosis and pneumoconiosis.¹

The body absorbs less than 1% of an ingested aluminum dose. The body burden of 30 to 40 mg is kept low by renal homeostatic mechanisms. Normal plasma aluminum level is 5 to 10 µg/L. Aluminum is concentrated in the bones and liver. Because excretion of aluminum is primarily renal, poisoning is a risk for persons with renal insufficiency who take aluminum-containing antacids, and infants who do not have renal failure may have elevated plasma concentrations after such antacid administration.³ Aluminum inhibits metabolic turnover of calcium, phosphorus, and iron. Its salts can bind to DNA and RNA, and inhibit a number of enzymes. Neurotoxicity may be due to substitution of magnesium ions in adenosine triphosphate (ATP).⁴

In gerbils, administration of aluminum trichloride caused biphasic stimulation of superoxide dismutase activity in various brain regions, indicating that oxidative stress is involved in aluminum central nervous system (CNS) toxicity.⁵ Aluminum toxicity was formerly suggested to be implicated in development of Alzheimer's disease. However, patients treated with long-term hemodialysis and aluminum-containing medications had dialysis-associated encephalopathy but *not* Alzheimer's disease morphology in the brain at autopsy.⁶

Aluminum toxicity is characterized by encephalopathy, microcytic anemia, and osteomalacia. *Dialysis encephalopathy* is attributed to accumulation of aluminum from the dialysate, as is dialysis osteodystrophy. These illnesses have largely disappeared since aluminum was removed from water used to prepare dialysate.

Two fatalities due to aluminum poisoning were reported when a cement containing aluminum-calcium fluorosilicate was used for bone reconstruction after middle ear surgery. In both cases, refractory status epilepticus occurred and death resulted despite deferoxamine chelation.⁷

Urinary excretion of aluminum was unchanged after administration of 2,3-meso-dimercaptopropane-1-sulfonate (DMPS).⁸

Aluminum phosphide is a fumigant pesticide⁹ that causes phosphine poisoning rather than aluminum toxicity (see Chapter 80).

Supportive care is all that is usually required for patients with aluminum toxicity. Hemodialysis and deferoxamine chelation may be considered in some cases.

Antimony

Antimony is a silver-gray metal and resembles arsenic in its toxic effects.¹⁰ Antimony exists primarily in two valence states, Sb^{+3} and Sb^{+5} . Stibine (antimony hydride, SbH_3) is an extremely toxic gas. Antimony is used in the textile industry, to harden lead, as an alloy with tin or copper, and in glass manufacture. Occupational antimony exposure may occur in metallurgy, welding, and zinc etching.

Antimony tartrate and sodium stibogluconate are antibiotics for the treatment of leishmaniasis and schistosomiasis. Cumulative sodium stibogluconate toxicity has resulted in fatality.¹¹ Urticaria has been described during pentavalent antimony leishmaniasis treatment.¹²

Antimony compounds are rapidly and completely absorbed from the lungs after inhalation. Gastrointestinal (GI) absorption is less efficient; only 10% to 20% of an oral dose is absorbed. Distribution and organ concentration depend on valence. Pentavalent antimony has no significant binding to blood elements and is concentrated in the heart, liver, and thyroid. Trivalent antimony is more than 90% bound to erythrocytes.¹³ After a single dose, more than 95% of pentavalent antimony can be recovered in the urine within 24 hours, and the elimination half-life is 2 to 4 hours. Trivalent antimony is primarily excreted in the feces, and only about 25% of a dose can be recovered in the urine. The distribution half-life of trivalent antimony is 30 hours, and the terminal half-life is 40 days.¹⁴

The mechanism of toxicity is unclear, but may be related to inhibition of thiol-containing enzymes.¹⁰ After ingestion, the most prominent manifestations are vomiting, diarrhea, and abdominal pain (*cholera stibie*). Severe fluid and electrolyte disturbances can quickly ensue. After acute inhalation, both forms of antimony can produce severe respiratory tract irritation; high-concentration exposures can result in noncardiogenic pulmonary edema. Cardiovascular disturbances (QT prolongation and T-wave abnormalities) and liver function abnormalities may occur with acute poisoning.

Epistaxis is a common presenting complaint in chronic antimony poisoning. Occupational exposure produces a pneumoconiosis resembling silicosis. Cardiomyopathy can develop. *Antimony spots* are white spots on a pustular base on parts of the skin with a high concentration of sweat glands. Death due to either acute or chronic antimony poisoning results from multiorgan system failure.

Stibine is an odorless, colorless gas. Similar to arsine gas, it is capable of producing massive intravascular hemolysis with resultant hemoglobinuria and acute renal failure.

Diagnosis is based on urinary measurement for pentavalent antimony exposure and blood measurement for trivalent compounds (although urinary trivalent antimony levels have some value). Twenty-four-hour urine collections should be obtained. Laboratory assessment includes pulmonary function tests and chest x-ray (after inhalation exposure), electrocardiogram (ECG), and liver function tests.

Supportive care is the mainstay of treatment. Activated charcoal administration has been recommended after ingestion, although it is doubtful that significant adsorption occurs.¹⁰ Fluid and electrolyte status should be monitored because of the risk for excessive GI losses. Chelation therapy with dimercaprol (BAL), dimercaptosuccinic acid (DMSA), or DMPS, if initiated early, appears to improve the clinical course.¹⁰ Treatment of stibine exposure consists of immediate removal from the toxic site, supportive care, and exchange transfusion.

Barium

Barium is a radiopaque heavy metal used as a radiographic contrast agent. Barium sulfate is insoluble and is not toxic when ingested. It has also been used as a pesticide. Safer pesticides have replaced barium carbonate, but it is still used in countries outside the United States, where it continues to pose a hazard of inadvertent food contamination.¹⁵ Barium compounds used industrially include barium hydroxide, barium chlorate, barium chloride, barium fluoride, barium acetate, and barium sulfide. Barium hexafluorosilicate is used in the manufacture of matches, explosives, and glass. Barium styphnate is used as a propellant. After an explosion involving this material, a patient had both traumatic injury and severe acute barium toxicity with prolonged GI dysfunction, severe and relapsing hypokalemia, cardiac arrhythmias, flaccid paralysis, myoclonus, respiratory failure, profound lactic acidosis, and hypertension.¹⁶

Soluble barium compounds are well absorbed after ingestion or inhalation, with peak serum levels occurring within 2 hours. The elimination half-life in serum is about 4 days. As much as 93% of an absorbed barium dose is ultimately sequestered in bone.

Symptom onset is rapid. The first signs are GI: epigastric pain, nausea, vomiting, and watery diarrhea.^{15,17}

Barium intoxication is characterized by severe, potentially fatal hypokalemia. Serum potassium concentrations of less than 0.8 mEq/L may occur.^{15,17} In one fatal case, barium levels at autopsy were as follows: blood, 9.9 mg/L; bile, 8.8 mg/L; urine, 6.3 mg/L; and gastric contents, 10.0 g/L.¹⁸ Patients usually have hypokalemic paralysis.¹⁷ Hypokalemia results from a shift of potassium into cells due to a specific potassium efflux channel blocking effect. Without affecting potassium uptake, hypokalemia results. Barium has no identified action on the sodium-potassium pump.¹⁹

The clinical presentation is initial GI toxicity followed by the sudden onset of areflexia and motor weakness.²⁰ Consciousness is not altered, and anal sphincter tone is typically preserved.¹⁷ Trismus has also been described.²¹ The degree of hypokalemia does not correspond to the extent of weakness,¹⁷ which is better correlated with plasma barium levels.²⁰ ECG changes may occur, including atrioventricular dissociation, QRS widening, or U waves. Fatal ventricular fibrillation¹⁹ or torsades de pointes polymorphic ventricular tachycardia²⁰ may occur. Other clinical features include bradycardia, premature ventricular beats, rhabdomyolysis, hypophosphatemia, and acute renal failure. Paralysis may persist from 8 hours to 5 days.¹⁷ One case of prolonged (3 months) superior esophageal sphincter contracture and sequelae of extrapyramidal syndrome with bilateral hyperdense lesions in the basal ganglia and thalamus on magnetic resonance imaging has been reported.²²

The estimated lethal dose of barium is 900 mg, although doses of 0.2 to 0.5 mg/kg have resulted in life-threatening toxicity.¹⁷ Children seem to have greater tolerance than adults and typically only have GI symptoms.¹⁹

Long-term barium inhalation can produce a benign pneumoconiosis (*baritosis*).¹⁷

The triad of GI upset, weakness, and profound hypokalemia evokes the diagnosis of barium intoxication. Other causes of hypokalemia—including β_2 -adrenergic agonists, theophylline, and chloroquine—do not have the other clinical signs as prominent features. Abrupt paralysis due to toxins including tetrodotoxin and tick paralysis is not associated with profound hypokalemia. A complete blood count and measurement of serum electrolytes, blood urea nitrogen, blood glucose, serum creatinine, calcium, and phosphorus should be done. Determinations of urinary potassium, arterial blood gases, muscle enzymes (creatinine phosphokinase and aldolase), and liver function tests are recommended.¹⁷ ECG may reveal hypokalemic cardiac disturbances. Exposure can be confirmed with serum barium levels (normal: 3 to 29 $\mu\text{g}/\text{dL}$).¹⁹ Because barium salts are radiopaque, they can be visualized on plain abdominal x-rays after ingestion.²⁰

Assess respiration and support circulation. After barium inhalation, move the victim to fresh air and administer supplemental oxygen if hypoxia is present. Severe skeletal muscle weakness may lead to respiratory depression, and the need for assisted ventilation should be anticipated. Cardiac disturbances should be treated according to advanced cardiac life support algorithms. GI decontamination should be done after ingestion of soluble barium compounds. Gastric lavage with the cathartics sodium sulfate or magnesium sulfate may precipitate soluble compounds as insoluble barium sulfate and might prevent further absorption. Activated charcoal does not adsorb significant amounts of barium and should not be administered.¹⁹ Whole bowel irrigation may be considered. Decontamination efficacy can be guided by plain abdominal x-rays.

Patients with significant hypokalemia, particularly those with ECG abnormalities, require potassium supplementation; doses up to 400 mEq may be required within the first 24 hours.¹⁹ Because total-body potassium is preserved, serum levels should be monitored frequently to prevent hyperkalemia.¹⁹ Parenteral administration of magnesium sulfate to render circulating barium insoluble risks precipitation in the renal tubules. Barium can be removed by hemodialysis.¹⁷ In one patient, continuous venovenous hemofiltration improved motor function and allowed better control of serum potassium levels and acid-base status.²⁰

Beryllium

Coal combustion is the principal source of environmental beryllium exposure.²³ Occupational exposure is the most common cause of beryllium sensitivity and chronic beryllium disease. From 1958 to 1989, the Rocky Flats, Colorado, nuclear weapons facility released beryllium into the air from normal operations and three accidental fires.²⁴ Beryllium-coated products such as computer components, telecommunications equipment, and consumer and automotive electronic products pose little risk.²⁵

Beryllium was used in the manufacture of fluorescent lights in the 1930s, and beryllium-related pneumonitis with lesions resembling those of sarcoidosis became epidemic. Beryllium is currently used primarily in the aerospace and nuclear industries. Toxic forms include elemental beryllium, beryllium oxide, beryllium fluoride, and beryllium-copper alloys. Observed acute experimental pulmonary lesions after intratracheal administration of beryllium-copper alloys are most likely due to the copper rather than the beryllium.²⁶

ACUTE EXPOSURE

Beryllium is an irritant that can cause conjunctivitis, periorbital edema, pharyngitis, tracheobronchitis, and pneumonitis. Skin exposure can produce a marked dermatitis. Pulmonary signs are most prominent with dyspnea, productive cough, chest pain, rales, and cyanosis. Infiltrates may be seen on chest x-ray, and hypoxia may occur at rest.²³

LONG-TERM EXPOSURE

Berylliosis is a systemic granulomatous disease resulting from long-term exposure.²³ It can appear anytime from a few months to 25 years after regular exposure. Noncaseating granulomas may appear in the liver, spleen, lymph nodes, heart, kidneys, bone, salivary glands, and skin. However, the primary target organ is the lung. Pulmonary manifestations include dyspnea, rales, and chest pain. Clubbing may be noted. Patients may present with right ventricular heart failure (*cor pulmonale*). Pulmonary function tests reveal either restrictive or obstructive lung disease. Chest x-rays characteristically demonstrate diffuse infiltrates and hilar adenopathy. The pulmonary toxicity of beryllium almost certainly represents a type IV immune-mediated hypersensitivity phenomenon.²³ A unique aspect of beryllium toxicity is its extremely slow elimination from the lungs.²³ CD4⁺ T cells likely play a critical role in the development of chronic beryllium disease, whereas CD8⁺ T cells do not.²⁷

The diagnosis of berylliosis is based on a history of beryllium exposure. However, berylliosis can be identical to sarcoidosis in appearance, and an extensive evaluation is required to distinguish the two. The peripheral blood lymphocyte proliferation test is the most sensitive and specific test available to identify patients with chronic beryllium disease and those with beryllium sensitivity who may go on to develop the disease and require corticosteroid treatment to arrest progression.²⁸⁻³¹

Although chelating agents such as DMPS, D-penicillamine, tiron, and calcium disodium EDTA and antioxidants such as selenium and glutathione have been effective in experimental animal models,^{32,33} the treatment of berylliosis in humans is largely supportive. Corticosteroids may improve pulmonary symptoms and may prevent patients with beryllium sensitivity from progressing to chronic beryllium disease. Lung transplantation could be considered in patients with progressive respiratory failure.

Bismuth

Bismuth is in the Vb group of elements with antimony and arsenic. Its current therapeutic use is limited to antidiarrheal effects (bismuth subsalicylate; Pepto-Bismol). Because it is water insoluble, poorly absorbed from the gut, and rapidly excreted in the urine, bismuth accumulation rarely occurs despite excessive use.³⁴

Although poorly absorbed, bismuth is measurable in blood after ingestion. The highest concentrations are found in the kidneys and liver. Bismuth also concentrates in the placenta.³⁵ Excretion of bismuth is primarily renal. It is rapid, being complete within 24 hours. Only about 10% of an absorbed dose is found in the feces.³⁵

The symptoms of bismuth poisoning have been compared with those of lead and mercury poisoning.³⁵ Early signs are hypersalivation and a characteristic blue discoloration of the gums resulting from deposition of bismuth sulfide in fibrous tissue.³⁵ Stomatitis may also occur. Renal injury has been reported³⁶ and presents as acute renal failure, reversible nephropathy, or Fanconi's

syndrome. Hepatic injury and peripheral neuritis have also been reported.³⁵ Skeletal disturbances, including osteoarthropathy, osteomalacia, and osteoporosis, have been associated with chronic bismuth intoxication and may result in pathologic fractures.³⁵ Nicolau's syndrome, characterized by a livedoid pattern on the skin followed by necrosis and scar formation, has followed intramuscular injection of bismuth salts.³⁷ Skin reactions, including erythema, exanthema, angioedema, and small-patch or maculopapular rashes, have been reported in patients treated with bismuth oxide.³⁸

Encephalopathy has been reported after long-term high-level exposure to bismuth salts. Manifestations include altered mental status, ataxia, myoclonus, and distinctively abnormal electroencephalogram (EEG) findings.^{34,35} Outbreaks of bismuth encephalopathy have been reported. Between 1973 and 1980, about 1,000 cases of bismuth poisoning with 72 fatalities were identified.³⁹ However, in a placebo-controlled clinical trial that included EEG evaluation, neurotoxicity was not demonstrated when bismuth was administered.³⁹

The diagnosis of bismuth poisoning is made on the basis of history, characteristic clinical findings, and laboratory evaluation. The normal serum bismuth level is less than 50 µg/L.³⁹

Supportive care is usually all that is required. Bismuth elimination can be enhanced by administration of BAL, DMPS, and DMSA; D-penicillamine and deferoxamine are ineffective.^{35,40}

Cadmium

Cadmium is one of the most common causes of environmentally associated renal injury. The major environmental sources of cadmium are industrial use and food contamination. Cadmium is a component of cigarette smoke.⁴¹ Cadmium is used in alloy fabrication, metal plating, pigments, and the manufacture of rechargeable (nickel-cadmium) batteries. Cadmium's high volatility makes it particularly hazardous to welders.⁴²

Cadmium is well absorbed after inhalation (up to 50% of an inhaled dose). In contrast, only about 5% of an ingested dose is absorbed.^{41,42} GI absorption is enhanced by low intake of calcium, protein, or iron. Cadmium is circulated and stored bound to metallothionein. The main storage organs are the liver and kidneys. The biologic half-life in the liver is 5 to 10 years; it is twice that in the kidney. The overall biologic human half-life of cadmium is 30 years.⁴²

Progressive accumulation occurs, and there is no effective endogenous cadmium elimination mechanism. Cadmium stimulates metallothionein production and reduces its overall toxicity. However, metallothionein binding is associated with selective cadmium accumulation, leading to renal injury.

Acute cadmium ingestion causes nausea, excessive salivation, abdominal pain, and diarrhea. Fatality results from cardiovascular collapse. The acute lethal oral dose is estimated at 350 to 8900 mg. Acute inhalation of cadmium oxide fumes as a result of welding, smelting, or soldering can produce a severe, sometimes fatal,

pneumonitis associated with elevated urinary cadmium concentrations.⁴³

With long-term cadmium exposure, the major target organs are the kidneys, expressed as proximal tubulopathy with excretion of proteins weighing less than 40,000 daltons (β_2 -microglobulin, lysozyme, retinol binding protein). Cadmium prevents tubular reabsorption of these proteins. Elevated urinary concentrations of *N*-acetyl- β -D-glucosaminidase (NAG) are an indicator of cadmium-induced proximal tubule disease. β_2 -Microglobulin is a sensitive indicator of early cadmium-induced renal disease. Marked excretion of calcium and phosphorus also occurs, leading to osteopenia or nephrolithiasis. Effects on calcium and phosphorus homeostasis result in part from cadmium inhibition of vitamin D hydroxylation. Chronic cadmium exposure has been linked to essential hypertension. Renal disturbances may first manifest more than 10 years after chronic cadmium exposure. Nonrenal clinical effects include ulceration of the nasal mucosa, anemia, and hepatitis.⁴²

An epidemic illness occurred in Japan during the 1940s called *itai-itai* (ouch-ouch) disease. Clinical characteristics were leg and low back pain, chest pain, and difficulty walking. Severe, diffuse osteopenia occurred, resulting in fractures after minor trauma and often producing physical deformities. Proteinuria, glycosuria, and aminoaciduria were common. Autopsy revealed marked renal tubular atrophy and degeneration. This epidemic was confined to the Jinzu River system, which suggested water contamination of rice, beans, fish, and other foodstuffs. The low-protein and low-calcium diet of the victims seemed to contribute to the development of the disease. Itai-itai occurred primarily in multiparous women, perhaps because they were already deficient in calcium and phosphorus. Vitamin D supplementation resulted in clinical improvement. Cadmium contamination of drinking water was ultimately identified as the cause, due to discharge from a zinc mine.⁴²

The diagnosis of chronic cadmium poisoning can be made not only by urinary β_2 -microglobulin excretion but also by measurement of blood cadmium. The normal blood cadmium level is less than 5 $\mu\text{g/L}$. The normal urinary excretion of cadmium is less than 1 $\mu\text{g/g}$ creatinine. Twenty-four-hour urine collections for measurement of cadmium, creatinine, low-molecular-weight proteins, and amino acids should be done.

Cadmium chelation is difficult because of its high affinity for metallothionein. BAL treatment has been associated with increased renal accumulation and accelerated renal injury. All treatment is therefore supportive.

Chromium

Chromium is abundant in the earth's crust. It is an essential micronutrient and acts as a cofactor in insulin function. Chromium is used for the manufacture of stainless steel and in tanning, photography, and electroplating. Chromium has three main valence states: bivalent,⁺² trivalent,⁺³ and hexavalent.⁺⁶ Hexavalent compounds include chromic acid, potassium and ammonium

dichromates, and chromium trioxide that is extremely corrosive when ingested.

Trivalent chromium is poorly absorbed (<1%) from the GI tract; however, more than 50% of ingested hexavalent chromium can be absorbed from the gut. Organ accumulation of chromium is extensive and includes the brain, liver, spleen, testes, bone marrow, and reticuloendothelial system. Serum half-life is 15 to 41 hours. About 80% of a chromium dose is excreted in the urine. Chromium toxicity results from its ability to penetrate cell membranes, inciting events resulting in cell death. Chromium VI (hexavalent) is carcinogenic and mutagenic, but it is reduced intracellularly to stable chromium III (trivalent). Chromium IV and V are produced in intracellular reduction pathways, and cellular damage may be at least partly due to these species.⁴⁴ Chromium is a redox-active metal that depletes cellular antioxidants.⁴⁵

Ingestion of trivalent chromium picolinate dietary supplement has caused systemic contact dermatitis and acute generalized exanthematous pustulosis.^{46,47}

Exposure to hexavalent chromium is associated with widespread organ toxicity. Respiratory tract effects include acute noncardiogenic pulmonary edema that can be delayed in onset up to 72 hours, nasal septal perforation, and diffuse pulmonary inflammation. Dermal exposure to chromium in felt produces eczematous changes referred to as *blackjack disease*, and painless ulcers can develop on the hands, periumbilical region, axillae, and forearms (*chrome holes*).⁴⁸ GI toxicity includes hemorrhagic gastroenteritis with characteristic yellow-green emesis. Hepatitis progressing to fulminant hepatic failure may result. Acute tubular necrosis and glomerulonephritis may occur, as well as methemoglobinemia, thrombocytopenia, anemia, and intravascular hemolysis. Circulatory collapse and shock may be seen, usually secondary to extensive GI corrosion or perforation. Corneal opacification, keratitis, and conjunctivitis may occur after ocular exposure. As little as 500 mg of ingested chromium can produce life-threatening toxicity; 1 to 2 g is potentially lethal.

A 2-year-old child ingested about 1 g of ammonium dichromate crystals.⁴⁹ Profuse diarrhea developed in association with coagulopathy, liver function disturbances, obtundation, and respiratory failure. Ascorbic acid was administered, and exchange transfusion was performed. Anuria, hypotension, and noncardiogenic pulmonary edema developed within 24 hours. Despite hemodialysis, progressive coagulopathy and hepatic failure occurred, resulting in death. The peak plasma concentration was 4163 $\mu\text{g/L}$.

Nasal insertion of a potassium dichromate crystal foreign body caused systemic chromium poisoning with diarrhea, vomiting, nasal obstruction, acute renal failure, pancreatitis, hepatitis, and drowsiness in a 3-year-old child.⁵⁰

Occupational hexavalent chromium exposure has been associated with an increased incidence of nasal cancers and bronchial carcinoma.

Normal serum chromium concentrations are 0.3 to 1.0 $\mu\text{g/L}$. Normal urinary chromium concentration should be less than 40 $\mu\text{g/L}$. The 95% upper fractile level for urine chromium in normal individuals is 13 nmol/L.⁵¹

Treatment of hexavalent chromium ingestion includes management of hypotension or shock, forced diuresis (furosemide administration may be required), and treatment of corrosive GI injury. Ascorbic acid (vitamin C) reacts with hexavalent chromium to form the poorly absorbed trivalent form. Oral doses of 2 to 4 g per 1 g of ingested chromium have been recommended if there are no symptoms of severe gastroesophageal injury. However, even doses as high as 10 g given intravenously, although not toxic, are unlikely to reduce the mortality in patients with systemic hexavalent chromium poisoning.⁵² Larger doses could be harmful because ascorbic acid is a metabolic precursor of oxalate that can cause nephropathy, especially if renal failure is already present.⁵² *N*-Acetylcysteine (NAC) has been advocated to maintain chromium in its less toxic trivalent state.⁴⁹ DMPS chelation does *not* increase the urinary excretion of chromium.⁸

Treatment of chromium inhalation includes movement to fresh air. The possibility of late-onset noncardiogenic pulmonary edema should be considered. Dermal exposures should be treated by cleansing the skin with copious amounts of soap and water. Early excision of burned skin remains the best method to decrease the body hexavalent chromium load and risk for systemic toxicity after dermal contact with hot hexavalent chromic acid because systemic poisoning may occur when as little as 1% to 10% of the total-body surface area is involved.⁵³ Topical ascorbic acid may be useful to decrease dermal absorption of hexavalent chromium.⁵² Ocular exposures require copious irrigation and ophthalmology consultation.

Chromium dietary supplement ingestions are generally nontoxic. Chronic overdosing with chromium picolinate has resulted in systemic chromium toxicity.⁵⁴ Additional ingredients in chromium dietary supplements (e.g., niacin and pyridoxine) also have the potential to produce toxicity. Death occurred in one patient who developed systemic chromium poisoning after ingesting a leather tanning solution containing 48 g of basic chromium sulfate.⁵⁵

Cobalt

Cobalt is an essential trace element as a component of vitamin B_{12a} (hydroxocobalamin). It has been used to treat selected anemias because it stimulates erythropoiesis. Normal serum cobalt levels are 2 to 17 nmol/L.⁵⁶

Long-term excessive cobalt exposure has been associated with development of flushing, chest pain, tinnitus, nausea, vomiting, nerve deafness, thyroid hyperplasia, congestive heart failure, and renal disease. Frank hypothyroidism can result. Alopecia is a manifestation of cobalt poisoning found with only a few other toxicants such as thallium.

In the past, cobalt was responsible for recurring epidemics of cardiomyopathy (*beer-drinkers' cardiomyopathy*), which occurred when cobalt salts were added to beer as a foam stabilizer.⁵⁷

Hard metal disease has occurred in workers who chronically inhale particulate matter during cutting or grinding operations on cobalt-containing metal alloys.

The interstitial pulmonary lesions seem to be due to inhalation of cobalt metal dust mixed with tungsten carbide particles, and not cobalt dust alone.⁵⁸

In normal individuals, urinary cobalt levels are 23 nmol/L in men and 31 nmol/L in women.⁵¹ Calcium disodium EDTA chelation has been used for the treatment of cobalt poisoning.⁵⁷ Administration of DMPS does not increase the urinary excretion of cobalt.⁸

Copper

Copper is an essential micronutrient. Catalase, peroxidase, and cytochrome oxidase require copper for their activity. Dietary copper deficiency is associated with microcytic anemia, leukopenia, and pathologic effects on the skeletal, cardiovascular, and nervous systems.

Copper is rapidly absorbed from the proximal GI tract. Copper is transported both by albumin and the specific α_2 -globulin carrier protein, ceruloplasmin. Copper is concentrated in the liver, kidneys, heart, and brain. Stored copper is bound to metallothionein. The primary route of copper excretion is in the feces.⁵⁹ Copper undergoes redox cycling that can produce reactive oxygen species and oxidant stress in cells.⁴⁵

Wilson's disease (hepatolenticular degeneration) is an inherited disease associated with systemic copper excess characterized by accumulation in the viscera and cornea.⁶⁰ *Indian childhood cirrhosis* also seems to be caused by copper excess. It is associated with elevated liver copper levels, early feeding with milk boiled or stored in copper-containing brass containers, a dramatic decrease in prevalence when milk preparation and storage vessels are changed to those not containing copper, and successful treatment with D-penicillamine.⁶⁰

Copper sulfate was previously used as an emetic, but resulted in serious copper toxicity and death. Ingestion of such copper salts has caused severe GI toxicity with blue-green emesis, hematemesis, hypotension, centrilobular hepatic necrosis, coma, seizures, and death. Hemolytic anemia and methemoglobinemia are also prominent features. Chronic exposure to copper either occupationally or as a result of excessive dietary copper intake (e.g., from storing or cooking foodstuffs in copper-containing pans or from acidic water in copper pipes) has been associated with development of hepatic injury and cirrhosis.^{59,61,62}

Alveolitis, interstitial inflammation, type II epithelial cell hyperplasia, and centriacinar fibrosis seen with intratracheal instillation of beryllium-copper alloy in experimental animals are due to the copper rather than the beryllium component.²⁶

Copper poisoning diagnosis is based on an elevated serum level (normal: 50 to 120 mg/dL).⁶² Copper elimination can be enhanced by chelation with either D-penicillamine or BAL. DMPS administration can produce a 2- to 119-fold increase in urinary copper excretion, whereas DMSA does not increase urinary copper excretion.^{8,63}

Gold

Gold is a precious metal with no known biologic function. Exposure can occur from environmental sources

including seafood, but most human gold exposure results from medicinal use (chrysotherapy) for rheumatoid arthritis treatment. Gold-containing pharmaceuticals include aurothioglucose, gold sodium thiomalate, and auranofin.⁶⁴

Medicinal gold salts are administered orally or parenterally. Circulating gold is mostly albumin bound.⁶⁴ Gold concentrations in synovial fluid are about one half those found in plasma. Gold has about a 7-day half-life, which lengthens during prolonged therapy because of avid tissue binding; blood gold levels remain measurable for up to 10 months after treatment termination.⁶⁵ Gold elimination is 60% to 90% fecal and 10% to 40% renal.⁶⁴

Despite its beneficial effects in rheumatoid arthritis patients, gold has significant dermatologic and renal toxicity resulting from formation of immune complexes. Dermatitis is the most common adverse effect and may be associated with elevated immunoglobulin E levels.^{61,65} Mucositis (stomatitis, tracheitis, gastritis, colitis, vaginitis) is a common adverse effect. Renal adverse effects may occur in 5% to 10% of patients treated with gold salts and consists of proteinuria, frank nephrosis, and immune complex glomerulonephritis. Thrombocytopenia, leukopenia, and (rarely) aplastic anemia may occur. Other adverse effects can include encephalitis, peripheral neuropathy, hepatitis, and pneumonitis.⁶⁴

One case of gold poisoning without cyanide toxicity resulted from suicidal ingestion of 5 mL of a gold potassium cyanide solution.⁶⁶ This patient developed vomiting, hyperamylasemia, hepatic dysfunction, and centrilobular cholestasis with eosinophilic degeneration. Whole-blood gold level was 4361 $\mu\text{g/L}$, serum gold level was 6011 $\mu\text{g/L}$, and 24-hour urinary gold excretion was 429 $\mu\text{g/day}$ on day 4 after ingestion.⁶⁶

Allergic manifestations are at least partly responsible for the mucocutaneous adverse effects of therapeutic gold compounds. The peripheral venous blood lymphocyte proliferation test, when cultured with gold compounds, may be useful in diagnosis.⁶⁷ A patient with known allergy to gold jewelry developed gold allergy symptoms after drinking Goldschlager, a schnapps liquor product that contains gold particles.⁶⁸

Treatment of gold toxicity is primarily symptomatic. Dermatitis and mucositis can be treated with antihistamines and corticosteroids. Corticosteroids can also be used to treat gold-induced nephrosis. Gold elimination can be enhanced with *N*-acetylcysteine, BAL, and D-penicillamine.^{64,69}

Magnesium

Magnesium is found in ores such as dolomite, in seawater, and as a component of asbestos. It is an essential nutrient involved in glycolysis and formation of cyclic adenosine monophosphate. More than 300 enzymes are known to be activated by magnesium. Renal homeostatic mechanisms maintain serum magnesium concentrations within a narrow physiologic range.

Hypermagnesemia has several causes, with excessive ingestion of magnesium-containing antacids or excessive administration of magnesium-containing cathartics being most common (see Chapter 2A). Magnesium is

administered intravenously for such conditions as pre-eclampsia, ischemic heart disease, asthma, and cardiac arrhythmias. Significantly elevated serum magnesium levels after therapeutic administration are usually seen only in patients with renal dysfunction.⁷⁰ Inhalation of magnesium oxide fumes can cause metal fume fever (MFF; see later). Dermal exposure to magnesium dust or fumes can cause contact dermatitis. Hypermagnesemia can result when the renal glomerular filtration rate decreases to less than 30 mL/min and magnesium intake is not reduced.⁷¹

Acute magnesium toxicity results in central nervous system depression with lethargy, coma, neuromuscular paralysis, hypotonia, and hyporeflexia. ECG changes may include prolonged QRS and PR and QT intervals. Inhalation exposure can cause respiratory tract irritation and noncardiogenic pulmonary edema.

Serum magnesium levels can confirm the diagnosis, although they may not correlate with clinical symptoms. In general, manifestations of magnesium toxicity according to serum concentrations are as follows: 3 to 9 mEq/L, vomiting, bradycardia, hypotension, hyporeflexia, lethargy; greater than 10 mEq/L, muscle paralysis, hypoventilation, stupor, cardiac conduction disturbances, ventricular arrhythmias; greater than 14 mEq/L, cardiac arrest, and death.⁷¹

Calcium administration ameliorates many toxic manifestations. Forced diuresis enhances magnesium elimination. Hemodialysis is effective for magnesium removal from the circulation but is rarely necessary in the absence of renal failure. Magnesium urinary excretion increased by 1.75- to 42.7-fold with DMPS chelation.⁸

Manganese

Manganese is an essential nutrient that crosses both the blood-brain and blood-cerebrospinal fluid barriers. Transferrin may be involved in this process.⁷² Several enzymes, including decarboxylases, kinases, and transferases, are activated by manganese. Pyruvate carboxylase and superoxide dismutase contain manganese.

Manganese is used in the manufacture of batteries and as an ingredient in paints and varnishes, bleaching agents, laboratory reagents, motor oils, and disinfectants. It is used for decolorizing glass and ceramics and as a fertilizer for grapes and tobacco.

Occupational and environmental manganese exposures occur in steel manufacturing, welding, and ingestion of contaminated water. The unleaded gasoline antiknock additive, methylcyclopentadienyl manganese tricarbonyl (MMT), can release manganese to the atmosphere.⁷¹ Manganese may occur in the Mn^{+2} , Mn^{+3} , and Mn^{+4} oxidation states after combustion of motor fuels containing the MMT additive.⁷³ Mn^{+2} is more toxic than Mn^{+3} .

Manganese can be absorbed from the GI tract as well as the lungs. Its absorption is enhanced by iron deficiency and calcium or phosphorus intake. Once absorbed, manganese is transported by transmagnin, a specific β_1 -globulin.⁷¹ The primary excretion route is fecal. Less than 6% of a dose is excreted in the urine.

Chronic poisoning causes neurologic toxicity,⁷² although manganese penetrates into the CNS poorly.

Manganese is concentrated in the globus pallidus and corpus striatum, resulting in decreased synthesis and depletion of catecholamines, including dopamine. Initial complaints are anorexia, insomnia, and fatigue. Delirium (*manganese madness*) may occur with inappropriate laughter, hallucinations, and confusion. Patients report vivid hallucinations and may commit violent acts. Marked diminution of spontaneous motor acts, ataxia, slurred speech, limb stiffness, tremor, paresthesias, amnesia, dysphagia, and a metallic taste in the mouth may develop. Impaired tandem gait and loss of associated movements may ensue, as well as masked facies, micrographia, and torticollis. Manganese poisoning mimics parkinsonism, and levodopa therapy may be effective.⁷⁴ Polymorphism of various metabolic genes may play a role in susceptibility to chronic manganese neurotoxicity.⁷⁵

Other manifestations include marked hypocalcemia and reduced spermatogenesis. Birth defects, including talipes equinovarus and cleft lip, have been associated with chronic manganese exposure.⁷¹

Acute inhalation of manganese oxide can produce either MFF (see later) or a distinct manganese pneumonitis.⁷¹ Unlike MMF, manganese pneumonitis is more severe and may have sequelae including persistent bronchospastic disease.

Manganese poisoning should be suspected on the clinical presentation (particularly a parkinsonian-like syndrome) and can be confirmed by measuring blood manganese levels. Normal mean whole blood manganese concentrations are 3 to 15 $\mu\text{g/L}$; normal mean serum concentrations are 1 to 3 $\mu\text{g/L}$.

Treatment of MMF is discussed later. Manganese pneumonitis may be treated with antibiotics and bronchodilators. For manganese-induced parkinsonian-like syndrome, therapy with either levodopa or a diet high in tryptophan may improve motor activity. No chelating agents are efficacious.

Nickel

Nickel exists in three major forms: elemental, inorganic (water soluble and water insoluble), and organic (including nickel carbonyl). Nickel is used in production of stainless steel, in electroplating, in the manufacture of nickel-cadmium (rechargeable) batteries and magnetic tape, and as a catalyst for the hydrogenation of soaps, fats, and oils.

Nickel carbonyl is an extremely toxic gas used as a catalyst in the petroleum, plastic, and rubber industries. This gaseous organometal is heavier than air and has a musty odor. With the exception of nickel allergic contact dermatitis, nearly all cases of acute nickel poisoning have resulted from nickel carbonyl exposure.⁷⁶ Nickel carbonyl readily oxidizes in air and is highly explosive.⁷⁷

Most exposures occur through water contamination or by dermal contact with nickel-plated jewelry. Nickel is poorly absorbed (<1% of a dose) from the gut. In the blood, it is bound to albumin and α_2 -microglobulin. Nickel induces metallothionein synthesis.⁷⁷

Rashes from wearing nonrusting jewelry usually are

due to nickel allergic contact dermatitis.⁷⁷ Chronic nickel exposure may also induce asthma and conjunctivitis. Other respiratory effects include chronic restrictive lung disease (nickel pneumoconiosis), sinusitis, nasal polyps, and nasal septum perforation.^{78,79} Parenteral injection of nickel-containing medications can cause anaphylaxis.⁷⁹ Nickel's reactivity and ability to participate in free radical reactions are thought to be the basis of its apparent carcinogenicity.⁷⁹

Inhalation of nickel carbonyl at 30 ppm for more than 30 minutes is lethal.⁷⁹ Death can be immediate but is typically delayed for several days.

Because it is highly lipophilic, nickel carbonyl readily penetrates into the CNS, producing delirium and coma. Hepatic injury, hyperglycemia, glycosuria, mucositis, and dermatitis may occur. Fatalities from acute nickel carbonyl poisoning result from respiratory and neurologic toxicity. Chronic nickel carbonyl exposure has been associated with lung cancer. Metallic nickel exposure does not increase the cancer risk, and exposure to carcinogenic forms of nickel does not pose a cancer risk other than to the lungs and nasal cavities.⁷⁶

The diagnosis of nickel intoxication is made on clinical suspicion and urine or serum nickel levels. Severity can be determined by 8-hour urinary elimination results: mild toxicity corresponds to a urinary nickel concentration less than 100 $\mu\text{g/L}$; moderate toxicity is seen with 100 to 500 $\mu\text{g/L}$; and severe toxicity is associated with urinary concentrations exceeding 500 $\mu\text{g/L}$. The 95% fractile upper reference limit for urinary nickel concentration in normal individuals is 52 nmol/L.⁵¹ Nickel carbonyl is metabolized by the liver, liberating carbon monoxide. Carboxyhemoglobin levels may be useful.

After ingestion, GI decontamination should include activated charcoal administration for organic nickel compounds; ingestion of inorganic or elemental nickel should require only gastric emptying. Nickel compounds can be chelated with sodium diethyldithiocarbamate (dithiocarb). This agent has substantially reduced morbidity and mortality after nickel carbonyl exposure, but its efficacy after elemental nickel exposure is not established.⁸⁰ However, dithiocarb enhances cerebral uptake of elemental nickel.⁷⁷ A potential dithiocarb alternative is disulfiram (Antabuse), which is metabolized to two molecules of dithiocarb, but 500 mg/kg of disulfiram offered no protection in acute rodent nickel carbonyl poisoning, and 1500 mg/kg was associated with increased mortality.⁸⁰ Currently available data are not sufficient to recommend disaffirm use.⁸⁰

Selenium

Selenium is an essential micronutrient. It is an active part of the enzyme glutathione peroxidase that catalyzes oxygen radical scavenging.^{81,82} Selenium deficiency is associated with *Keshan's cardiomyopathy*.⁸¹ Dietary selenium supplements have become popular because of evidence suggesting they are helpful in preventing cancer, cardiovascular disease, cataracts, and arthritis.⁸³

Normal serum selenium concentrations are about 100 ng/mL. Organic selenium compounds are more

bioavailable and less toxic than the inorganic selenites and selenates.⁸¹

Selenium is used in paints, dyes, semiconductors, photoelectric cells, fertilizers, ceramics manufacture, rectifiers, steel production, and rubber manufacturing.⁸² Gun bluing preparations contain highly toxic selenious acid as well as nitric acid, copper nitrate, and, occasionally, methanol and other solvents.

Selenium can penetrate through the skin, can be inhaled as dust, or can be absorbed after ingestion. Most of an absorbed selenium dose is excreted within 2 weeks.⁸³

Excessive dietary selenium produces fingernail abnormalities, peripheral neuropathy, fatigue, muscle spasms, nausea, vomiting, alopecia, and a garlic breath odor.^{82,84} Liver function abnormalities, prolonged QT interval, and hypotension (from decreased cardiac contractility and systemic vascular resistance) may occur.⁸⁵ Low-grade occupational exposure has been associated with abdominal pain, chronic diarrhea, alopecia, garlicky breath, a metallic taste in the mouth, and transverse nail creases similar to Mees' lines.⁸³ Occupational exposure can result in chemical pneumonitis.

Acute selenium poisoning from ingestion of gun bluing can result in death.^{86,87} Gun bluing compounds produce severe burns of the stomach and esophagus with hypersalivation and vomiting, followed by metabolic acidosis, leukocytosis, myocardial depression, hepatitis, renal injury, pulmonary dysfunction (including adult respiratory distress syndrome), and seizures.⁸⁶ Ingestion of 15 mL of gun bluing solution has been fatal.⁸³

The diagnosis of chronic selenium poisoning is based on clinical suspicion. Alopecia with a garlic odor of the breath is suggestive. Urinary selenium concentrations of 150 µg/L or less are normal.

Treatment consists of general supportive measures and appropriate management of corrosive ingestion or toxic inhalation.

Case reports have suggested a beneficial role for forced diuresis and BAL administration. DMPS can increase urinary selenium excretion 30- to 42.7-fold.⁸

Silver

Silver was used medicinally in the past. Silver nitrate is an astringent and is used for treatment of burns and granulation tissue and as prophylaxis for *ophthalmia neonatorum*. Topical silver nitrate treatment may result in hyperpigmentation.⁸⁸

Skin exposure may occur during the extraction of precious metals. Silver is used in jewelry manufacture and as a component of films, inks, and ceramics. Occupational exposure produces irritation of the mucous membranes and conjunctiva and respiratory complaints including coughing, wheezing, chest tightness, respiratory insufficiency, and epistaxis.⁸⁹

Argyria is a condition with discoloration of the skin, nails, mucous membranes, and organs as a result of silver deposition.⁹⁰ Hyperpigmentation is pathognomonic for this otherwise asymptomatic condition.⁸⁹ The most vivid

areas of discoloration are on sun-exposed skin (e.g., face, hands).⁹¹ Corneal deposition of silver can result in nyctalopia (disturbed night vision).⁸⁹

Colloidal silver proteins have been promoted as mineral supplements and for the prevention of a variety of diseases. There is no evidence for the efficacy of colloidal silver proteins, and they can result in toxic effects, including argyria.⁹⁰

The diagnosis of argyria can be made by skin biopsy showing silver deposits. Normal silver concentrations in unexposed individuals are 1 to 2 µg/L in urine and less than 0.27 µg/dL in blood.⁸⁹ There is no effective treatment for argyria and the pigmentation is permanent.⁹¹

Thallium

Thallium compounds are odorless, colorless, and tasteless and were formerly widely used as rodenticides. Thallium is used in the optical, electronic, and chemical research industries.⁹²

Thallium is rapidly absorbed from the GI tract after ingestion and from the lungs after inhalation. Once absorbed, its distribution is extensive; no significant protein binding occurs. The estimated volume of distribution is 20 L/kg. There is significant enterohepatic recycling. Elimination half-life ranges from 3 to 8 days, although half-lives as long as 15 days have been reported. About two thirds of a thallium dose is excreted in the feces, and the remainder is excreted in the urine. Seventy percent of a single dose is excreted within 1 month.⁹³

Thallium's toxicity results from its similarity to potassium.⁹⁴ It depolarizes excitable membranes and disturbs the function of sodium-potassium ATP. Mitochondria are particularly susceptible. Severe toxicity occurs with ingestions exceeding 200 mg, and the average lethal adult dose is 1 g.⁹⁵

Thallium poisoning produces the triad of gastroenteritis, polyneuropathy, and alopecia. The immediate phase of intoxication consists of GI effects that appear within 3 to 4 hours, with nausea, vomiting, diarrhea, abdominal pain, and hematochezia. An intermediate phase appears within 1 week, consisting of hypertension, tachycardia, and chest pain. At this stage, signs of central and peripheral nervous system toxicity appear. CNS signs include optic neuritis, ptosis, confusion, coma, and psychosis. Peripheral neuropathy is more striking, with intense hyperesthesia of the soles making walking difficult. Weakness and ataxia may also occur.⁹² Respiratory failure may ensue.⁹⁶ Gingival hyperpigmentation and pigmentation of the hair may appear. Severe, intractable constipation may develop. The late stage of thallium poisoning, appearing 2 to 4 weeks after exposure, consists of marked alopecia, a diffuse nonspecific rash, palmar erythema, perioral lesions, and Aldrich-Mees lines on the fingernails.^{93,95-97} A "residual" stage, occurring more than 4 weeks after exposure, consists of memory loss, ataxia, tremor, and foot drop. Death generally occurs 10 to 15 days after severe exposure. Neurologic sequelae may occur in survivors.⁹⁸ Laboratory abnormalities consist of

anemia, thrombocytopenia, increased levels of hepatic transaminases, and decreased complement levels.⁹⁵ Flat or inverted T waves may be seen on ECG.⁹⁵ Axonal destruction and demyelination may be present on sural nerve biopsy.⁹⁵

Twelve cases of combined thallium and arsenic poisoning in a group of workers were reported by Rusyniak and colleagues.⁹⁹ Of these, 89% had myalgias and arthralgias, 78% had paresthesias and synesthesias, 67% had joint stiffness and insomnia, and 52% had alopecia and joint pain. Diarrhea and constipation were uncommon. Seven of 11 patients tested had blackened or darkened hair roots. Eight of 11 tested patients had sensorimotor peripheral neuropathies ranging from mild to moderate-severe. Two patients with both elevated thallium and arsenic blood levels had the most severe peripheral neuropathies. Eleven of the 12 patients were reevaluated 6 months later, and all had improvement of peripheral neuropathies. However, 6 of 11 still complained of dysesthesias, mainly involving the feet. Five developed early complete alopecia that began about 14 days after exposure and resolved over 4 months. Sequelae of anxiety and depression were common. None had Mees' lines.

Thallium poisoning during pregnancy has resulted in a wide range of fetal effects from severe toxicity and residual sequelae to apparently normal development.¹⁰⁰ There is a trend toward low birth weight and prematurity. Thallium crosses the placental barrier and is excreted in the breast milk.

Diagnosis is made on the basis of clinical manifestations and confirmed by measurement of thallium in serum or urine. Serum levels greater than 50 µg/dL suggest poisoning, but because 70% of thallium is bound to erythrocytes, whole-blood measurements are likely to be more accurate.⁹⁷ Urinary excretion of greater than 10 to 20 mg per 24 hours is considered excessive. Other potential methods for identifying thallium poisoning are electroretinography and electromyography (which demonstrates decreased distal motor units and membrane instability). Thallium poisoning may be misdiagnosed as Guillain-Barré syndrome, selenosis, arsenic poisoning, or acute porphyria.^{96,97}

Treatment goals are enhancing fecal excretion, enhancing urinary excretion, and, when necessary, extracorporeal elimination. Early GI decontamination may decrease absorption. Fecal elimination may be enhanced by administration of Prussian blue (ferric ferrocyanide). Activated charcoal should be administered initially because there is no pharmaceutical preparation of Prussian blue available in the United States, and obtaining it from a chemical supply company may take an inordinately long time; 250 mg/kg of Prussian blue daily should be given orally in 4 divided doses with a cathartic.⁹⁹

Administration of sodium iodide can form an insoluble thallium-iodine complex that is poorly absorbed.⁹⁶ Forced diuresis also has potential benefit; human studies have suggested that it increases thallium urinary elimination two- to sixfold.¹⁰¹ Forced diuresis with potassium chloride supplementation has also been advocated; however, exogenous potassium may displace thallium

into the serum and thus provide greater opportunity for nervous system penetration.⁹⁷

Dithiocarb is a chelating agent that enhances urinary elimination of thallium; however, the resulting thallium chelate is highly lipophilic, crosses the blood-brain barrier, and exacerbates neurologic toxicity. Therefore, dithiocarb administration is *not* recommended.

Extracorporeal removal techniques including peritoneal dialysis are unlikely to be efficacious.

Tin

Tin is a ubiquitous trace element. It exists in three forms (metallic, inorganic, organic), with the metallic and inorganic forms being the least toxic.¹⁰² Organotins are used as stabilizers in polymers and as catalysts.

Most tin salts are insoluble, with less than 5% absorbed from the GI tract. Once absorbed, tin is distributed and deposited in the kidneys, lungs, and bone. Most circulating tin is bound to erythrocytes.

Trialkyltins are the most toxic organotins. Being highly lipophilic, they readily penetrate into the CNS.^{103,104} Organotin exposure has been associated with altered mental status, confusion, and amnesia.¹⁰³ Ingestion results in abdominal pain, diarrhea, and vomiting.¹⁰⁵ Other complaints include headache, tinnitus, deafness, disorientation, syncope, and loss of consciousness; EEG changes may be present.¹⁰⁵ Triethyltin, unlike trimethyltin, may also produce acute cerebral edema. Ingestion of triphenyltin acetate has caused nephropathy with proteinuria, azotemia, polyuria, hematuria, and pyuria.¹⁰⁶ Hepatitis and pancreatitis may develop.¹⁰⁶ Delayed onset of sensorimotor peripheral neuropathy may occur.¹⁰⁵ Long-term tin inhalation can produce a benign pneumoconiosis (*stannosis*).¹⁰² Delayed bullous irritant contact dermatitis has occurred after skin contact with a marine antifouling paint containing bis-tributyltin oxide.¹⁰⁷

De-butylated metabolites of tributyltin chloride, particularly dibutyltin chloride, are responsible for observed hepatotoxicity. Cytochrome P-450 plays some role in metabolism.^{108,109}

Diagnosis is based on the clinical presentation, history, and elevated serum tin levels. In a case of trimethyltin exposure, urinary excretion was 52 µg/dL, compared with a normal urine tin concentration of about 0.1 µg/dL.¹⁰³

Treatment is supportive. No chelating agents alter the course of tin poisoning.

Zinc

Zinc is an essential micronutrient. More than 70 metalloenzymes require zinc for proper function. There is also a strong relationship between zinc and copper metabolism. Zinc has been used to treat copper accumulation associated with Wilson's disease.¹¹⁰ Zinc dietary supplements are widely promoted, but their use can result in toxic manifestations.¹¹¹ Overexposure can occur in the workplace and in patients being hemodialyzed with water stored in galvanized steel tanks.¹¹²

Acute ingestion of 2 g or more results in GI irritation and vomiting. Continual excessive zinc intake results in

reductions in serum copper levels, (hypocupremia), sideroblastic anemia, and neutropenia.^{110,111} A child with long-term zinc ingestion developed listlessness, anemia, neutropenia, poor weight gain, and sideroblastic anemia, indicative of copper deficiency.¹¹¹ A child who ingested an acid soldering flux solution with a zinc chloride concentration of 30% to 60% and a pH of 3.0 developed severe corrosive injury of the stomach and an antral stricture, but not systemic zinc poisoning.¹¹³

The diagnosis of zinc poisoning is confirmed by an elevated serum zinc level (normal: 9.2 to 23 $\mu\text{mol/L}$).

Treatment of zinc poisoning is supportive. After ingestion, GI decontamination measures include administration of activated charcoal. Chelation is very effective for reducing elevated zinc levels. Options include calcium disodium EDTA, BAL, D-penicillamine, and N-acetylcysteine.^{112,114}

METAL FUME FEVER

MFF is an occupational disease caused by inhalation of freshly oxidized metal fumes with a particle size smaller than 0.5 to 1.0 μm .¹¹⁵⁻¹¹⁷ MFF is also referred to as *Monday morning fever*, *the smothers*, *brass founder's ague*, *brazier's disease*, *foundry fever*, *galvanizer's poisoning*, *smelter's chills*, *zinc chills*, *zinc fume fever*, *brass chills*, and *copper fever*.¹¹⁸ Although welding is the occupation most often associated with the disease,¹¹⁹ MFF is encountered after soldering, forging, melting, and metal casting.

MFF is associated with a number of metals, including zinc, copper, magnesium, cadmium, manganese, and antimony (Box 75-1). Zinc, iron, and copper are the most common causes of MFF. Inhalation exposure to a powder catalyst containing vanadium used in production of maleic anhydride has caused an MMF-like syndrome with associated neutrophilic alveolitis.¹²⁰ Cadmium and tin, although associated with MFF, produce a more severe respiratory illness that shares some features with MFF; urinary cadmium levels may be elevated, and there can be associated transient renal impairment.⁴³

The clinical presentation consists of chills, fever, leukocytosis, myalgias, chest pain, nonproductive cough, dry throat, intense thirst, and a metallic taste in the mouth.¹¹⁸ These symptoms usually appear 4 to 12 hours after acute exposure. Temperature may be as high as 104° F (40° C), accompanied by sinus tachycardia and

rales. Chest x-rays may appear normal or may reveal a diffuse patchy infiltrate.¹²¹ These findings characteristically appear to be more severe than the patient's clinical presentation would suggest. Bronchoalveolar lavage, if performed, may reveal inflammatory cells. Other clinical features include elevated lactate dehydrogenase levels and hypoxia.¹²² Tolerance to MFF often develops. As a result, workers often complain of illness developing at the beginning of the week, improving by the end of the week, and completely resolving during the weekend. The benign clinical course of MFF distinguishes it from acute cadmium or tin pneumonitis.¹²²

The cause of MFF is unclear, although it has been attributed to release of endogenous pyrogens or production of antigenic metal proteinates.¹²² Delayed hypersensitivity pneumonitis and allergic reaction have been suggested as mechanisms.¹¹⁸ MFF might result from a direct toxic effect on alveolar cells. Inhalation of purified zinc oxide fumes results in a dose-dependent increase in polymorphonuclear cells and proinflammatory cytokines in the lungs, indicating a role for cytokine networking in MFF development.¹²³

MFF is self-limited and usually resolves within 48 hours. Bed rest and antipyretics are recommended. Corticosteroids have been recommended for patients with interstitial infiltrates on chest x-ray after a history of zinc fume exposure. A history of exposure to cadmium or tin fumes warrants hospitalization for observation and supportive care. No permanent sequelae of MFF have been identified. Elevated serum zinc levels and increased urinary copper levels have been reported, but their significance is unclear.¹¹⁵

CHELATORS

Exogenous

A number of chelating agents have been explored as potentially effective treatments for exposure to toxic metals. Table 75-1 summarizes their potential roles. A complete review of the pharmacology of these agents is beyond the scope of this chapter.

Endogenous

A number of endogenous metal-carrying proteins have been identified in humans and animals, such as transferrin, ferritin, ceruloplasmin, and transferrin, that carry iron, copper, and manganese. Because they form stable bonds with metals, these agents have been referred to as *endogenous chelators*.

Metallothionein is a low-molecular-weight protein transport molecule, but its exact role has not been fully defined.¹²⁴ Its high sulfur content permits the formation of several types of stable bonds with metals.^{124,125} Although found primarily in intracellular sites, it is also secreted into the bile, urine, and plasma. Zinc has a profound influence on metallothionein production, and synthesis decreases with zinc deficiency. Zinc excess produces a marked increase in metallothionein production.

BOX 75-1

METALS COMMONLY ASSOCIATED WITH METAL FUME FEVER

Zinc
Magnesium
Manganese
Iron
Copper
Cadmium
Tin

TABLE 75-1 Metal Chelators

CHELATOR	USEFUL	POSSIBLY EFFICACIOUS	UNLIKELY TO BE EFFICACIOUS	POTENTIALLY HARMFUL
Calcium disodium EDTA	Zinc Cobalt		Chromium Nickel Thallium	Selenium
Dimercaprol (BAL)	Lead Nickel Copper Antimony Bismuth Gold Zinc Arsenic Mercury	Chromium		Selenium Cadmium
Dithiocarb (sodium diethyldithiocarbamate)	Nickel carbonyl	Cadmium		Thallium Elemental Nickel
D-Penicillamine (currently not often used except for treatment of chronic copper accumulation)	Copper Lead Arsenic Mercury Zinc Gold		Nickel	Selenium
Dimercaptosuccinic acid (DMSA)	Antimony Lead Arsenic			
Dimercaptopropane sulfonic acid (DMPS)	Antimony Lead Mercury			
Deferoxamine	Iron			
N-acetylcysteine (NAC)	Aluminum Gold Zinc			

Metallothionein synthesis can also be induced by exposure to toxic metals, including cadmium, mercury, silver, platinum, gold, and bismuth. Cadmium is a particularly potent inducer of metallothionein synthesis. Very little is known about the degradation of this protein, although its loss is directly related to the bound metal. In experimental animal models, the half-lives, of cadmium-, zinc-, and copper-induced metallothioneins are 80, 20, and 17 hours, respectively.¹²⁵ Cadmium toxicity is reduced by the presence of metallothionein.⁶¹
