76 *Organophosphates and Carbamates*

CYNTHIA K. AARON, MD

At a Glance...

- Organophosphate and carbamate compounds produce toxic effects largely from inhibition of acetylcholinesterase.
- Manifestations of poisoning are variable but commonly include muscarinic signs (e.g., salivation, diaphoresis, abdominal cramps, vomiting, diarrhea, bronchorrhea, bradycardia, miosis, coma, seizures, apnea) and nicotinic signs (e.g., fasciculations, flaccid paralysis, tachycardia).
- The most common cause of death is respiratory failure associated with refractory hypotension.
- Treatment for poisoning from these agents includes health care provider self-protection and patient airway protection; administration of atropine, oximes, and benzodiazepines; and decontamination.
- Atropine is frequently underdosed in serious poisonings and should be titrated to clearing of pulmonary secretions and adequate oxygenation.
- Atropine should be administered rapidly and in escalating doses.
- Benzodiazepines may be cerebroprotective and should be used liberally in all severely ill patients.
- Oxime therapy should be used in all patients requiring atropine.
- Oxime therapy is recommended for all carbamate poisonings with the exception of carbaryl.
- Clinical findings suggestive of severe organophosphate poisoning warrant immediate treatment presumptively, before the results of lab testing are available.

RELEVANT HISTORY

Pesticides are the leading cause of fatality from acute poisoning worldwide.^{1,2} In 1990, the World Health Organization (WHO) estimated that 3 million severe pesticide poisonings occur annually and are associated with up to 200,000 deaths.³ To better characterize and track the epidemiology of these exposures, the WHO established the International Programme on Chemical Safety

Poison Information Database Management (IPCS INTOX) Pesticide Project in 2002.⁴ In the United States alone, the Environmental Protection Agency (EPA) estimates 10,000 to 20,000 physician-documented pesticide exposures annually among 3,380,000 agricultural workers. The EPA has instituted the Sentinel Event Notification System for Occupational Risk (SENSOR) Pesticides Program to monitor the incidence of these exposures.⁵

Pesticides are a diverse group of chemicals designed to kill and control various insects, animals, fungi, or plants. Insecticides, or chemicals designed to kill insects, are within the class of pesticides. Organophosphorus compounds, organophosphates (OPs), and carbamates, or other cholinesterase inhibitors, are the most commonly used insecticides worldwide and account for more human poisonings and death annually than any other pesticide class.⁶ In 2004, there were 10,994 OP and carbamate exposures reported to U.S. poison centers; 70 (0.6%) resulted in major toxicity and 3 (0.3%) in death.⁷ As potent eukaryotic toxins, OPs have been used broadly, serving as both military-based nerve agents and agricultural pesticides. Nerve agents have been in military arsenals since World War II. One of these agents, sarin, achieved international notoriety after its release by terrorists in Matsumoto and Tokyo in 1995⁸ (see Chapter 105A).

OP and carbamate insecticides are a mixed group of chemicals. OPs are derived from phosphoric acid-containing compounds.⁹ The OPs achieved great popularity after World War II because of their effectiveness and lack of environmental persistence. For the most part, they have an unstable chemical structure and disintegrate into harmless by-products within days under the influence of sunlight, oxygen, and reactive soil chemicals.¹⁰ Except for the highly fat-soluble agents, OPs are less persistent in body tissues and the environment than dichlorodiphenyltrichloroethane (DDT) and other organochlorines. Because of their lack of persistence, OPs have replaced DDT as the insecticide agent of

choice. Carbamates are commonly used both as insecticides and medicinals for the treatment of human disease. Pyridostigmine and neostigmine are both used to treat myasthenia gravis, neostigmine has been effective for adynamic ileus, and physostigmine is most often used to treat the anticholinergic syndrome. Donepezil and memantine, central nervous system (CNS) reversible inhibitors of acetylcholinesterase, are used to treat the relative acetylcholine deficiency existing in Alzheimer's disease.

The first OP, tetraethyl pyrophosphate (TEPP), was synthesized in 1854, but the class was not actively used commercially until World War II when the Germans used TEPP as a substitute for the scarce botanic insecticide nicotine. The human toxicity of OPs was exploited by the Germans at the end of World War II with the development of the nerve agents tabun, sarin, and soman (GA, GB, and GD). The allies developed VX after the war (see Chapter 105A).

OP poisoning can occur in various settings. Occupational exposures occur during application in farm workers and pest control workers and during their manufacture, storage, and transport. Children are accidentally exposed to these agents through domestic use or inappropriate home storage. Intentional or unintentional misuse and suicide gestures and attempts account for the remainder of civilian cases. The toxicity

of OPs varies greatly. The most highly toxic group is used primarily for agricultural and military purposes. Those with lower toxicity are available for use by households and commercially around populated areas. Table 76-1 lists some of the better-known commercial OPs, their uses, and their relative human toxicity. Table 76-2 lists some common commercial carbamates (in decreasing order of toxicity).

STRUCTURE

OPs are a heterogeneous group of compounds but share some common chemical properties. OPs contain a central phosphorus atom with a double bond to either oxygen (P=O) or sulfur (P=S), two organic side chains (R₁ and R₂), and an additional side chain that becomes the leaving group (X). The leaving group is specific to the individual OP and may be a cyanide, thiocyanate, halide, phosphate, phenoxy, thiophenoxy, or carboxylate group (Fig. 76-1). The R₁ and R₂ groups are aryl or alkyl groups and, in most of the common pesticides, are either two methyl or two ethyl ester groups that form the dimethyl (dimethoxy) or diethyl (diethoxy) OPs. Carbamates are similar but have nitrogen bound to oxygen or sulfur instead of a phosphoric acid residue (Fig. 76-2).

TABLE 76-1 Examples of Organophosphate Insecticides

COMMON NAME	PRODUCT EXAMPLE	CHEMICAL NAME	ESTIMATED FATAL ORAL DOSE (g/70 kg)
<i>Agricultural Insecticides (high toxicity)</i>			
Tetraethyl pyrophosphate	Miller Kilmite 40	Tetraethyl pyrophosphate	0.05
Phorate	Thimet (American Cyanamid)	<i>O,O</i> -Diethyl (S-ethylmercaptomethyl) dithiophosphate	
Parathion	Niagara Phoskil Dust	<i>O,O</i> -Diethyl- <i>O-p</i> -nitrophenyl phosphorothioate	0.1
Phosdrin	Mevinphos (Shell)	Dimethyl- <i>O</i> -(1-methyl-2-carbomethoxyvinyl) phosphate	0.15
Disulfoton	Disyston	Diethyl- <i>S</i> -2-ethyl-2-mercaptoethyl phosphorodithioate	0.2
<i>Animal Insecticides (intermediate toxicity)</i>			
Coumaphos	Co-Ral Animal Insecticide	Diethyl- <i>O</i> -(3-chloro-4-methyl-7-coumarinyl) phosphorothioate	
Chlorpyrifos (Dursban)	Rid-A-Bug (Kenco)	<i>O,O</i> -Diethyl- <i>O</i> -(3,5,6-trichloro-2-pyridyl) phosphorothioate	
Trichlorfon	Trichlorfon Pour On (Hess & Clark)	Dimethyl trichlorohydroxyethyl phosphonate	
Ronnel	Korlan Livestock Spray (Dow)	<i>O,O</i> -dimethyl- <i>O</i> -(2,4,5-trichlorophenyl) phosphorothioate	
<i>Household Use or Golf Course/Community Spray (low toxicity)</i>			
Diazinon	Security Fire Ant Killer (Woolfolk)	Diethyl- <i>O</i> -(2-isopropyl-4-methyl-6-pyrimidyl) phosphorothioate	25.0
Malathion	Ortho Malathion 50 Insect Spray	Dimethyl- <i>S</i> -(1,2-bis-carboethoxy) ethyl phosphorodithioate	60.0
Vapona (dichlorvos, DDVP)	Shell No-Pest Strip	<i>O,O</i> -Dimethyl- <i>O</i> -2,2-dichlorovinyl phosphate	
Acephate	Chevron Orthene	<i>O,S</i> -Dimethylacetylphosphoramidothioate	

**TABLE 76-2** Carbamate Insecticides

COMMERCIAL NAME	CHEMICAL
Temik	Aldicarb
Matacil	Aminocarb

PHARMACOKINETICS

Organophosphorus agents are a diverse group of agents with widely variable human toxicity. The toxicity is largely determined by the individual agent, formulation, dose, route of exposure, duration of contact, and health status of exposed individuals. Estimates of relative human toxicity are typically based on the acute oral LD₅₀ measured in rats. The WHO updated its toxicity ratings in 2002 and classified agents as extremely hazardous (Ia) (liquid state: LD₅₀ < 20 mg/kg); highly hazardous (Ib) (20–200 mg/kg); moderately hazardous (II) (200–2000 mg/kg); and slightly hazardous (III) (>2000 mg/kg).¹¹ Extremely and highly hazardous agents are designated as “Poison or Toxic” on commercial labels. The WHO classification is different from that promulgated by the EPA, which classifies OP compounds as high toxicity (rat LD₅₀ < 50 mg/kg), intermediate or moderate toxicity (LD₅₀, 50–1000 mg/kg) and low toxicity (LD₅₀ > 1000 mg/kg)¹² (see Table 76-1). Thus, lethal doses for human

adults may vary from a few milligrams for the highly toxic agents (e.g., TEPP) to 50 g for the low-toxicity agents (e.g., malathion). Nerve agents are even more potent, with as little as 1 mg of sarin or soman being lethal to adult humans after inhalation of its vapors.¹³ For nerve agents and other highly volatile or aerosolized OPs, toxicity is designated by a concentration time (Ct) variable that is a better measure of exposure by inhalation. For nerve agents, the lethal Ct₅₀ ranges from 10 to 400 mg/min/m³ (see Chapter 105A).¹⁴

Most OPs are effectively absorbed by all routes—dermal, respiratory, gastrointestinal, and conjunctival. The rapidity of onset and severity of effects may vary after exposure by different routes. The most common route of exposure is dermal, as occurs from most occupational and accidental poisonings. Most suicide attempts result from ingestion. Inhalation exposure may occur when agricultural pesticides (malathion and parathion) are dispersed as aerosols of solids in a liquid carrier or as a dust. Liquids may be mixed in a hydrocarbon vehicle for easy dispersal. The latter may facilitate absorption and add to the toxic effects (e.g., pulmonary toxicity). Aerosols can be absorbed through the skin, mucous membranes, and lungs, whereas liquids can be absorbed through the skin or ingested. Breaks in the skin may enhance absorption, and hot, humid environments or persistent skin contact can enhance toxicity. Gaseous, aerosolized, or dust forms of OPs have a rapid onset of action because they are taken immediately into the pulmonary circulation, leading to shortness of breath, bronchorrhea, bronchoconstriction, and rapid development of systemic signs and symptoms. Liquid and aerosolized forms can be absorbed through the skin; absorption depends on agent volatility, ambient temperature, and lipophilicity. These agents may show immediate local effects (local fasciculations and diaphoresis) or have delayed systemic effects. Ingested agents tend to have a rapid onset of action. Many OPs are highly lipophilic, which enhances their dermal absorption. High lipophilicity may also lead to agent sequestration in body fat stores and result in delayed and erratic toxicity that could occur for several days to weeks after initial exposure.

After absorption, OPs are commonly metabolized by hepatic oxidation, hydrolysis, and conjugation with glutathione. Some agents may undergo glucuronidation and demethylation. Oxidation occurs through the cytochrome P-450 system and often leads to bioactivation, or production of a more reactive oxon metabolite. Serum enzymes such as paraoxonase 1 (PON1) contribute to endogenous hydrolysis of several OPs, lipids, and other prodrugs.¹⁵ Most OPs are rapidly degraded and eliminated in the urine; some may be detectable more than 48 hours after exposure.¹⁶ OPs that are metabolized to para-nitrophenol, however, can be detected by measuring this metabolite in the urine. There is a rough correlation between the excretion of para-nitrophenol and the occurrence of illness.¹⁷ Because the effect of cholinesterase inhibition is cumulative, toxicity may be evident after complete elimination of the OP, particularly with the fat-soluble agents.

Although OP and carbamate insecticides are rapidly absorbed through dermal, respiratory, gastrointestinal (GI), and conjunctival routes, all OPs must be in the oxon form ($P=O$) to inhibit acetylcholinesterase. Those agents that do not initially have the phosphorus bound to oxygen, such as the phosphorothioate ($P=S$), are metabolized by the hepatic cytochrome P-450 system into the activated oxon.⁹ Parathion and malathion are examples of oxon activation; they must first be converted to paraoxon and malaoxon, respectively (by substitution of an oxygen for sulfur), to be physiologically active. Because of this activation step, the rapidity of symptom onset after OP exposure is partially dependent on the OP's initial state. Rate of activation and rate of enzyme inhibition may be equally important for toxicity. For example, in Sri Lanka, patients with dimethoate ingestions presented extremely ill but had acetylcholinesterase levels about one third to one fourth of normal, whereas patients similarly ill from chlorpyrifos and fenthion had almost no detectable cholinesterase levels. Most deaths from dimethoate occurred 24 to 36 hours after ingestion, at a time when their enzyme activity was continuing to decrease. All agents shared similar solvents, and the difference may reflect the low fat solubility of dimethoate, leading to a higher blood concentration.¹⁸

OPs that are already in the oxon form may cause symptoms earlier than those that need metabolic activation. However, some agents, such as parathion, are rapidly activated and can produce symptoms in less than 30 minutes.¹⁹ Most OPs are readily lipid soluble, but certain agents (i.e., azinophos-ethyl, bromophos-ethyl, chlorpyrifos, coumaphos, diazinon, parathion, phosalone, sulfotep, and fenthion and chlorfenthion) are highly lipid soluble and tend to accumulate in adipose tissue.¹⁵ Initial exposure may not lead to acute signs and symptoms of toxicity. After agent bioaccumulation and a time delay, the signs and symptoms of toxicity become evident.⁹

Carbamates have rapid onset but are less fat soluble. They may significantly inhibit acetylcholinesterase but undergo spontaneous hydrolysis with resumption of enzyme activity, usually within 24 hours. This is not an absolute, as some carbamates, such as carbosulfan, may have prolonged systemic effects.²⁰

PHARMACOLOGY AND PATHOPHYSIOLOGY

OPs and carbamates produce toxicity by binding to and inhibiting the action of acetylcholinesterase at its serine active site. Acetylcholine accumulates at nerve terminals, initially stimulating, then paralyzing, cholinergic neurotransmission at both central and peripheral nicotinic and muscarinic receptors. Under normal physiologic conditions, acetylcholinesterase hydrolyzes acetylcholine into two primary inert fragments, acetic acid and choline, decreasing postsynaptic effect and neurotransmission and generating choline for reuptake and resynthesis. When acetylcholinesterase is inhibited, acetylcholine cannot be broken down and accumulates at the nerve or myoneural terminal, leading initially to

postsynaptic excitation followed by inactivation of the synapse or myoneural junction.²¹ Inactivation occurs from depolarizing blockade at postsynaptic receptors.

True acetylcholinesterase (E.C. 3.1.1.7) is important for physiologic neurotransmission and is found primarily in nervous tissue but is also expressed on the surface of red blood cells (erythrocyte or red blood cell cholinesterase). Pseudocholinesterase or butyrylcholinesterase is found in serum and the liver and is important in the metabolism of xenobiotics. Erythrocyte acetylcholinesterase activity closely mimics neuronal acetylcholinesterase and is a more accurate measure of its physiologic activity.²²⁻²⁴ Because butyrylcholinesterase (EC 3.1.1.8) measurements are technically simpler to perform, this is the more readily available assay in hospitals and in the field.²⁵

Acetylcholinesterase is a convoluted protein structure with a pit containing a serine binding site and a catalytic site. Initially, the electrophilic OP oxon forms a reversible Michaelis-Menten complex, binding to the serine enzymatic active site followed by rapid phosphorylation of the serine residue. Once this happens, the leaving group (X) on the OP is released. As this reaction occurs, the OP becomes covalently bound to the enzyme, sitting in the pit and changing the conformation of the enzyme, preventing the active site from binding acetylcholine, and subsequently inhibiting catalytic activity.²⁶ The organophosphorylated enzyme can then undergo two different reactions. The enzyme can become "aged" or irreversibly bound and inactivated by cleavage of one of the R groups. This dealkylation process leads to a monosubstituted phosphoric acid residue that remains firmly attached to the enzyme. The rate of aging depends on the specific OP agent. Alternatively, reactivation of the enzyme can occur when the bond between the serine and organophosphorus moiety hydrolyzes. Enzyme reactivation occurs spontaneously at an extremely slow rate for diethyl-containing organophosphates or may be markedly accelerated with the addition of a nucleophilic oxime. The rate of reactivation and irreversible inactivation by aging is highly dependent on the attached R groups. Smaller side groups allow for more rapid reactivation and aging, whereas the presence of branched side chains provides steric hindrance and greater bond stability, thereby delaying reactivation and aging.²⁷ For instance, dimethyl OPs have significantly faster rates of spontaneous reactivation and aging (half-lives of about 0.7 hours and about 3.7 hours, respectively) than diethyl OPs (half-lives of 31 hours and 33 hours, respectively). Although dimethyl phosphorylated OPs age more rapidly than diethyl OPs, they are relatively resistant to oxime therapy, particularly pralidoxime. Although there is more time to reactivate diethyl OPs, they require significantly more oxime to achieve this reactivation.^{9,28} Regardless of these differences, however, once the enzyme has "aged," it is no longer susceptible to reactivation by endogenous hydrolysis or oxime therapy.^{9,29}

Carbamates bind to the same binding site of acetylcholinesterase by carbamylation (C-O bond). The carbamate-acetylcholinesterase covalent bond is not as

strong as that produced by OPs (P-O or P-S bond). Because of this, spontaneous hydrolysis or decarbamylation occurs more readily, usually reactivating acetylcholinesterase within 24 hours. Some carbamates may take longer to spontaneously hydrolyze. For example, in Sri Lanka, carbofuran-poisoned patients required ventilatory support for up to 48 to 72 hours.¹⁷ Carbamylated acetylcholinesterase does not undergo irreversible binding or “aging” and can be reactivated using oximes.^{24,30,31}

Acetylcholinesterase inhibition is not an equilibrium-dependent reaction and is most sensitive to the concentration of OP present at the enzyme interface. After a person is exposed to an OP, the formation of oxon peaks and then declines in the serum. However, even with a declining OP and oxon serum concentration, acetylcholinesterase inhibition continues to increase because this reaction proceeds by covalent binding. Physiologically, the exposed individual can continue to function normally until a minimum amount of functioning acetylcholinesterase is left unbound. Once this threshold has been reached, even removal of circulating OP will not enhance enzyme function. Enzyme catalysis then becomes entirely dependent on the restoration of a critical mass of uninhibited acetylcholinesterase. However, if the phosphorylated acetylcholinesterase can undergo a rapid endogenous reactivation such as with some dimethoxy OPs, then removal of the offending agent may contribute to recovery, but this is not true for dimethoate. The ability of a nucleophilic oxime to reactivate the enzyme depends then on the structure of the OP bound to acetylcholinesterase, the time that the reactivator is present at the site, and the concentration of the reactivator.^{9,28}

The actual process of reactivating the phosphorylated acetylcholinesterase with a nucleophilic oxime involves formation of an intermediate step. At some point, a transient complex forms consisting of the phosphorylated enzyme and oxime. Because formation of this complex undergoes saturation kinetics, further increases in oxime concentration does not enhance reactivation. After the oxime has pulled off the OP from the enzyme, the phosphorylated oxime complex becomes a strong inhibitor of acetylcholinesterase. In addition, oximes themselves can inhibit acetylcholinesterase. The net effect is that even during treatment of an OP-inhibited enzyme with an oxime, there may be a transient, but undocumented, increase in inhibited acetylcholinesterase and worsening of symptoms.⁹ This has not been shown to occur with pralidoxime because the phosphorylated oxime formed is very unstable, transiently present, and likely without clinical effect. More likely, there is no net difference. If the oxime removes the organophosphate from acetylcholinesterase and forms an active phosphorylated oxime, it can still only react with one acetylcholinesterase molecule so the stoichiometry remains unchanged (personal communication, Peter Eyer, 2006). Obidoxime produces a much more stable phosphorylated oxime and could have clinical consequences. This, however, has not yet been documented in vivo in humans.³²

Despite oxime treatment, poisoning with highly fat-soluble agents (e.g., fenthion) or large exposures to

agents that require bioactivation or prolonged elimination (e.g., fenthion) may lead to recurrent or delayed clinical toxicity. This is because the newly regenerated enzyme becomes reinhibited as the OP leaches out of the fat tissue or is bioactivated over a longer period of time.

The signs and symptoms of OP intoxication result from the overabundance of acetylcholine. This leads to initial excitation followed by paralyzed neurotransmission at cholinergic synapses.²⁶ Cholinergic neurotransmission occurs throughout the CNS, at the parasympathetic nerve endings, at a few sympathetic nerve endings such as the sweat glands (muscarinic effects), and in the somatic nerves (e.g., neuromuscular junction) and ganglionic synapses of autonomic ganglia (nicotinic effects). The signs and symptoms of OP poisoning are an expression of acetylcholine excess at numerous different nerve terminals (Table 76-3) and can manifest predominantly as muscarinic or nicotinic effects, or as a combination of both. The effects of OPs on acetylcholinesterase affect m-receptors differently than n-receptors and may account for some of the clinical variation. The OP effect on cholinesterase affecting m-receptors appears to be long-lasting, whereas n-receptors rapidly desensitize. Acetylcholine overstimulation at the neuromuscular junction leads to depolarization inactivation of myocytes; repolarization and, thus, recontraction are inhibited. This leads to muscle paralysis. In addition, the cholinergic nervous system has significant interplay with other neurotransmitters (i.e., γ -aminobutyric acid [GABA]) and results in additional toxic effects. CNS effects result largely from m-receptor stimulation but also occur from activation of n-receptors and *N*-methyl-*d*-

TABLE 76-3 Clinical Effects of Organophosphate Poisoning (Acetylcholine Excess)

ANATOMIC SITE OF ACTION	SIGNS AND SYMPTOMS
Muscarinic Effects	
Sweat glands	Sweating
Pupils	Constricted pupils
Lacrimal glands	Lacrimation
Salivary glands	Excessive salivation
Bronchial tree	Wheezing
Gastrointestinal	Cramps, vomiting, diarrhea, tenesmus
Cardiovascular	Bradycardia, decrease in blood pressure
Ciliary body	Blurred vision
Bladder	Urinary incontinence
Nicotinic Effects	
Striated muscle	Fasciculations, cramps, weakness, twitching, paralysis, respiratory embarrassment, cyanosis, arrest
Sympathetic ganglia	Tachycardia, elevated blood pressure
Central Nervous System Effects	
	Anxiety, restlessness, ataxia, convulsions, insomnia, coma, absent reflexes, Cheyne-Stokes respirations, respiratory and circulatory depression

aspartate (NMDA) glutamate receptors and inhibition of central GABA neurotransmission.^{19,33,34}

After the OP–acetylcholinesterase complex has undergone complete aging, enzyme resynthesis is the only means to restore acetylcholinesterase function. This may take weeks to months and necessitate prolonged pulmonary support for patients until sufficient enzyme resynthesis has occurred.⁹

TOXICOLOGY

Clinical Presentation

The onset and severity of clinical effects is variable and depends on the identity of the agent, its formulation, and the dose, duration, and route of exposure. Initial symptoms may range from mild to immediately life threatening. The most rapid onset of symptoms occurs with inhalation, and the slowest with dermal exposure. The onset of clinical effects may take up to 24 hours after skin exposure to highly lipophilic agents that require bioactivation. In contrast, systemic effects and respiratory arrest can occur within minutes of inhalation of an aerosol or vapor of nerve agents. After OP ingestion, clinical effects usually occur within 30 to 90 minutes. Although OP toxicity generally occurs within 4 to 12 hours, full-blown toxicity may not manifest for 24 hours.³⁵

Stimulation of the muscarinic parasympathetic system will cause miosis, bradycardia, hypotension, bronchoconstriction, hyperactivity of GI smooth muscle, and oversecretion of the exocrine glands (salivary, lacrimal, bronchial, and pancreatic). Stimulation of the autonomic ganglia (nicotinic effects) produces sympathomimetic effects that include tachycardia, hypertension, and mydriasis. Nicotinic effects at the neuromuscular junction lead to muscle weakness, fasciculations, and muscle paralysis. This is also known as type I paralysis.¹⁸ (see Table 76-3). GI symptoms are the most common manifestations early after ingestion of OPs. Aerosol exposure typically presents with respiratory and ocular complaints, whereas dermal exposure may cause localized fasciculations and sweating. The wide and mixed spectrum of clinical effects that occur with significant exposures may lead to misdiagnosis. In one study, 16 of 20 transfer patients were incorrectly diagnosed as having other conditions.³⁶ The presence of excessive salivation, lacrimation, fasciculations, noncardiogenic rales or rhonchi, and muscle weakness during the initial phase of poisoning is suggestive of OP poisoning. Miosis, a typical muscarinic sign, is not always present because mydriasis may result from concomitant and overriding nicotinic stimulation. Senanayake and colleagues developed a nonvalidated scoring system for organophosphorus intoxications called the Peradeniya Organophosphorus Poisoning Scale (POP Scale).³⁷ This system ranks the severity of poisonings using five clinical signs (miosis, bradycardia, heart rate, level of consciousness, and respiratory rate). Each sign is graded on a scale from 0 to 2, with an additional point given for those

that seize. Based on results from the initial study, severe intoxications (score of 8 to 11) have a higher mortality rate, greater need for ventilatory support, and higher dose of atropine in the first 24 hours.

CNS effects generally include anxiety, restlessness, agitation, slurred speech, ataxia, confusion, lethargy, stupor, coma, seizures, and centrally mediated respiratory depression.³⁸ In addition, chorea, psychosis, depression, and choreoathetosis have been described.³⁹ Muscle weakness and paralysis develop in severe exposures. The most common cause of death is primary respiratory failure with subsequent cardiac arrest.⁴⁰ Early respiratory failure is largely mediated by CNS respiratory center depression from increased, uncoordinated CNS muscarinic neuronal activity.^{19,26} In animal studies, such early respiratory depression can be prevented by anticholinergic agents that cross the blood-brain barrier.²⁶ Peripheral nicotinic and muscarinic effects contribute to respiratory failure and include excessive oral and tracheobronchial secretions, laryngospasm, bronchoconstriction, and paralysis of the diaphragm and intercostal muscles. There may be additional noncholinergic-mediated effects.³⁴

Other findings associated with acute OP intoxication include hyperamylasemia with or without clinical pancreatitis.⁴¹ Electrocardiogram abnormalities have been reported and include conduction disturbances (e.g., atrioventricular block, ST-segment elevation, QTc prolongation) and arrhythmias (e.g., supraventricular and ventricular dysrhythmias, including torsades de pointes).^{42,43}

Diagnosis

The diagnosis of acute OP poisoning is made clinically and based on history and suggestive physical findings. The diagnosis should be considered whenever a patient presents with the cholinergic toxidrome or muscarinic signs and symptoms such as miosis, increased airway secretions, lacrimation, bradycardia, and GI complaints. The added presence of nicotinic findings such as muscle fasciculations and weakness further suggests the diagnosis of OP poisoning. A history of exposure is helpful but not often available. The simultaneous presence of muscarinic and nicotinic findings on physical exam are characteristic of organophosphorus poisoning and often warrant empiric treatment with atropine and oxime therapy. Clinical findings suggestive of severe OP poisoning (i.e., mental status changes, coma, seizures, bronchorrhea, bronchoconstriction, fasciculations, autonomic instability, and paralysis) warrant immediate treatment presumptively. When multiple victims become comatose or seize within minutes of an inhalational exposure, a terrorist incident with nerve agents should be suspected and empiric antidotal treatment given provided that supportive physical findings are present¹⁴ (see Chapter 105A). When the diagnosis of OP poisoning is not evident or when toxicity is mild or chronic, a depressed serum or red blood cell cholinesterase level may be obtained to assist diagnosis. Cholinesterase levels, however, are rarely available in a timely manner.

Thus, if OP poisoning is suspected, therapy should be initiated before confirmation by laboratory values.

Laboratory confirmation of poisoning is demonstrated by depressed erythrocyte or butyrylcholinesterase activity. Because non-hemoglobin normalized acetylcholinesterase levels are extremely variable between individuals, a mild intoxication may not be confirmed until serial levels document a steady increase in enzyme activity over time.^{22,23} Erythrocyte acetylcholinesterase that is standardized to hemoglobin does not exhibit the same interindividual variability. As erythrocyte acetylcholinesterase is expressed on the erythrocyte membrane, in the absence of reactivation, restitution of normal, preintoxication enzyme activity levels are dependent on formation of new erythrocytes, a process that takes about 90 to 120 days and mimics neurologic function.^{23,24} However, erythrocyte acetylcholinesterase regenerates more slowly than neuromuscular junction acetylcholinesterase. Butyrylcholinesterase is an acute-phase reactant and may normalize in 14 to 30 days. There is a genetic variant in about 3% of the population, causing baseline depression of butyrylcholinesterase activity level. Other conditions that may depress butyrylcholinesterase include parenchymal liver disease, secondary hepatic insufficiency from congestive heart failure, metastatic carcinoma, reduced levels of serum albumin, pregnancy, and several medications.^{44,45}

The remainder of diagnostic studies are nonspecific and include elevated leukocyte count and hyperglycemia.⁴⁶ Occasionally, elevated levels of urinary p-nitrophenol may be found in cases of OP intoxication in which para-nitrophenol is the leaving group (e.g., parathion).^{19,47}

Management

Treatment of OP poisoning consists of aggressive supportive care and antidotal therapy.

Initial management of the OP- or carbamate-poisoned patient requires immediate attention to the airway. Cyanosis or other evidence of hypoxia, rales, excessive oral secretions, or bronchorrhea should be treated with oxygen and rapid atropinization. Although most texts state that the patient should be oxygenated before atropine administration, it may be impossible to oxygenate until secretions are controlled. In a large cohort of OP-poisoned patients, Eddleston successfully administered early atropine without evidence of enhanced cardiovascular toxicity.⁴⁸ Atropine should be dosed until the secretions have dried and evidence of pulmonary fluid has diminished. During rapid atropinization, respiratory paralysis or excessive secretions should be managed by controlling the airway with intubation, ventilation, and continuous suctioning. When rapid sequence intubation (RSI) is necessary to control the airway of an OP- or carbamate-poisoned patient, the use of a depolarizing paralytic (e.g., succinylcholine), although not contraindicated, is discouraged. In such cases, succinylcholine may result in prolonged paralysis because it is metabolized through butyrylcholinesterase.⁴⁹ In one patient poisoned with chlorpyrifos, the use of succinylcholine resulted in

neuro-muscular paralysis that lasted 192 minutes.⁴⁹ There are no data on the effect of prolonged chemical paralysis with a nondepolarizing agent in the OP-poisoned patient.⁵⁰ Thus, the use of rocuronium or other rapidly acting nondepolarizing agents is preferable for RSI in these patients. Concomitant with atropinization, patients should be resuscitated with intravenous (IV) fluids. OP pesticides result in significant GI fluid losses and probably cause nitric oxide-induced vasodilation.⁵¹ Rapid IV administration of 2 L or more of an isotonic solution may be necessary to return the patient to euvolemia. Vasopressors are indicated when hypotension is unresponsive to atropine and fluids. A direct-acting α -adrenergic agent (e.g., phenylephrine) is preferred because poisoned patients have a reduced systemic vascular resistance and relatively normal inotropic state.^{38,43,52-54} Dopamine and norepinephrine may increase the heart rate, which could prove beneficial or detrimental, depending on the initial pulse. These pressor recommendations, however, are based on pharmacologic principles and not animal or clinical data.

Seizure activity should be rapidly controlled with an IV GABAergic agent such as diazepam, midazolam, or lorazepam. Aggressive use of benzodiazepines may improve survival and prevent cardiac and CNS injury in OP-poisoned patients with seizures.^{34,55-62} Many dosing regimens have been suggested. Initial dosing recommendations include the use at least 10 mg IV diazepam or 5 to 10 mg intramuscular (IM) midazolam in adults (pediatric dosing, diazepam 0.1–0.2 mg/kg IV or midazolam, 0.1–0.3 mg/kg IM) and then titrate upward as needed. There is some evidence to suggest that OP-induced seizures involve NMDA-glutamate receptors in addition to GABA, suggesting that propofol may be a useful adjunct for continued seizure activity. Both central GABA and NMDA-glutamate receptor pathways are likely involved with seizure production and delayed CNS neuropathology associated with significant poisoning with these agents (personal communication, M. Eddleston and A. Dawson, 2004).^{58-61,63,64}

After initial stabilization, patient decontamination becomes a priority. Patients with liquid contamination of skin and clothing may have ongoing percutaneous absorption of a pesticide. In addition, they may pose a skin contact risk to health care personnel. Interestingly, there have been almost no reports of clinically significant healthcare worker secondary contamination coming from the South Asian and Indian continents, where OP intoxication is extremely common.^{65,66} Thus, as soon as possible, the patient should be disrobed completely and the skin thoroughly washed with alkaline soap and water. This should not delay initial life-saving treatment and administration of antidotes. The removal of clothing eliminates 85% to 90% of a contamination hazard.⁶⁷ Although hypochlorite solutions deactivate OPs *in vitro*, their use on human tissues is discouraged and may lead to corneal burns and other toxicity.⁶⁸ A standard hypochlorite solution (5%) can be used to decontaminate equipment.⁶⁹⁻⁷² Alternatively, the U.S. Military has adopted dry agents for field decontamination.⁶⁸ In civilian use, agents such as soil, flour, or

talcum powder may be applied to the skin and then mechanically removed.⁷¹

One of the first priorities in OP and nerve agent treatment is health care provider self-protection and decontamination. Medical personnel participating in the decontamination process should have adequate personal protective equipment (PPE) and training. Ideally, the patient should have undergone initial decontamination at the scene by appropriate personnel trained in Hazardous Materials in Level A or Level B protection. At the Health Care Facility, medical staff should be dressed at the minimum in Level C PPE, including impermeable gowns and shoe covers; butyl, neoprene, or nitrile gloves; and facial splash protection^{70,73} (see Chapter 103). Standard latex gloves are readily permeable to and do not protect from transdermal absorption of OP agents. Solutions or dry agents used for decontamination are considered hazardous materials, and arrangements for their disposal should be prearranged. Further discussion on appropriate PPE and training should be directed to the local Poison Control Center, Metropolitan Medical Response System, HazMat team, Hospital Disaster Plan, or State Department of Health.⁷²

The utility of GI decontamination after ingestion of an organophosphorus ester pesticide is controversial. Because these agents are highly emetogenic, most patients have vomited before presentation. If a patient presents early (less than 30–60 minutes) after ingestion, empiric nasogastric aspiration of an ingested solution seems appropriate. There are, however, no published randomized controlled trials (RCTs) that have evaluated the efficacy of this modality. Some OP agents are known to bind activated charcoal. Thus, the administration of oral activated charcoal is usually recommended after oral OP pesticide exposure. As for gastric lavage and aspiration, the efficacy of activated charcoal for OP poisoning by ingestion has been not been adequately studied. Because many of the OP agents are dissolved in hydrocarbon solvents that can result in significant pneumonitis when aspirated, the potential benefits of gastric decontamination must be balanced against the risk for enhanced morbidity from aspiration for each patient treated.⁵⁰ Currently, there is an ongoing large RCT in Sri Lanka investigating these issues.^{73,74} Gastrointestinal decontamination is rarely necessary after nerve agent exposure because these patients have been poisoned by inhalation or dermal contact (see Chapter 105A).

ANTIDOTAL THERAPY

The accepted mainstays of antidotal therapy in OP poisoning are adequate use of atropine to treat muscarinic symptoms and an oxime to regenerate the acetylcholinesterase.^{9,28} Atropine, a competitive antagonist at muscarinic cholinergic receptors, inhibits the postsynaptic binding of acetylcholine. As a tertiary amine structure, atropine crosses the blood-brain barrier and works at both peripheral and central muscarinic sites. It has no effect at nicotinic cholinergic receptors. Although there have been no RCTs to demonstrate the efficacy of

atropine for OP and carbamates poisoning, there are innumerable case reports that substantiate its efficacy and usefulness for this poisoning.⁵⁰ Atropine is indicated for muscarinic symptoms, primarily bronchorrhea and, sometimes, bradycardias and hypotension. The dosing of atropine is variable, and the dosing regimen used by Eddleston and colleagues is recommended. From their experience with OP poisonings in Sri Lanka, Eddleston and colleagues have shown that the administration of rapid, escalating doses of atropine (“rapid atropinization”) followed by an atropine infusion is successful in controlling the airway and other muscarinic symptoms.^{48,50} With this approach, patients with evidence of muscarinic excess are initially given 1 to 2 mg IV atropine, and doses are then doubled every 5 minutes as needed. This dosing regimen will rapidly yield a cumulative dose of 25 mg by 20 minutes and 75 mg by 25 minutes.⁴⁸ Patients with severe toxicity may require 75 to 100 mg atropine. The adequacy of atropine dosing is determined clinically by clearing secretions from the pulmonary tract as assessed by resolution of crepitus and rales, a heart rate greater than 80 beats/minute, dry skin, and a reasonable blood pressure (mean arterial pressure > 60 mm Hg or evidence of end-organ perfusion). Pupil dilation can be delayed up to 30 minutes and is not a useful sign initially, but the eventual aim is to have nonpinpoint pupils. However, in the Sri Lankan experience, patients with severe OP poisoning had mid to large but mildly reactive pupils after an adequate atropine dose had been administered (personal communication, M. Eddleston and A. Dawson, 2004).^{48,50} After the patient has been stabilized, an atropine drip is established to maintain the patient at the appropriate level of atropinization, usually around 20% of the total loading dose per hour, and is titrated as needed. More than 5 mg/hr of atropine is rarely needed.⁷⁵ Glycopyrrolate has been suggested as an alternative to atropine. However, because it does not cross the blood-brain barrier, it should be reserved for patients with a purely peripheral muscarinic syndrome.^{33,76-79} The use of inhaled atropine or ipratropium bromide has been recommended when pulmonary symptoms predominate to minimize systemic side effects produced by intravenous atropine administration.^{33,34}

Although “rapid atropinization” is life saving, this method of atropine administration may occasionally overshoot and produce an anticholinergic delirium. In this situation, the atropine infusion should be halted and the patient closely observed until signs of cholinergic excess begin to reappear. At this point, the atropine can be restarted.⁴⁸ When this occurs, the patient may need sedation until the delirium recedes. Benzodiazepines appear to be the safest option in this situation.

Nerve agent intoxication does not appear to require similar atropine dosing (see Chapter 105A). Experience from the Matsumoto and Tokyo sarin incidents and declassified case reports suggest that 2 to 20 mg atropine appears to be adequate.^{13,14,71,80,81} In the Tokyo sarin attacks, only 19% of poisoned patients required more than 2 mg of atropine.⁷ Topical ocular homatropine or

atropine preparations may be effective for focal ocular cholinergic toxicity (e.g., eye pain, dim vision) produced by aerosol nerve agent exposures.⁷¹

Oximes are used early after OP poisoning to regenerate active acetylcholinesterase. The use of oximes has become somewhat controversial after several Asian studies failed to demonstrate their efficacy for OP poisoning.^{82-84,85} The conclusions of these studies, however, have been questioned because of flawed trial design and other reasons.^{28,29} In Western countries, use of oxime therapy is fairly well accepted, and there are multiple animal studies and human case reports supporting its efficacy.^{24,28,30,86-92} Pralidoxime (2-PAM chloride, Protopam) and obidoxime (Toxogonin) are the most commonly used agents, although P2S (pralidoxime mesylate), pralidoxime methiodide, TMB-4, HI-6 and HLö-7 (experimental use only) are used in other parts of the world. The H-series oximes (e.g., HI-6 and HLö-7) have greater efficacy against certain nerve agents (e.g., soman) and may be preferable for such poisoning. Multiple textbooks and the package insert for Protopam suggest that oxime therapy should be reserved for nicotinic signs and symptoms. There is no scientific basis for this because oximes will regenerate acetylcholinesterase at both muscarinic and nicotinic receptors. Many patients who were treated with only atropine may have had adequate endogenous hydrolysis of the phosphorylated acetylcholinesterase. Use of oxime therapy in carbamate poisoning is another area of uncertainty. On average, carbamylated acetylcholinesterase will spontaneously hydrolyze within 24 hours. Patients poisoned with carbamates, however, may become severely ill and require ventilatory support for greater than 24 hours, similar to an OP poisoning. There is good evidence to suggest that oximes are effective for treating these carbamate-poisoned patients and shortening intensive care unit time.^{24,31,87,93-97} The exception to this may be carbaryl (Sevin), for which there is animal evidence to suggest that oxime use may worsen the cholinesterase block. There are no human data that demonstrate enhanced toxicity from oxime use in carbaryl-poisoned patients.^{93,94,97} Currently, oxime therapy is recommended for all carbamate poisonings with the exception of carbaryl.

The apparent ineffectiveness of oximes for OP poisoning has several possible explanations. First, reactivation of acetylcholinesterase may be slowed and ineffective because of steric effects of certain OP compounds at the active site. Second, the rate of acetylcholinesterase inhibition may be greater than its rate of reactivation because of insufficient oxime dosing relative to the degree of OP exposure. Third, formation of phosphoryloximes during the reactivation process may paradoxically inhibit acetylcholinesterase to a greater extent and longer duration than would be present without oxime therapy. This is more significant with obidoxime than pralidoxime. Finally, oxime therapy may not be provided for a long enough time in instances in which OP metabolic activation or tissue redistribution occurs. Similarly, oxime therapy may not be initiated for patients who present late because of the belief that all the cholinesterases will have aged. Aging is a process,

and it is believed that as the acetylcholine accumulates at the receptor, acetylcholinesterase competes with the OP for the binding site.²⁷

Most oxime controversy relates to appropriate dosing. Most U.S. textbooks suggest a pralidoxime dose of 1 to 2 g IV or IM followed by 1 g every 6 to 12 hours. This dose has not been subjected to rigorous scrutiny and may lead to low serum oxime concentrations. A serum concentration of 4 mg/L has been suggested as the minimum oxime “therapeutic level” for OP poisoning; this value was derived from animal data.^{98,99} A subsequent pharmacokinetic study by Medicis used a pralidoxime infusion in human volunteers to maintain this serum concentration.¹⁰⁰ Further study has suggested that 1 g pralidoxime every 6 to 8 hours or the infusion rate from the Medicis study are inadequate to treat significantly poisoned patients and that larger oxime doses are necessary.^{32,98,101-103} There are a number of reasons for this, which include poor affinity of oximes for the phosphorylated enzyme complex, overwhelming inhibition by a large OP exposure, reinhibition of the enzyme by sustained or high levels of OP, OP persistence in a deep compartment such as seen with extremely fat-soluble agents (duration of treatment), and aging of the enzyme.^{9,28} The WHO has recommended an initial dose of 30 mg/kg pralidoxime IV followed by an IV infusion of 8 mg/kg/hr. Alternatively, if a continuous infusion is not possible, 30 mg/kg pralidoxime should be administered IM or IV every 4 hours. Obidoxime is dosed at 4 mg/kg initially then 0.5 mg/kg/hr or 4 mg/kg initially then 2 mg/kg every 4 hours. Both agents may be administered IV or IM.¹⁰⁴ Based on computer kinetic modeling, Eyer and associates have determined that an ideal plasma concentration of 50 to 100 $\mu\text{mol/L}$ for pralidoxime and 10 $\mu\text{mol/L}$ for obidoxime should produce an acceptable half-life of reactivation of about 10 minutes.¹⁹ These can be achieved with a pralidoxime dosing of 1 g IV followed by 0.5 g/hr or an obidoxime dosing of 250 mg initially followed by 750 mg over 24 hours.²⁷ Regardless, the ideal oxime dose has not yet been established and will probably depend on the OP agent, time since exposure, body load, pharmacogenetics, and other variables. The South Asian Clinical Toxicology Research Collaboration initiated a study in 2004 that compares the WHO pralidoxime regimen versus placebo in the treatment of OP poisoning in Sri Lanka (personal communication, M. Eddleston and A. Dawson, 2004). These data should help to clarify the optimal pralidoxime dosing strategy.

It is important to be aware of the treatment distinction between diethyl and dimethyl phosphoryl OPs. Dimethyl-poisoned patients have a shorter window of opportunity for oxime treatment and necessitate higher doses. This discrepancy may be partially responsible for the variable results reported in the literature. Treatment of nerve agent poisoning follows similar precepts but uses a different dosing strategy. Because the G nerve agents age extremely rapidly, treatment must be started immediately (see Chapter 105A).

Adverse reactions from oxime therapy include hypertension, transient increases in neuromuscular block, and projectile vomiting after bolus administration of pral-

idoxime (personal communication, M. Eddleston and A. Dawson, 2004).^{29,100,104} There are no good data on the effects of pralidoxime in the first trimester of pregnancy.^{106,107} Pralidoxime is categorized by the U.S. Food and Drug Administration as a pregnancy category C medication. Thus, it should only be used with initial careful consideration of the relative risks and benefits to the mother and child.^{108,109}

INTERMEDIATE SYNDROME

In 1987, Senanayake described a syndrome of proximal muscle weakness, weak neck flexors, and respiratory failure, which he designated as the intermediate syndrome (IMS) or type II paralysis.^{110,111} The IMS has onset within 24 to 72 hours after the acute cholinergic crisis and can last several days to weeks.¹¹²⁻¹¹⁶ Many authors have debated the existence of IMS versus continued neuromuscular junction (NMJ) acetylcholinesterase depression in the face of inadequate oxime therapy.¹¹⁷⁻¹¹⁹ The syndrome has been characterized by absent muscarinic symptoms but continued severe acetylcholinesterase inhibition as measured by cholinesterase activity, and there is no therapy other than supportive care.^{112,120-122} Electromyograms—Nerve Conduction Velocity Studies done during IMS have shown decrement pattern in neuromuscular transmission with repetitive stimulation at low rates consistent with presynaptic and postsynaptic impairment at the NMJ and desensitization.^{123,124} At this time, there is no consensus on etiology; the pralidoxime study in Sri Lanka may provide some insight on this problem. Treatment of IMS is primarily supportive. Some recommend the administration of additional oxime, but few data support this recommendation.

DELAYED POLYNEUROPATHY (ORGANOPHOSPHATE-INDUCED DELAYED NEUROPATHY OR POLYNEUROPATHY)

Several classes of OPs (phosphates, phosphoramidates, and phosphonates) inhibit both acetylcholinesterase and neuropathy target esterase (NTE).^{125,126} NTE is found on the Schwann cells lining the axons and, when aged, causes loss of the myelin sheath with a “dying back” axonopathy that is unresponsive to atropine and pralidoxime.^{125,127-129} This leads to a symmetric demyelinating process with the patient complaining about cramping pain, paresthesias, and distal limb weakness. Patients notice the onset of weakness and paresthesias about 3 to 6 weeks after initial illness, with subsequent progression over weeks to months.^{130,131} A lymphocyte NTE assay has been developed to assist diagnosis; depression of lymphocyte NTE correlates with development of organophosphate-induced delayed neuropathy (OPIDN).¹³²⁻¹³⁸ There is no known treatment for OPIDN. Resolution may occur over 6 months to a year for those with mild symptoms, whereas those with severe OPIDN usually have persistent deficits.^{125,130-136}

CHRONIC NEUROPSYCHIATRIC SEQUELAE

A number of other neurologic sequelae that have been associated with OP intoxication. Acutely, patients may

develop severe encephalopathy.¹³⁹ Long-term effects have included short-term memory loss, fatigue, confusion, depression, psychosis, parkinsonism, and other extrapyramidal findings.¹³⁹⁻¹⁴⁴ Some of these findings may resolve over time.

NEW TREATMENT DEVELOPMENTS

One of the difficulties in treating OP-poisoned patients is determining when to stop oxime therapy. Eyer and associates have started to assay whole blood for the ability of oximes to reactivate red blood cell cholinesterase before and during treatment. Ongoing acetylcholinesterase inhibition, recrudescence poisoning, and response to therapy could be recognized and diagnosed from a decrease in the ability to reactivate red blood cell cholinesterase in patient whole blood.¹⁹ The increasing importance of pharmacogenomics is also being investigated. Depending on the paraxon concentration, studies in liver microsomal studies have shown that paraoxon has variable effects on the cytochrome P-450 enzymes (e.g., CYP1A2, 2B6, and 3A4). During parathion desulfuration, an electrophilic sulfur is released, which inactivates the cytochromes, leading to significant effects on other metabolic processes and detoxification of xenobiotics.¹⁹

Research on the use of hydrolases to treat OP toxicity has led to the potential for use of bacterial phosphotriesterases to cleave OPs.¹⁴⁵⁻¹⁴⁷ The discovery of polymorphism in the *PONI* genetic coding suggests that there is a variable sensitivity to toxicity of OPs.^{14,148} This may help to explain why some people exhibit a higher degree of toxicity when exposed to the same agents.

Other promising novel therapies for OP pesticide poisoning are being researched. There has been at least 10 years of work on the Hagedorn agents HI-6 and HLö-7. These two agents and others continue to show promise as the preferred oximes for nerve agent toxicity (see Chapter 105A).^{28,86,89,90,149-152} Alkalinization with sodium bicarbonate has increased survival in animal models and may be useful in humans.^{153,154} A recent Cochrane review of alkalinization for the treatment of OP intoxication suggested that it may be useful clinically, but there is insufficient evidence for routine use.¹⁵² A promising new line of investigation is the use of OP hydrolases to break down OPs before they can covalently bind to acetylcholinesterase. Data from in vitro and animal models have demonstrated that the combined use of bacterial OP hydrolases and oxime therapy has been successful in preventing reinhibition of acetylcholinesterase.¹⁵⁵⁻¹⁵⁷ Finally, human butyrylcholinesterase has been used to increase survival in soman-poisoned rats.^{158,159}

STEPHEN W. BORRON, MD, MS

At a Glance...

- Pyrethrins, pyrethroids, and newer compounds are rapidly replacing the organochlorines, organophosphates, and carbamates in many geographic areas, particularly in the consumer pesticide market.
- Pyrethrins and pyrethroids have low mammalian toxicity, even in overdose, compared with the aforementioned pesticide families.
- Amitraz exposure is generally benign; however, large overdoses may result in central nervous system depression, bradycardia, and hypotension. It is an α_2 -adrenoceptor agonist.
- The avermectins may induce coma, metabolic acidosis, and rhabdomyolysis after large ingestions.
- Two newer pesticides, imidacloprid and fipronil, are discussed. Serious toxicity has been rarely reported in humans.
- DEET is the most widely used insect repellent. Neurotoxicity has been reported with topical application and with ingestion, but the incidence of serious adverse reactions is small in comparison with the widespread use of these products.
- The chemical and physical characteristics (e.g., volatility) of the active ingredients of pesticides and of the adjuvants and solvents associated with them should be considered in any evaluation of their toxicity and approach to treatment.

The relatively high mammalian (including human) toxicity of the organophosphates and carbamates (see Chapter 76) and environmentally persistent organochlorines (see Chapter 81) has led regulators and manufacturers of pesticides to search for safer alternatives. This chapter covers the family of pyrethrins and pyrethroids, as well as a number of other established and more recent compounds used as pesticides or repellants of biting insects. These include DEET, amitraz, imidacloprid, fipronil, and the avermectins. The pesticides covered here represent the present and near future of pesticides, owing to improved safety of these products relative to organophosphates, carbamates, and organochlorines. These compounds, in general, have limited toxicity in humans, animals, and the food supply but nonetheless require respect in their application and an understanding of the risks they pose in acute overexposure.

Although most life-threatening human poisonings have been reduced by the move away from the more traditional pesticides, there is concern among some that the pyrethroids and newer pesticides also pose unnecessary human risk. This chapter briefly examines the concerns for potential long-term and subtle forms of toxicity but focuses on the acute toxicity of these compounds in unintentional and intentional overexposure.

No discussion of the risks associated with chemical agents is appropriate without a balancing view of their benefits. We are continually placed at significant risk for disease and death by infectious disease vectors. Malaria continues to kill millions of people throughout the world, particularly in developing nations. The World Health Organization (WHO) estimated the worldwide incidence at 213 million cases in 1998.¹ Snow and colleagues believe that the number is much higher, about 515 million cases of *Plasmodium falciparum* malaria alone.² The developed world is not spared from vector-borne diseases. The United States has seen significant numbers of cases of West Nile Fever, dengue fever, Lyme disease, encephalitides, and other arthropod-borne illnesses in recent years (see www.cdc.gov/ncidod/dvbid/). The judicious use of pesticides and repellants has a significant effect on the incidence of these diseases. For example, Alten and colleagues showed a reduction of malaria from 8.29% to 1.57% in a test city when mosquito nets impregnated with deltamethrin (a pyrethroid) were employed, whereas malaria incidence slightly increased in a control area (no intervention) and in two areas where nonimpregnated nets were employed.³ Flea- and tick-borne diseases have also been diminished by the appropriate use of insecticides and repellants by humans and their pets. Pesticides also decrease the amount of food that is wasted.

In any evaluation of pesticide safety, it is critical to remember the roles of solvents in which the pesticides are dissolved and any adjuvants used to increase their efficacy or ease of use. It is not uncommon, particularly among the newer “insect-selective” pesticides, that the solvent has greater acute toxicity to the patient than the active ingredient. This is important to recall not only in caring for patients but also when reporting cases in the medical literature. Furthermore, some cases of reported “pesticide poisoning” occurring through inhalation are probably solvent exposures because many pesticides have low vapor pressures and are unlikely to be inhaled unless dispersed as droplets or mists.

In addition to their accepted mechanisms of action, which often involve alteration of neural transmission, most of the pesticides show evidence of inducing oxidative stress, which naturally raises concern about long-term effects, such as the induction of cancer and other chronic adverse events. This issue is generally of greater concern to scientists and risk assessors on a population basis, rather than at the individual level. The reader is referred to the article by Abdollahi and associates⁴ for a current review of the issue of oxidative stress induced by various pesticides.

PYRETHRUM, PYRETHRINS, AND PYRETHROIDS

Substances and Mechanisms of Action

Pyrethrum is an oleoresin mixture derived from the common chrysanthemums, *Chrysanthemum cinerariifolium* and *Tanacetum cinerariifolium*. The natural pesticide pyrethrins are derived from pyrethrum. To enhance certain characteristics, particularly resistance against degradation by ultraviolet light, synthetic analogous compounds have been developed, which are referred to as *pyrethroids*. Pyrethroids constitute more than 30% of worldwide pesticide use, based on their efficacy in knockdown and killing of insects, low mammalian toxicity, and limited environmental persistence.⁵ For reasons of simplicity and because the use of synthetic compounds now outweighs that of natural compounds, the term *pyrethroids* is used hereafter as a collective term for this family of pesticides when further precision is not required.

Pyrethroids act by altering the voltage dependence and rate of activation of the gated sodium channel and by inhibiting inactivation of the channel, increasing the likelihood that the channel opens or remains open. Although insect and mammalian voltage-gated channels share morphologic features and physiologic characteristics, natural toxins have developed that are highly specific for insect channels. The pyrethrins and pyrethroids are believed to be relatively specific based in part on their greater affinity for insect channels. Furthermore, body temperature differences between mammals and insects predispose the insect to greater effects from a pyrethroid of given toxicity because degradative metabolism is faster in mammals. Additionally, the insect's smaller size means that the toxicant is more likely to reach its target before deactivation by the organism.⁵

Uses

Pyrethroids are applied by a variety of methods. They are applied directly to fabrics, such as mosquito netting and curtains, to serve as insect repellants. Their efficacy in reducing disease-carrying insects for malaria and Chagas' disease has been demonstrated.^{3,6} They are used in smoke coils and intermittent and total release sprays. Permethrin is applied in humans as a 5% cream for

treatment of scabies and as a 1% cream rinse or lotion for the treatment of pediculosis capitis.

Toxicology

Gammon (cited in Zlotkin) has divided the pyrethroids into two classes, which differ based on the absence (type I) or presence (type II) of an α -cyano group and which provide them with distinct toxicologic activities⁵ (Fig. 77-1). Type I pyrethroids induce a tremor syndrome, composed of hyperexcitation, ataxia, and convulsions, followed by flaccid paralysis. Type II pyrethroids have greater effects in mammals and may cause a writhing syndrome (hypersensitivity, tremors, hypersalivation, and paralysis).

EXPOSURE ROUTES

Pyrethroids may enter the body by ingestion, inhalation, or dermal absorption, although the first two routes are certainly of greatest potential consequence. The "no observed adverse effect level" (NOAEL) for ingestion in animals is 1 mg/kg/day, above which neurotoxic effects may be seen.⁷ The "acceptable daily intake" of permethrin and cypermethrin, as established by the WHO, is 0.05 mg/kg/day.⁸ Schettgen and colleagues⁹ have provided evidence that most pyrethroid body burden is due to ingestion of food-borne residues, based on an earlier experimental study by Woollen and colleagues.¹⁰ Inhalation of pyrethroids is likely of significant concern only during the actual spray application of the products, owing to the low volatility of these compounds. For example, permethrin has a vapor pressure of only 45 μ Pa at 25° C (3.4×10^{-7} mm Hg).⁹ Barlow and colleagues recently assessed the risk involved with the use of deltamethrin-impregnated bed nets for prevention of malaria.⁷ They identified a NOAEL of 1000 mg/kg/day in animals. Applying safety factors, an "acceptable exposure level" (AEL) of 10 mg/kg/day was established for humans. Tests using the nets revealed that actual exposures incurred in use are less than one tenth of the AEL. The authors concluded that the risk-to-benefit ratios for mosquito net use are quite favorable.⁷ The WHO has determined that the use of pyrethroid-treated bed nets reduces malaria mortality and morbidity, particularly in children and newborns, and may reduce transmission of malaria when used on a large scale.¹¹

FIGURE 77-1 Pyrethroids. **A**, Permethrin (type I). **B**, Cyfluthrin (type II). Note the α -cyano group.

METABOLISM

Pyrethroids are rapidly hydrolyzed by esterases in the liver.¹² The metabolites are then eliminated in the urine. There is no correlation between urinary metabolite concentrations and symptoms. According to Leng and associates, the unchanged pyrethroids must be determined in plasma to explain clinical effects, but pyrethroids are detectable in plasma for only a few hours after exposure.¹³

ACUTE TOXICITY

Ray and Forshaw have published a useful review of the acute toxicity of pyrethroids, particularly as applies to animal studies.¹⁴ The toxicity can be reduced to two clinical syndromes, type I (tremor syndrome) and type II (choreoathetosis/salivation syndrome), although some pyrethroids may produce a superimposed combination of both types. Type I syndrome is compared to the toxicity of DDT (see Chapter 81). The tremor may be severe, increasing the metabolic rate, and can lead to prostration and death in animals. Type II pyrethroids induce much longer delays in sodium channel conduction (>10 msec, the normal time constant of the unmodified sodium channel being about 0.5 msec). The effects of this prolongation include incoordination, choreoathetosis, seizures, and direct effects on skeletal and cardiac muscles and salivary glands, as well as reflex hyperexcitability.¹⁴ Most human case reports of acute poisoning refer to type II (α -cyano) pyrethroids. Descriptions of acute poisoning in humans are relatively rare. An International Programme on Chemical Safety document cited three cases of deltamethrin poisoning, including a report by Rousselin¹⁵ of a 13-year-old who ingested 5 g of deltamethrin (LD₅₀ in rats, 30–140 mg/kg¹⁶) in a suicide attempt. The patient developed loss of consciousness, muscle cramps, miosis, and tachycardia. She received gastric lavage, 2-pyridine aldoxime methiodide (2-PAM), sodium nitrite, sodium thiosulfate, and high doses of diazepam and had complete recovery at 48 hours. The same document further cited an unpublished case of a 23-year-old man who ingested 1.75 g of deltamethrin with no neurologic signs or symptoms. Digestive and hepatic signs were attributed to the xylene used as a solvent.¹⁷ He and colleagues reported on 573 cases of acute pyrethroids poisoning in China. Deltamethrin was involved in 325 cases.¹⁸ About one third of cases were of occupational origin and due to poor utilization conditions and lack of personal protection. Two of 158 occupational cases died of convulsions, whereas the remainder of the 573 total cases survived with 1 to 6 days of treatment. Burning skin and paresthesias were the most common symptoms reported in a group of unprotected cotton workers in China in the 1980s.¹⁹ Diarrhea, severe headaches, dizziness, fatigue, nausea, and anorexia were also reported. Transient electroencephalogram changes and fasciculations were noted, as well as convulsions in one case, with all patients making a complete recovery.

Yang and colleagues reported on 48 cases of acute ingestion of mixtures of permethrin, xylene, and surfactant.²⁰ Ten of these were accidental and 38

intentional attempts at suicide. Gastrointestinal symptoms predominated, with sore throat, mouth ulcerations, dysphagia, epigastric pain, and vomiting being common findings. Pulmonary abnormalities occurred in 29% and aspiration pneumonitis in 8 cases, with 1 fatality. Confusion (13%), coma (21%), and seizures (8%) were observed as well. A small percentage (3 of 48) had arrhythmias or shock. Mild renal and liver function abnormalities were seen in, respectively, 10% and 6% of patients. The authors concluded that this combination was responsible for significant poisonings, but that the relative contributions to toxicity were uncharacterized. Clearly, a number of these symptoms may have been attributable to the xylene carrier. LoVecchio and Knight recently reported on the case of a 36 year-old man who injected 6 mL of Real Kill Ant and Roach Killer 2 into the antecubital fossa and another 2 mL subcutaneously in a suicide attempt.²¹ This product contains tralomethrin 0.01% and *D-trans*-allethrin 0.05%, as well as mineral spirits, a glycol ether, and simple hydrocarbons. The patient suffered pain and erythema at the injection site during a 4-hour observation period with resolution. No further symptoms were noted during a 3-day psychiatric evaluation.

Allergic Phenomena

Both acute exacerbations of hypersensitivity pneumonitis²² and asthma, including fatalities,^{23,24} have been described after pyrethroid exposures. A report from the New York City Department of Health and the Centers for Disease Control and Prevention (CDC), however, revealed that widespread spraying of urban pesticides for control of West Nile Virus in 2000 did not increase the incidence of emergency department asthma visits.²⁵ Allergic contact dermatitis^{26,27} and irritant contact dermatitis²⁸ have also been reported. Amer and colleagues found that 70% of pesticide workers exposed to pyrethroids had positive patch tests.²⁹

Skin Hyperesthesia

Paresthesia may be produced by dermal exposure to these compounds. This is apparently a dose-related phenomenon and is reversible. It represents local effects on skin nerve terminals rather than systemic toxicity. Vitamin E cream has been shown to ameliorate the unpleasant sensation.³⁰

CHRONIC TOXICITY

Chronic toxicity from pyrethroids is not a generally accepted clinically recognized entity, although it is a hotly contested concern in Germany. Altenkirch reported in 1996 on 64 cases of "chronic pyrethroid toxicity" referred to the Federal Health Office.³¹ Twenty-three of these patients underwent examination in a neurologic department on an inpatient basis, using clinical neurologic, neuroradiologic, and laboratory investigations, including the examination of pyrethroid concentrations in blood and urine. The presumed sources of chronic exposure included carpets, moth repellants, pesticide sprays, and wood preservatives. Nine patients were found to have severe somatic or psychiatric

disorders determined to be unrelated to pesticide exposure, including Guillain-Barré syndrome, pituitary tumor, and spinal muscle atrophy. An additional eight were determined to meet criteria for “multiple chemical sensitivities” (see Chapter 85). In six of those cases, “a causal link between acute complaints and pyrethroid exposure could be established or not ruled out.” However, the authors found no evidence for irreversible central or peripheral nervous system lesions. Muller-Mohnssen and Hahn published a series of cases of cerebro-organic dysfunction, locomotory disorders reminiscent of multiple sclerosis or Parkinson’s disease, polyneuropathy, and immunosuppression, which they ascribed to chronic pyrethroid toxicity.³² They have recently updated their findings.³³ The methodology of their findings has been sharply criticized.³⁴ Hildebrand and colleagues speculated that effects of pyrethroids on voltage-gated calcium channels may be responsible for “chronic effects of low-level pyrethroids poisoning.”³⁵ This issue will likely not be settled in the near future but warrants careful analysis. Kolaczinski and Curtis have reviewed the literature and provide a useful summary of this contentious debate.³⁶

Laboratory Studies and Biologic Monitoring

Biologic monitoring of manufacturing workers and pesticide applicators of pyrethroids is possible, employing either measurement of the intact compounds in the blood (possibly useful for very recent high exposures) or measurement of the intact compounds or their metabolites in the urine. Hydrolysis of the ester bond of permethrin, cypermethrin, deltamethrin, cyfluthrin, and fenvalerate produces acid metabolites and 3-phenoxybenzyl alcohol (4-fluoro-3 phenoxybenzyl alcohol in the case of cyfluthrin). These metabolites may be measured in urine shortly after oral or dermal exposure, up to a maximum of 5 days. A variety of methods of detection are described.³⁷ For plasma analysis, gas chromatography with electrochemical detection (GC-ECD) has been employed.³⁸ Measurement of deltamethrin and fenvalerate has been carried out using both high-performance liquid chromatography (HPLC) and GC-ECD.^{39,40} Although useful for monitoring workers, these tests have little applicability to acute poisoning because they are not widely available and are unlikely to alter therapy.

Treatment

Treatment of pyrethroid overdose is generally supportive because there are no specific antidotes. Because of the risk for aspiration related to the associated hydrocarbon solvents and surfactants, careful attention to the airway must be ensured, particularly in the case of intentional oral overdose. Seizures are rare and may be expected to respond to benzodiazepines. The proconvulsant effects of pyrethroids are believed to be due to binding to peripheral-type benzodiazepine receptor ligands, to which diazepam has significant affinity.⁴¹

FORMAMIDINE COMPOUNDS

Substances and Mechanisms of Action

Chlordimeform and amitraz (Fig. 77-2) are the two representative compounds of this group of pesticides. Chlordimeform was voluntarily withdrawn from the U.S. market because of concerns of increased incidence of bladder cancer in manufacturing workers.⁴² Amitraz is an insecticide and acaricide. Both of these agents act on the α_2 adrenoreceptors as agonists. Amitraz is available as an emulsifiable concentrate in an aromatic hydrocarbon solvent.

Uses

Amitraz is used in the United States to control red spider mites, leaf miners, scale insects, and aphids. On cotton, it is used to control bollworms, white fly, and leaf worms. On animals, it is used to control ticks, mites, lice, and other animal pests. It is approved for use on pears, cotton, hogs, and cattle.⁴³ It is used in some countries as treatment of generalized demodicosis of dogs and for control of ticks and mites on sheep.⁴⁴

Toxicology

Both amitraz and chlordimeform are thought to exert their principle acute toxicity by agonism of α_2 adrenoreceptors, in a manner similar to clonidine. These effects are discussed later. In addition, chlordimeform has been implicated in the production of symptomatic methemoglobinemia (probably through one of its metabolites, an aromatic amine) and also hematuria (hemorrhagic cystitis). Although amitraz has not been associated with either of these in case reports, Garnier and coworkers pointed out that amitraz also has as one of its main metabolites 2,4-dimethylaniline and that methemoglobinemia is a possibility.⁴⁵ The oral LD₅₀ of amitraz in rats is 800 mg/kg.⁴⁶

ACUTE TOXICITY

Amitraz poisoning is typically benign⁴⁵ and requires only supportive care, but there are reported cases of significant toxicity, described later. A NOAEL of 0.125 mg/kg

FIGURE 77-2 Formamidines. A, Chlordimeform. B, Amitraz.

has been established in healthy male volunteers.⁴⁷ The acute toxicity of amitraz is characterized by central nervous system (CNS) depression, bradycardia, and hypotension. In some cases, miosis is observed. Hyperglycemia may also be present. Most of these symptoms are attributable to α_2 -adrenoceptor stimulation. Mydriasis may be seen with great stimulation of these receptors. The vomiting commonly seen has been attributed to the solvent, most often a petroleum distillate, as has aspiration pneumonitis and CNS depression. Agin and colleagues⁴² published a series of seven cases of poisoning admitted to a children's hospital in Turkey between 1999 and 2001. Six cases were of oral route and one dermal. Amounts ingested were small (25–30 mL) in two cases and unknown in the rest. Dermal poisoning resulted from its misuse as a treatment for lice. Four children presented in coma, two with somnolence. CNS depression resolved within 6 to 20 hours. One was hypotensive, responding to intravenous fluids. Respiratory failure was noted in four cases, two requiring brief mechanical ventilation support (<10 hours). Mild increases in blood glucose were seen. Laboratory studies were otherwise normal. Some patients received up to four doses of atropine for bradycardia and miosis. All cases recovered within 3 days.

Doganay and colleagues previously reported two cases, one of which resulted in severe hypotension and bradycardia.⁴⁸ One case involved a 35-year-old man who drank between 50 and 100 mL (6.25–12.5 g) of amitraz in a suicide attempt. On arrival at the hospital, about 3 hours after ingestion, his heart rate was 35 beats/minute, and his blood pressure was unobtainable. The patient was in respiratory arrest. His Glasgow Coma Scale score was 3, and his body temperature was 34.5° C. He was intubated and ventilated, and atropine and dopamine were administered, along with intravenous fluids. He became conscious 22 hours after ingestion and was extubated after 24 hours. Hyperglycemia, with blood glucose as high as 500 mg/dL, persisted over a 5-day period. He was discharged without sequelae.⁴⁸

Laboratory Studies

The presence of cyanosis should prompt obtaining of arterial blood gases and methemoglobin levels. Garnier and colleagues reported plasma amitraz concentrations of 100 ng/mL 2 hours after ingestion in an asymptomatic patient and of 500 ng/mL after 2 hours in a patient with drowsiness.⁴⁵ Plasma levels are generally unlikely to be of clinical use because of their limited availability. The reader is reminded that manufacturers can often be of assistance in quantifying or at least confirming the presence of particular compounds when there is doubt about the diagnosis or when forensic issues exist.

Treatment

As in all poisonings, supportive care is vital. Given the generally limited toxicity of amitraz and the presence of petroleum distillates, gastric emptying is generally not recommended, except in cases of massive exposure or if

other, more toxic compounds are ingested. The airway should be protected if a decision is made to undertake gastric emptying by any means. A number of α_2 -adrenoceptor antagonists have been proposed as potential “antidotes” against amitraz. Yohimbine and atipamezole have been successfully employed in dogs,⁴⁹ but human experience is lacking. Phentolamine has likewise been suggested in case of ingestion of a large amount of amitraz.⁵⁰ Chen and Lu⁵¹ have recommended dimethylpropane sulfonate (DMPS) for treatment of chlordimeform poisoning and cite Chinese animal literature demonstrating its efficacy in mice, rats, and pigeons. They also report efficacy in clinical treatment of two patients poisoned with chlordimeform. The mechanism of supposed antidotal efficacy is not clearly explained.

AVERMECTINS

The avermectins are natural compounds produced by fermentation of the actinomyces, *Streptomyces avermitilis*.⁵² This species produces eight macrocyclic lactones identified as members of “A” and “B” series. The B series has been shown effective against helminths and arthropods.⁵³ Chemical modification of the natural lactones resulted in the production of ivermectin (Fig. 77-3), which is approved for use in humans and animals as an antihelminthic. It is effective against *Onchocerca volvulus*, the nematode responsible for river blindness. The U.S. Food and Drug Administration (FDA) has approved its use for strongyloidiasis and onchocerciasis. It is subject to widespread off-label use and is effective against ectoparasites (scabies and lice) and cutanea larva migrans. Its use is restricted to adults and children older than 5 years.^{54,55} Ivermectin has also been shown to improve the therapeutic response to chemotherapy drugs (paclitaxel [Taxol] and vincristine) by inhibiting multidrug resistance.⁵⁶

Ivermectin

FIGURE 77-3 Ivermectin.

An additional compound, abamectin, is used in agriculture as an insecticide on vegetables and in fruit trees. It is widely used in the control of parasites and insects, and its use is increasing, particularly as ectoparasites develop resistance to pyrethroids. The avermectins have complex effects on both vertebrate and invertebrate γ -aminobutyric acid (GABA) channels and invertebrate glutamate gated chloride channels. The net increase in intracellular chloride ions leads to paralysis and death in the target organism.⁵⁷ A more recently developed product, emamectin, is also employed as an insecticide. This product is approved in the United States on fruiting vegetables (tomatoes and peppers), leafy vegetables, and leafy brassica (cole) vegetables, as well as head and stem cole crops, head lettuce, and celery, along with aerial application.

The incidence of avermectin poisonings appears to be low. None are identified specifically in the 2003 Annual Report of the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS). Because these agents are used both as insecticides and as antiparasitics, they are likely classified under "other" categories in the database and are difficult to discern. Clinical use of ivermectin has resulted in itching, edema, malaise, cephalgia, and hypotension, as well as dyspnea, in a few patients. According to Elgart and Meinking, ivermectin has been therapeutically used in millions of patients without major adverse effects.⁵⁴ Overdose experience has been extremely limited. Chung and colleagues reported on the experience in Taiwan with two forms of avermectin, a 2% wt/wt or 2.5% wt/vol preparation of abamectin, used as an insecticide, and a 1% wt/vol preparation of ivermectin, used as an antiparasitic in hogs.⁵⁷ The authors report on the management of 19 patients seen between 1993 and 1997. Eighteen of the patients were exposed to abamectin and 1 to ivermectin. There were 15 ingestions, only 1 of which was accidental. Four of these patients remained asymptomatic, 8 had minor symptoms after a mean ingestion of 23 mg/kg or after dermal or inhalation occupational exposures. Seven patients had severe symptoms: coma (7), aspiration and respiratory failure (4), and hypotension (3), after a mean ingestion of 100 mg/kg. Metabolic acidosis was observed in four patients and rhabdomyolysis in three. One of 19 patients went on to die; his death attributed to multi-organ failure 18 days after exposure.

More recently, Yen and Lin, also of Taiwan, published a case report of an acute suicidal ingestion exposure to emamectin, a substituted benzoate salt of abamectin.⁵⁸ The 67-year-old man drank about 500 mL of a fourfold diluted solution. He subsequently developed gastrointestinal upset, with esophagoscopy-proven gastric erosions and superficial gastritis, mild CNS depression, and aspiration pneumonitis. It is worthy of mention that the 2.15% concentrate is dissolved in a substituted phenol (butylated hydroxyl toluene) and 1-hexanol, which may be responsible for the erosive lesions and mild CNS depression noted. He left the hospital on day 7 with no sequelae.

Drug Interactions

Avermectins have been shown to be potent inhibitors of the multidrug-resistant proteins [P-glycoprotein (Pgp) and others].⁵⁶ This is probably of little concern in an isolated avermectin overdose; however, other antiparasitic drugs, like colchicine, are largely dependent on elimination by Pgp.⁵⁹ This results in a theoretical increased risk if the drugs are taken in combination.

Laboratory Studies

Given the reports of metabolic acidosis and rhabdomyolysis in suicidal overdose, it seems prudent to obtain arterial blood gases and serum creatine phosphokinase concentrations in patients with significant ingestions.

Treatment

Treatment of avermectin poisonings is supportive. Given the propensity of the agents to cause CNS depression (whether due to the active ingredient or the carrier solvents), careful attention to the airway is in order. Rhabdomyolysis may necessitate urinary alkalization, which may also correct the metabolic acidosis sometimes observed. Hypotension may respond to catecholamines and judicious use of crystalloids. Hsu and coworkers demonstrated in a rat model that the hypotension sometimes associated with abamectin is due to an increase in baroreflex sensitivity and to increased serum nitric oxide levels. The latter responds to treatment with epinephrine, whereas the baroreflex sensitivity does not.⁶⁰

FIPRONIL

Fipronil (Fig. 77-4) is an *N*-phenylpyrazole, which competitively antagonizes the β subunit of the GABA α receptor. The binding to insect GABA is 1000-fold greater than that in human brain,⁶¹ likely accounting for the low toxicity in humans.

Absorption and Metabolism

Fipronil appears to be poorly absorbed from the gastrointestinal tract, based on a rat model, with 45% to 75% being excreted in the feces.⁶² Jennings and associates warned of possible human adverse effects due to skin absorption after repeated exposures to dogs treated with fipronil.⁶³ This conclusion was based on a

FIGURE 77-4 Fipronil.

study of fipronil concentrations in gloves after petting treated dogs. Metabolism is by the liver, with CYP3A4 the major isoform responsible for fipronil oxidation in humans. CYP2C19 is considerably less active. Other human CYP isoforms have minimal or no activity toward fipronil.⁶⁴

Toxicology

The oral LD₅₀ in rats is 97 mg/kg, and the dermal LD₅₀ is more than 2000 mg/kg. The no observed effect level (NOEL) in rats for neurologic effects is 0.5 mg/kg, and the lowest observed adverse effect level (LOAEL) is 5 mg/kg.⁶⁵ Fung and colleagues reported the accidental ingestion of a single ant bait (0.14 mg) of fipronil by a 77-year-old woman, who mistook it for a biscuit.⁶⁵ She had transient subjective impairment of sensorium 30 minutes after ingestion, which resolved about 30 minutes later. She had no other symptoms and no sequelae. Chodorowski and Anand reported on a 50-year-old man with occupational exposure while spraying with a solution of fipronil (Regent 200 SC) over a 5-hour period.⁶⁶ He complained of headache, nausea, vertigo, and weakness. All symptoms resolved over a 5-hour period.⁶⁶ The largest series of cases published so far comes from Mohamed and colleagues in Sri Lanka,⁶⁷ where seven patients taking intentional overdoses were described. Two patients suffered nonsustained generalized tonic-clonic seizures, which were responsive to treatment with diazepam. One patient with very high plasma concentration (1040 mg/L) remained entirely asymptomatic. There are no other reports of serious toxicity in humans.

IMIDACLOPRID

Imidacloprid (Fig. 77-5) is an insecticide of the chloronicotinyl neonicotinoid family. It has been suggested that mammalian toxicity should be low, as compared with insects, because of differences in nicotinic receptor subtypes. There have been very few reports of overdose from these compounds. Wu and colleagues have published a single clinical case involving a 64-year-old man who ingested an insecticide formulation (Tie-Boo-Tzang) containing 9.6% imidacloprid, less than 2% surfactant, and the balance a solvent, *N*-methyl pyrrolidone.⁶⁸ The patient experienced drowsiness, disorientation, dizziness, oral and esophageal erosions, hemorrhagic gastritis, productive cough, fever, leukocytosis, and hyperglycemia. Despite this, the patient recovered without sequelae and was discharged on

Imidacloprid

FIGURE 77-5 Imidacloprid.

hospital day 4. Follow-up revealed no persistent gastrointestinal lesions on barium studies. The authors concluded that the solvent was likely responsible for the CNS depression, gastrointestinal irritation, and hyperglycemia. More recently, Proença and colleagues reported two fatalities involving presumed suicidal ingestions of imidacloprid.⁶⁹ Both patients were found dead at home, thus clinical details are lacking. The authors provide technical information on the liquid chromatography/mass spectrometry (LC/MS) analysis of the compound.

DEET

DEET is *N,N*-diethyl-*m*-toluamide (Fig. 77-6) and is one of the most widely employed insect repellants worldwide. It was developed in 1946 by the U.S. Department of Agriculture for use by the military and approved for civilian use in 1957. DEET has a colorful history in terms of its reported human toxicity, having been implicated, along with pyrethrins and organophosphates, in the development of Gulf War syndrome.⁷⁰ This issue has been studied intensively and reviewed by the Institute of Medicine, which reached no definitive conclusions about the involvement of DEET or other pesticides in the syndrome.⁷¹ However, research continues in this area.⁷² The complexity of this matter (multifactorial etiologies, problems with case definitions) does not permit its further discussion here.

The U.S. Environmental Protection Agency (EPA) issued a Reregistration Eligibility Decision (RED) in 1998 for DEET. After completing a comprehensive reassessment of DEET, the EPA concluded that, as long as consumers follow label directions and take proper precautions, insect repellents containing DEET do not present a health concern. Human exposure is expected to be brief, and long-term exposure is not expected. Based on extensive toxicity testing, the EPA believes that the normal use of DEET does not present a health concern to the general population.

Uses

DEET is widely employed as a mosquito and tick repellant in concentrations varying from 5% to 100%. The American Academy of Pediatrics previously recommended application of only dilute (<10%) products in children but now states that the safety of DEET does not appear to relate to differences in concentrations between 10% and 30%, recommending selection of the lowest concentration effective for the amount of time spent outdoors and no more than one application per day. The Academy does not recommend DEET for use in children younger than 2 months of age.⁷³

FIGURE 77-6 DEET.

Routes of Entry

DEET may be toxic by ingestion, inhalation, or skin or eye absorption, although most cases of significant toxicity and death have followed multiple applications to the skin. Studies in normal male adult volunteers found dermal absorption in the range of 5.63% to 16.7% after single-dose applications.⁷⁴

Metabolism

DEET is metabolized through cytochromes P-450 by an oxidation process (CYP2B6 and CYP1A2) to *N,N*-diethyl-*m*-hydroxymethylbenzamide (BALC) or by dealkylation by CYP2C19 and CYP3A4 to *N*-ethyl-*m*-toluamide (ET).⁷⁴

Toxicity

Osimitz and Murphy reviewed the literature, clinical reports, and poison center records with regard to neurotoxicity.⁷⁵ They identified 14 reports concerning 20 individuals with reported adverse effects. These included 1 report of manic psychosis, 1 of anaphylaxis, a cardiovascular event, and 3 cases of alleged teratogenicity. The remaining 14 reports were of neurologic symptoms, including headaches, ataxia, seizures ($n = 7$), opisthotonos, disorientation and encephalopathy, myoclonus, and a movement disorder. Most were in children younger than 8 years of age, and three children died. Alternative diagnoses were proposed by the authors, including idiopathic seizures and various forms of infectious diseases and encephalopathy. The authors concluded that, given the widespread use of DEET, the paucity of such reports of neurologic toxicity and the case records of poison control centers, that the risk for adverse events was low. They recommended a prospective evaluation, in the form of a DEET registry, which was established by manufacturers and marketers. Bell and associates subsequently summarized the reports of DEET human exposures to the TESS database of the AAPCC from 1993 to 1997.⁷⁶ Of 20,764 reported exposures (oral, inhalation, dermal, ocular, and multiple routes), most had no effect, an unknown effect judged nontoxic, or minimal toxicity. There were two deaths associated with dermal exposures and none with other routes. Major effects were reported in just 26 cases (0.1%). Interestingly, the percentage of moderate effects involving adults (50%) exceeded that in children (38%) despite 64% of exposures being reported in children. Sudakin and Trevathan also recently reviewed the human toxicity of DEET.⁷⁴ They concluded that reports of adverse effects from topical application are rare, compared with their widespread use. They pointed out that the mechanisms for neurotoxic effects remain elusive, and advised prudent compliance with label directions and reporting of adverse events and careful identification of the implicated formulations. They also underlined the limitations of the retrospective review of poison center data by Bell and colleagues, pointing out that the medical outcome was unknown in nearly 40% of exposure cases, making interpretation of the dataset difficult.

Ingestion of DEET may result in rapid and severe toxicity. Petrucci and Sardini reported on a case of ingestion of 80 mg/kg (4 mL of a 20% solution) in a 10-kg, 3-year-old girl.⁷⁷ The child developed coma, with a Glasgow Coma Scale score of 6 and left horizontal nystagmus. She subsequently became hypertonic with opisthotonic episodes and three brief (<1 minute) generalized seizures. She received 15 mg of rectal diazepam and assisted ventilation with 100% oxygen. The level of consciousness improved over 4 hours, and the child was alert and responsive 10 hours later. She was discharged after 24 hours, without sequelae.⁷⁴ Tenenbein had previously reported on five ingestions of DEET. Each patient ingested large amounts of concentrated (47.5%–95%) products. Their common symptoms and signs were coma, seizures, and hypotension occurring within 1 hour of ingestion. Two patients died; three survivors had no sequelae.⁷⁸

In summary, toxic neurologic complications have been reported after skin exposures (generally repeated) and ingestions of DEET. Toxicity with recommended use appears to be rare.

Laboratory Studies

DEET may be quantified in plasma and urine by an HPLC technique.⁷⁹ This test is not generally available in hospital laboratories and therefore is unlikely to guide therapy, but it may be useful for forensic purposes.

Treatment

Treatment of suspected DEET-related toxicity is supportive. Careful attention to the airway is necessary in the case of CNS depression or seizures. Seizures may be treated with benzodiazepines, when necessary. Refractory seizures may be treated with phenobarbital.

At a Glance...

- Herbicides form a diverse group of compounds designed to selectively or indiscriminately kill plants.
- While use of herbicides far outweighs that of insecticides, significant poisoning by herbicides is relatively rare.
- Herbicide toxicity varies significantly, and may be attributable to both active ingredients and adjuvants, such as solvents and surfactants.
- The bipyridyls, diquat and paraquat, are highly toxic when ingested, through their production of highly reactive oxygen species. Diquat is primarily toxic to the kidneys, while paraquat causes often irreversible pulmonary injury. Plasma paraquat concentrations are helpful in predicting outcomes. Various antioxidant therapies have been proposed, but are unproven.
- Chlorophenoxy herbicide ingestions likewise may result in severe toxicity. This is characterized by early persistent vomiting, metabolic acidosis, cardiac conduction and rhythm disturbances, and in severe cases, development of coma. Hemodialysis enhances removal of these compounds from the blood.
- Glyphosate is widely used and is available as four different salts in association with various surfactants. Discerning the toxicity of the active ingredient from the surfactant is thus difficult. Severe poisonings may result in corrosive effects on the gastrointestinal tract with hemorrhage, hypovolemia, and cardiogenic shock, as well as aspiration pneumonitis. Pulmonary edema, metabolic acidosis, and hyperkalemia are poor prognostic indicators. Treatment is generally supportive.
- Triazine herbicides rarely result in serious toxicity.
- Urea herbicides may induce methemoglobinemia.
- Bentazon poisoning is rare but may be fatal.

Herbicides comprise a diverse group of chemicals that kill plants either selectively or indiscriminately. They may be applied to clear ground of weeds before planting the crop to be grown, on ground so that weeds are killed as they emerge, and to weeds after they have emerged (called *preplanting*, *pre-emergence*, and *postemergence application*, respectively). Herbicides can also be classed according to chemical groups, as shown in Table 78-1. Although the tonnage of herbicides manufactured worldwide annually outweighs that of insecticides several-fold, herbicide poisoning in humans, both acute and chronic, is of considerably less importance than that caused by insecticides, especially in the developing world. Indeed, acute poisoning of humans with herbicides is uncommon. Therefore, despite the long list of herbicides available, this chapter considers only those that are likely to be of clinical importance today.

BIPYRIDYL HERBICIDES**Diquat**

Diquat contains a bipyridyl ring (Fig. 78-1) and exists as a divalent cation associated with anions such as bromide and chloride. Diquat is classed as a nonselective, contact herbicide and is used as a preharvest desiccant on seed and fodder crops such as rice and sunflower.¹ Potential toxic effects on the environment are minimized by swift photochemical degradation and rapid adsorption to aquatic weeds and clay particles in soil.² Although there are many formulations containing diquat alone, it is also found in formulations with paraquat.

Most cases of diquat poisoning reported to date have resulted from the intentional, usually suicidal, ingestion of concentrated solutions, and rarely, accidental ingestion has occurred as a consequence of decanting diquat concentrates into soft drink bottles.³ During the period from 1968 to 2004, only 34 cases of diquat poisoning were reported in detail in the literature,^{4,8} of which 13 (43%) were fatal.

MECHANISMS OF TOXICITY

Diquat is a potent redox cycler, and its toxic effects depend on its ability to undergo a single electron addition to form a free radical. This occurs in the presence of

TABLE 78-1 Chemical Classification of Herbicides

CLASS	PRINCIPAL HERBICIDES
Aryphenoxypropionic acids	Diclofop and related compounds
Benzoic acids	Dicamba
Bipyridyl*	Paraquat, diquat*
Chloroacetanilides	Alachlor, propachlor
Chlorophenoxy*	2, 4-D*
Dinitrophenols	Dinoseb, di-nitro-orthocresol
Hydroxybenzotriazoles	Bromoxynil, ioxynil
Organophosphonate*	Glyphosate*
Sulfonylureas	Triasulfuron
Triazines*	Atrazine, simazine, terbutryn*
Triazoles	Amitrole
Ureas*	Diuron, monolinuron*
Others	Bentazon(e)*

*Most likely to be of clinical importance today.

nicotinamide adenine dinucleotide phosphate (NADPH) and cytochrome P-450 reductase.⁹ The diquat radical formed in this step is highly unstable and transfers an electron to molecular oxygen to form a superoxide anion radical, a highly reactive species. In this way, diquat is cycled in a continuous process of oxidation and reduction, hence the term *redox cycling*. The superoxide anion radicals produced react with each other, forming hydrogen peroxide and molecular oxygen, a reaction that may occur spontaneously or through the enzyme superoxide dismutase. Under normal circumstances, hydrogen peroxide is detoxified by catalase and glutathione peroxidase, but when such protective mechanisms are overwhelmed, it is free to cause devastating effects on cells.¹⁰ In the presence of iron, the superoxide anion radical reacts with hydrogen peroxide, generating the even more potent hydroxyl radical, which can attack the lipid chains of biologic membranes, initiating lipid peroxidation that results in membrane damage and ultimately cell death.¹⁰

The oxidative stress induced by diquat is associated with the release of iron from hepatic ferritin^{11,12} and the depletion of reducing equivalents, including glutathione and NADPH.^{9,11} In experimental studies, protection against the toxic effects of diquat is provided by catalase, especially in the presence of the iron chelator, deferoxamine.¹³ This suggests that hydrogen peroxide and transition metal ions may have important roles in the cytotoxicity of diquat. Unlike paraquat, diquat is not accumulated by the lung,¹⁴ where it has a half-life 5 times shorter than paraquat.¹⁵

TOXICOKINETICS

In rats, less than 10% of an orally administered dose was absorbed, the unabsorbed portion being excreted in the feces.¹⁶ Intact human skin is a very effective barrier against diquat absorption, and only 0.3% of an applied dose was absorbed in one study.¹⁷

CLINICAL FEATURES

Local Toxicity

Local toxicity has been reported after oral, dermal, inhalational, eye, and vaginal exposure to diquat-containing formulations. Corrosive damage to the oral mucosa, leading to burning in the mouth and painful hemorrhagic ulceration, is a common early feature of diquat ingestion. Mucosal edema of the tongue and oropharynx^{18,19} may also develop and be severe enough to necessitate endotracheal intubation.¹⁸ A male worker developed full-thickness burns of the feet after diquat dibromide leaked into his boots from a backpack sprayer²⁰; skin grafting was required. Nail growth disturbances have been observed after contact of the nail base with diquat solutions for a few minutes, and shedding of the nail was reported after prolonged contact with concentrated diquat.²¹

Epistaxis and throat irritation have followed the inhalation of splashes or droplets caused by the careless mixing of diquat solutions.²¹ Conjunctivitis and corneal scarring may occur if diquat-containing formulations are splashed directly into the eye.²² Rudez and colleagues²³

described extensive mucosal necrosis of the vagina and vulva after the intravaginal application of a 6% diquat solution.

Systemic Toxicity

Because skin absorption is poor, exposure by this route is unlikely to lead to systemic toxicity. The latter is usually associated with the ingestion of diquat, although it has followed the installation of 6% diquat solution intravaginally.²³

Diquat may cause severe and extensive mucosal damage not only to the mouth but also to the esophagus, stomach, and small intestine.^{19,24-26} As a consequence, generalized abdominal pain, vomiting, and diarrhea can occur within a few minutes of ingestion.^{18,23,24,26-33} At endoscopy, severe panesophagitis and hemorrhagic gastritis at the fundus have been observed,²⁴ together with first- and second-degree burns of the esophagus and stomach.¹⁹ Paralytic ileus may develop 1 to 4 days after ingestion^{3,30,34} and is thought to be responsible for the accumulation or "sequestration" of large amounts of fluid in the gut, leading to hypovolemic shock.³⁰ Deranged liver function, as shown by a rise in hepatic aminotransferase/transaminase (SGOT, SGPT) activities, is reported commonly but is usually mild and transient and resolves spontaneously.^{18,25,26,30-35}

Nephrotoxicity has been reported frequently and ranges from transient proteinuria^{24,34} to acute renal failure.^{3,18,19,23,26-30,32,33,35,35-39} Renal failure has developed between 1 hour²⁶ and 5 days³⁸ after ingestion and was invariably present in patients who died.

Bronchopneumonia has been reported at autopsy in four patients,^{3,29,30,32} although it was diagnosed clinically in only two.^{3,30} However, the radiologic appearances of pulmonary infiltration and exudates observed are similar to those in the adult respiratory distress syndrome, which may be the etiology of these features.

Coma has also been reported^{3,30,32} and developed between 18 hours³⁰ and 4 days after ingestion.³ It has been observed in association with pontine hemorrhages, and sometimes infarction, in life³ and at autopsy.^{3,29,30,32} Grand mal seizures, which progressed to status epilepticus, were observed in two patients.^{18,26}

Of all the clinical features described, the rapid onset of acute renal failure, intestinal ileus, and subsequent fluid sequestration, pulmonary complications requiring ventilation and coma herald a poor prognosis.

MANAGEMENT

The use of methods to reduce diquat absorption may be considered. Gastric lavage and the administration of activated charcoal may be considered within 1 hour of a potentially life-threatening ingestion, although no controlled studies have been performed to support the value of this approach. If it is considered appropriate to undertake lavage, this must be done with extreme caution because there is a risk for perforation in the presence of corrosive mucosal damage. Oropharyngeal ulceration may be severe, and topical preparations, including local anesthetics, should be used to alleviate discomfort. Skin burns should be treated conventionally.

Because vomiting, diarrhea, and massive fluid sequestration in the gut can cause clinically significant hypovolemia, vigorous attention should be paid to fluid and electrolyte replacement, if necessary with the aid of central venous pressure or pulmonary capillary wedge pressure measurements. Hemofiltration or hemodialysis will need to be employed if acute renal failure supervenes.

Hemodialysis does not remove clinically and toxicologically relevant quantities of diquat^{37,38} at the serum concentrations encountered in acute poisoning.

Paraquat

Paraquat contains a bipyridyl ring (Fig. 78-2) and exists as a divalent cation associated with anions such as chloride. From an agricultural point of view, it is the most important of the bipyridyl herbicides and is marketed in many countries either in granular form or as a water-soluble concentrate.

Although paraquat can be absorbed through the skin if improperly handled, poisoning much more commonly follows ingestion or, rarely, injection. Occasionally, food and drink may be adulterated with paraquat with intent to harm⁴⁰ or murder.⁴¹ Less commonly, poisoning may follow careless handling of paraquat during occupational use. Normally, the surface epithelium of the skin is an excellent barrier to paraquat,⁴² but prolonged skin contact with the herbicide may cause not only a chemical burn with blistering and ulceration but also serious and even fatal poisoning. Systemic toxicity is more likely to result if the paraquat solution is concentrated, exposure is prolonged, and the skin traumatized.⁴³ These conditions have been encountered as the result of poor occupational practice, including the use of leaking spray apparatus,⁴⁴⁻⁴⁸ the nonuse of protective clothing,⁴³ prolonged wearing of contaminated clothing and failure to wash contaminated skin,⁴⁸ carelessness as with a farmer from Belize who fell off his bicycle with a bottle of paraquat in his pocket,⁴⁹ cleaning the perineum with paraquat by mistake,⁵⁰ and a mistaken belief that paraquat can be used as a treatment for lice and scabies.^{47,51,52}

Systemic toxicity has followed the subcutaneous,⁵³ intraperitoneal, and intravenous^{54,55} injection of paraquat. There is no conclusive evidence that systemic toxicity has ever followed inhalational exposure to paraquat.

MECHANISMS OF TOXICITY

Paraquat is thought to exert its cellular toxicity by, first, undergoing oxidation and reduction in a cyclical manner (redox cycling) to produce free radicals such as superoxide anion ($O_2^{\bullet-}$) and, second, depleting NADPH. Under anaerobic conditions, NADPH-dependent micro-

somal flavoprotein reductase reduces paraquat from its cation (PQ^{2+}) to form a stable free radical ($PQ^{\bullet+}$).⁵⁶ In the presence of oxygen, the radical will immediately reform the cation,⁵⁷ with the concomitant production of superoxide anion ($O_2^{\bullet-}$). Provided there is a continuous supply of electrons to paraquat and that oxygen is present, paraquat will rapidly cycle from oxidized to reduced forms with the continuous production of superoxide anions.

The mechanism by which the redox cycling of paraquat leads to lung damage has not been established with certainty. There is indirect *in vitro* evidence that superoxide anions directly or indirectly, through the formation of more reactive species of oxygen such as hydroxyl radicals (OH^{\bullet}), cause peroxidation of vital lipid membranes.^{58,59} However, some experiments have failed to demonstrate lipid peroxidation *in vivo*,⁶⁰ although there is a report that suggests that such a process can occur in humans after paraquat poisoning.⁶¹

An alternative or additional explanation for cellular toxicity of paraquat is that significant depletion of NADPH occurs by two mechanisms. First, redox cycling occurs to such an extent that NADPH levels within cells are decreased. Second, NADPH is used in the detoxification of hydrogen peroxide and lipid hydroperoxides through the glutathione peroxidase and reductase enzyme systems. It is postulated that depletion of NADPH not only disrupts essential physiologic and biochemical functions but also renders cells more susceptible to lipid peroxidation.⁶² Baker and colleagues⁶² have postulated that if the glutathione peroxidase or reductase systems, together with endogenous levels of antioxidant, are inadequate to defend against peroxidation, it is possible that cell damage may occur. The depletion of NADPH by the redox cycling of paraquat leads to additional use of the remaining NADPH in an attempt to provide reduced glutathione for the glutathione enzyme activity. Thus, NADPH will be depleted both in the production of superoxide anion and in a defense to it. Consequently, the pentose phosphate pathway is stimulated in an attempt to regenerate NADPH.

The pathways dependent on NADPH appear to be inhibited either as a compensatory mechanism or because NADPH is depleted within the cell. With further generation of NADPH, this cofactor is available either to regenerate reduced glutathione or to further reduce paraquat cycling with oxygen. On balance, the evidence suggests that the concentration of paraquat in lung cells causes a severe redox stress that leads eventually to sustained depletion in NADPH levels. This by itself, or in combination with lipid peroxidation, initiates the cascade of biochemical events that lead to cell death.⁶²

The biochemical effects described previously probably also occur in other organs in addition to the lung. It is likely that death occurring within a few hours of paraquat ingestion is due to massive depletion of NADPH with consequent destruction of energy metabolism, particularly in the liver. On the other hand, the clinical course observed in those suffering from less severe intoxication is in keeping with cell membrane destruction initiated by lipid peroxidation.

FIGURE 78-2 Paraquat.

TOXICOKINETICS

Paraquat is absorbed incompletely from the gut, and in humans, it has been estimated that less than 10% of an ingested dose is absorbed over a 1- to 6-hour period.^{63,64} Although absorption from the gut may be incomplete, it is rapid; paraquat may be detected in the urine as early as 1 hour after ingestion, and peak concentrations in humans are attained within 4 hours.⁶⁵

CLINICAL FEATURES

Local Toxicity

Paraquat, especially in concentrated solutions, strongly irritates various types of epithelia. Thus, it causes erythema, blistering, and ulceration of the skin, and eczematous dermatitis has been reported.⁶⁶ Concentrated solutions may also cause localized discoloration or a white transverse band affecting the nail plate, although the latter may not become apparent for several weeks. Transverse ridging and furrowing progressing to gross deformity and nail loss may also occur.⁶⁶⁻⁶⁸ Severe inflammation of the cornea and conjunctiva may follow the accidental splashing of paraquat concentrate into the eye. The inflammation develops gradually, reaches a maximum after 12 to 24 hours, and may lead to ulceration⁶⁹ with the risk for secondary infection. Lachrymal duct stenosis has also been described.⁷⁰ Inhalation of fine spray droplets through careless use can cause epistaxis and sore throat.

The corrosive action of paraquat when ingested causes patients who are moderately or severely poisoned to develop a burning sensation, soreness, and pain in the mouth, throat, chest (retrosternally), and abdomen (usually epigastric and sometimes associated with guarding). Ulceration in the mouth, sloughing of the oropharyngeal mucosa, inability to swallow saliva ("pseudo-hypersalivation"), dysphagia, and dysphonia are common. Prominent pharyngeal membranes ("pseudodiphtheria") have been reported,⁷¹ and perforation of the esophagus may result in mediastinitis, surgical emphysema, and pneumothorax. Most patients develop a cough, which may be productive and blood stained.

Systemic Toxicity

Three degrees of intoxication may usefully be distinguished.⁷²

GROUP 1. Mild poisoning follows the ingestion or injection of less than 20 mg of paraquat ion per kilogram body weight. Patients are asymptomatic or develop vomiting and diarrhea. Full recovery occurs, but there may be a transient fall in the gas transfer factor and vital capacity.

GROUP 2. Moderate to severe poisoning follows the ingestion or injection of 20 to 40 mg/kg of paraquat ion. Patients suffer vomiting and diarrhea and develop generalized symptoms indicative of systemic toxicity. Pulmonary fibrosis develops in all cases, but recovery may occur. In addition, renal failure and, sometimes, hepatic dysfunction may supervene. Death occurs in most cases but can be delayed for 2 or 3 weeks.

GROUP 3. Acute fulminant poisoning follows the ingestion of more than (usually considerably in excess

of) 40 mg/kg of paraquat ion. In addition to nausea and vomiting, there is marked ulceration of the oropharynx with multiple organ (cardiac, respiratory, hepatic, renal, adrenal, pancreatic, neurologic) failure. In this group, at least in our experience, the mortality rate is 100%. Death commonly occurs within 24 hours of ingestion of paraquat and is never delayed for more than 1 week.

Within 24 hours of ingestion, patients in groups 2 and 3 develop lethargy, a widespread burning sensation, generalized weakness, myalgia, giddiness, headache, anorexia, and fever. Fear and apprehension are prominent features, and restlessness is sometimes observed.

Oliguria or nonoliguric renal failure may supervene and is due usually to acute tubular necrosis, although, exceptionally, glomerular and tubular hemorrhage may be found.⁷³ Proximal tubular dysfunction, which results in proteinuria, microscopic hematuria, glycosuria, aminoaciduria, phosphaturia, and excessive leaking of sodium and urate, is common.⁷⁴ Jaundice, hepatomegaly, and central abdominal pain due to pancreatitis, together with associated biochemical abnormalities, are frequent complications in patients severely poisoned with paraquat. Centrilobular hepatic necrosis and cholestasis are seen at postmortem examination in these patients.

Dyspnea is a prominent feature and occurs early in those patients who have ingested a substantial amount and, in these circumstances, is due to the development of the adult respiratory distress syndrome. In less severely poisoned patients, the onset of dyspnea may be delayed and is then caused by pulmonary fibrosis. Rarely, pneumothorax (in association with mediastinitis), pleural effusion, and iatrogenic pulmonary edema, may precipitate dyspnea.

In addition to a falling gas transfer factor and vital capacity (which may return to normal in patients in group 1 and, less commonly, in those in group 2), severely poisoned patients will have a low and falling PO₂ with resultant central cyanosis. Radiologic changes do not always parallel the severity of clinical symptoms. Thus, the chest x-ray may be normal, particularly in those dying early from multiorgan failure. More usually, patchy infiltration occurs, which may progress to an opacification of one or both lung fields.

Except for sinus tachycardia, cardiovascular complications are not usually observed until the terminal phase of intoxication. Then, ventricular tachycardia, intraventricular conduction disturbances, and nonspecific T-wave changes on electrocardiogram (ECG) occur. Sinus bradycardia, hypotension, and cardiac arrest may supervene. The chest x-ray may show massive cardiomegaly, and at autopsy, toxic myocarditis is found histologically.

Coma is a common and terminal event, although other neurologic features, such as ataxia and facial paresis,⁵³ are observed occasionally. Convulsions have been reported⁷⁵⁻⁷⁷ and may be due to cerebral edema⁷⁸ precipitated by fluid overload.⁷⁹

A polymorphonuclear leucocytosis is a frequent finding, but rarely, erythrocyte aplasia leading to a normochromic anemia⁸⁰ has been reported. Metabolic acidosis, probably secondary to cardiovascular collapse and hypoxia, is a common complication. Hypocalcemia,

which sometimes results in tetany, is usually iatrogenic after either inappropriate attempts at forced diuresis in the presence of renal impairment⁷⁹ or charcoal hemoperfusion.⁸¹ In addition, elevation of serum creatine kinase activity is seen, secondary to paraquat-induced muscle damage.

MANAGEMENT

Management has several aspects:

1. If the patient presents early (<1 hour after paraquat ingestion), attempts should be made to reduce paraquat absorption by the administration of activated charcoal.
2. Fluid loss induced by vomiting and diarrhea should be replaced.
3. The diagnosis should be confirmed and the prognosis determined by measurement of paraquat in blood.
4. Symptoms due to ulceration of the oropharynx must be relieved.
5. The use of specific therapy should be considered.
6. Appropriate supportive care for the patient and relatives must be provided.

Methods to Reduce Absorption

Gastric lavage and the administration of activated charcoal may be considered within 1 hour of a potentially life-threatening ingestion, although no controlled studies have been performed to support the value of these approaches. If it is considered appropriate to undertake lavage, this must be done with extreme caution because there is a risk for perforation in the presence of corrosive mucosal damage.

Supportive Measures

There is good evidence that, as a result of vomiting and diarrhea and the administration of purgatives, many patients poisoned with paraquat are fluid depleted.⁸² An intravenous infusion should therefore be commenced on admission to reduce the risk for renal dysfunction and diminished renal excretion of paraquat.

Confirmation of the Diagnosis and Assessment of Prognosis

A qualitative urine test should be performed with alkaline sodium dithionite on presentation. If this test is negative within 4 hours of the overdose, there is no clinical need for a quantitative assay on the blood and the patient may be reassured accordingly. If, however, the urine test is positive, measurement of the plasma paraquat concentration is extremely helpful in determining prognosis⁸³ and may be interpreted by reference to published data,^{65,84,85} which are summarized in Table 78-2.

Specific Therapy

Based on an understanding of the mechanism of paraquat toxicity, further management should theoretically be directed toward preventing the accumulation of paraquat in the lungs and reducing the acute alveolitis

Based on Proudfoot AT, Stewart MS, Levitt T, et al: Paraquat poisoning: Significance of plasma-paraquat concentrations. *Lancet* 1979; 2:330; and Scherrmann JM, Houze P, Bismuth C, et al: Prognostic value of plasma and urine paraquat concentration. *Hum Toxicol* 1987; 6:91.

and pulmonary fibrosis that develop in severe cases of intoxication. However, there is no current clinical evidence that superoxide dismutase, propranolol, vitamin E, ascorbic acid, riboflavin, niacin, deferoxamine, clofibrate, acetylcysteine, cyclophosphamide, or corticosteroids are effective clinically.^{86,87}

Use of Techniques to Increase Paraquat Elimination

Excretion of paraquat is almost exclusively renal; biliary excretion is very small.^{16,64,88} The renal clearance of nontoxic doses of paraquat exceeds the glomerular filtration rate because of an active transport process⁸⁹ and may be in excess of 200 mL/min when renal function is normal.⁸⁹⁻⁹² As a result, more than 1000 mg/L paraquat ion may be excreted within the first few hours after ingestion.⁹³ Because renal failure supervenes early in severely poisoned patients, dialysis and hemoperfusion have been employed to increase paraquat elimination.

The clearance values achieved by hemodialysis are impressive (as much as 150 mL/min⁹⁴), yet the amount removed is disappointingly small (often only a few milligrams of paraquat ion), in comparison to both the dose ingested and the contemporaneous renal clearance of paraquat.^{64,95,96} The very small fraction of the dose eliminated by dialysis could not be expected to influence outcome in the more severely poisoned.

Similarly, despite impressive clearance data, the amount of paraquat removed by hemoperfusion is very small^{94,97-100} and falls in parallel with the decrease in plasma paraquat concentrations.¹⁰¹ Okonek and asso-

ciates¹⁰² have proposed that hemoperfusion be performed for several days (8 hours per day for 2–3 weeks), and the authors claim that this approach has reduced the mortality from paraquat; their observations have not been confirmed.

Pond and colleagues¹⁰³ assessed the value of continuous arteriovenous hemofiltration (CAVH) in a patient whose presenting plasma paraquat concentration 4 hours after ingestion was 3 mg/L. CAVH was commenced 180 hours after paraquat ingestion (plasma concentration, about 0.34 mg/L). Over 46 hours of CAVH, 1.1 mg paraquat ion was removed, and a paraquat clearance of 6.1 mL/min was achieved.

In summary, there is no irrefutable evidence^{95,101} that extracorporeal techniques used alone or together remove sufficient paraquat to alter the outcome in those patients who present with plasma paraquat concentrations above the predictive lines of Proudfoot and colleagues⁶⁵ and Bismuth and coworkers.¹⁰¹

Terminal Care: Relief of Local Pain and General Distress

No discussion of paraquat poisoning would be complete without considering how best to manage patients who are dying from this condition. It is of vital importance that the patient is not neglected or isolated. Frequent visits from medical and nursing staff are mandatory because bad or infrequent communication increases the suffering of the patient. Those who are dying reach out for support and companionship not only from their friends and relatives but also from their medical advisers. If asked, one should be honest about the prognosis while at the same time offering some hope.

Attention should be directed away from incurable organ damage to the alleviation of symptoms because there is always something that can be done to provide symptomatic relief. Pain and distress should be reduced to a minimum. It is difficult to abolish the severe pain produced by local ulceration. Mouth washes, ice-cold fluids (e.g., ice cream, lemon mucilage), local anesthetic sprays, and lozenges have all been employed with varying degrees of success. Opiates will be required in most patients to relieve general, as well as local, pain and distress. Above all, inappropriate treatment should be avoided. Thus, for example, the repeated use of cathartics when the outlook is hopeless is therapeutically irrelevant and clinically harmful. Although oxygen administration is theoretically harmful in paraquat poisoning, it should not be withheld in the terminal patient with air hunger.

CHLOROPHENOXY HERBICIDES

Chlorophenoxy herbicides are chemical analogs of auxins, a type of plant growth hormone, and produce uncontrolled and lethal growth in target plants. Because they are very effective selective weed killers, chlorophenoxy herbicides are used widely for the control of broad-leaved weeds in pastures, lawns, cereal crops, and public rights of way. In addition, closely related compounds are used as the active ingredients in rooting powders.

Structurally, chlorophenoxy herbicides comprise an aliphatic carboxylic acid moiety attached to a chlorine- or methyl-substituted aromatic ring. The most common is 2,4-D (2,4-dichlorophenoxyacetic acid); its formula and that of related compounds are shown in Figure 78-3. Dicamba is not a phenoxyacetate but is often considered with the chlorophenoxy compounds because it is an organic acid. 2,4,5-T has been largely withdrawn from worldwide use because of concerns that arose from contamination of some formulations with dioxin, the most notorious of which was Agent Orange, used as a defoliant in Vietnam.

Chlorophenoxy herbicides often are coformulated with ioxynil, bromoxynil, or both, which generally are more toxic and similarly uncouple oxidative phosphorylation. Formulations may also contain hydrocarbon solvents.

Chlorophenoxy herbicide poisoning is uncommon but may produce severe sequelae. Most cases of serious poisoning involve deliberate ingestion of 2,4-D either alone or in combination with other chlorophenoxy herbicides or ioxynil/bromoxynil.

Among more than 11.2 million human toxic exposures reported by U.S. Regional Poisons Centers to the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) between

FIGURE 78-3 Chemical structure of some chlorophenoxy herbicides.

1998 and 2002,¹⁰⁴⁻¹⁰⁸ 11,385 involved chlorophenoxy herbicides; at least 30% involved children younger than 6 years old and may not have been toxic exposures. Thirty-three exposures resulted in life-threatening or significant residual effects, and there were two deaths.

Mechanisms of Toxicity

Dose-dependent cell membrane damage is likely to be important in the mediation of chlorophenoxy-induced central nervous system (CNS) toxicity, for example by damage to the blood-brain barrier and disruption of neuronal and mitochondrial membranes. Mitochondrial membrane damage may trigger apoptosis.¹⁰⁹ In addition, chlorophenoxy herbicides are related structurally to acetic acid and can form analogs of acetyl coenzyme A (CoA; such as 2,4-D-CoA) or enter the acetylcholine (ACh) synthetic pathway to form choline esters (e.g., 2,4-D-ACh). Thus, they can disrupt metabolic pathways and act as “false” neurotransmitters. Uncoupling of oxidative phosphorylation is a further likely mechanism of toxicity.

Toxicokinetics

Chlorophenoxy compounds are absorbed rapidly after oral administration in humans,^{110,111} but absorption dermally^{17,111,112} and by inhalation¹¹³ is limited. They bind extensively to serum albumin^{114,115} and have relatively high volumes of distribution (between 0.1 L/kg¹¹⁶ and 0.2 L/kg¹¹⁰ for 2,4-D in humans). Some 82% of an administered dose is eliminated unchanged in urine.¹¹⁰ Clearance occurs by first-order processes,¹¹⁰ although at high doses, the organic anion secretory system may be overwhelmed, and elimination then follows Michaelis-Menten kinetics, at least in animals.¹¹¹

Substantial interindividual and interspecies variation in elimination of chlorophenoxy herbicides is apparent.¹¹⁷ The elimination half-life in humans of 2,4-D 5 mg/kg orally varies between 11.6¹¹⁰ and 33 hours.¹¹⁶

Clinical Features

INGESTION

Nearly all reported cases of chlorophenoxy herbicide ingestion have involved 2,4-D, either alone or with other chlorophenoxy herbicides, such that it is difficult to distinguish between members of this pesticide class in terms of toxicity.¹¹⁸ Vomiting is a prominent early feature and may be accompanied by burning in the mouth, abdominal pain, diarrhea, and occasionally gastrointestinal hemorrhage. Severe corrosive damage is rare and probably due to surfactants or solvents in the formulation. Gastrointestinal fluid loss, vasodilation, and direct myocardial toxicity contribute to the development of hypotension, which is common. Electrocardiogram abnormalities such as T-wave flattening or inversion,¹¹⁹ QT-interval prolongation,^{120,121} supraventricular or ventricular tachycardia, and rarely, sinus bradycardia¹²² have been reported.

In severe cases, gastrointestinal features are followed frequently by the onset of coma, which is an almost

invariable feature in fatal cases and often lasts several days in those who survive.¹¹⁸ Hypertonia, hyperreflexia, clonus, and occasionally extensor plantar responses suggest upper motor neuron involvement.^{119,123-128} Cerebral edema,¹²⁰ miosis, nystagmus, ataxia, alterations in color vision, memory loss, hallucinations, and convulsions have also been reported.¹¹⁸

Coma is associated frequently with respiratory distress, tachypnea, inadequate ventilation, and occasionally pulmonary edema. Hypoventilation secondary to CNS depression is the primary cause of hypoxia, although respiratory muscle weakness may contribute also as part of a generalized myopathy.^{119,129} The latter is characterized by limb weakness, reduced or absent tendon reflexes,^{119,123,127,130,131} and increased creatine kinase activity.^{119,130,132} Aspiration of gastric contents may contribute to pulmonary complications.^{123,131} Hemoptysis is a rare complication.¹³³

Some degree of peripheral neuromuscular involvement is common, as evidenced by loss of tendon reflexes, muscle twitching, fasciculation, weakness, or myotonia.¹¹⁸ Nerve damage with electromyographic evidence of a peripheral neuropathy has been reported rarely.^{119,134} These effects may persist for several weeks in patients who survive.

Other reported features of chlorophenoxy herbicide ingestion include metabolic acidosis,^{119,120,122} hyperthermia in the absence of infection (possibly reflecting uncoupling of oxidative phosphorylation),^{119,122,129} renal failure,^{126,135} rhabdomyolysis,¹³² increased transaminase and aminotransferase activities (SGOT, SGPT), and lactate dehydrogenase,^{130,136} thrombocytopenia,^{132,137} hemolytic anemia, and hypocalcemia.¹²⁵

Although the prognosis is poor in patients who rapidly become shocked and comatose, full recovery can ensue over weeks to months despite initial severe toxicity and prolonged neuromuscular effects.

It is not possible to derive a dose–response relationship from published cases because the dose was rarely, if ever, known with accuracy. Flanagan and coworkers¹²² suggested that a total plasma chlorophenoxy concentration in excess of 500 mg/L was associated with severe toxicity. This view is supported by the postmortem findings in a 61-year-old woman who ingested a formulation containing 2,4-D, mecoprop, and dicamba: the blood concentrations for 2,4-D, mecoprop, and dicamba were, respectively, 520 mg/L, 530 mg/L, and 170 mg/L,¹³⁸ but more data are required.

DERMAL EXPOSURE

Because dermal absorption of chlorophenoxy herbicides is poor, acute poisoning through this route is uncommon. Local skin irritation may occur, but there are few reports of systemic toxicity following such exposures. Interpretation of cases in which systemic effects are described is complicated, and the etiologic role of chlorophenoxy herbicides in many has been challenged.¹³⁹ Five cases were published between 1959 and 1963.¹⁴⁰⁻¹⁴² All patients recovered, although mild weakness was present at 2- to 3-year follow-up in three cases.^{141,142} It is noteworthy that there have been no published reports of

Mechanisms of Toxicity

The mechanisms of toxicity of glyphosate formulations are complex, not least because glyphosate is used as four different salts in combination with surfactants, which vary in nature and concentration. It is therefore difficult to separate the toxicity of glyphosate from that of the formulation as a whole or to determine the contribution of surfactants to overall toxicity.

GLYPHOSATE

Glyphosate alone is of very low toxicity orally ($LD_{50} > 5000$ mg/kg) and dermally ($LD_{50} > 2000$ mg/kg). It may enhance adenosine triphosphatase activity and uncouple mitochondrial oxidative phosphorylation,¹⁵⁹⁻¹⁶² although this has been disputed.¹⁵⁶ In rats, it decreases hepatic cytochrome P-450 and monooxygenase activities and the intestinal activity of aryl hydrocarbon hydroxylase.¹⁶³ Although at high concentrations *in vitro*, glyphosate inhibits acetylcholinesterase, there is no evidence that it inhibits acetylcholinesterase *in vivo*.

There is very limited evidence that products containing glyphosate trimesium are more toxic than those with other glyphosate salts.¹⁶⁴

SURFACTANTS

Surfactants in concentrations of up to 50% are added to nearly all glyphosate preparations. In general, they interfere with the walls of mitochondria, destroying the proton gradient required for energy production, effects consistent with the poorly responsive multiple-organ failure generally seen after surfactant ingestions. Because some are strongly alkaline, adjustment to a neutral pH is required when they are coformulated with glyphosate.

The most widely used surfactant is polyoxyethyleneamine (POEA), although this name refers to a group of compounds rather than a single chemical entity. The concentration of polyoxyethyleneamine ranges from less than 1% in ready-to-use glyphosate formulations to 21% in some concentrated professional products.

Other surfactants used in glyphosate-containing herbicides include those derived from plant fats, alkyl polyoxyphosphate amine, polyethoxylated-alkyletheramine, trimethylethoxypolyoxypropyl-ammonium chloride, and ethoxylated phosphate ester.

The main controversy regarding the toxicity of glyphosate formulations is whether toxicity is due to the herbicide itself or to coformulants, notably surfactants. The evidence suggests that the toxicity of the surfactant, POEA, is greater than the toxicity of glyphosate alone. There is insufficient evidence to conclude that glyphosate preparations containing polyoxyethyleneamine are more toxic than those containing alternative surfactants. However, the weight of evidence is against surfactants potentiating the toxicity of glyphosate; indeed, the reverse may be more likely.

Toxicokinetics

The existing knowledge of the toxicokinetics of glyphosate is mainly derived from animal studies and has

been reviewed recently.¹⁶⁵ Only some 30% is absorbed after oral administration to rats^{165,166}; peak plasma concentrations are attained within 1 to 2 hours^{165,167,168} and decline quickly.¹⁶⁹ Most absorbed glyphosate is then rapidly excreted unchanged in the urine.

A similar pattern of absorption, metabolism, and elimination after ingestion is seen in humans, although the data are limited. Absorption of glyphosate through human skin is poor (<1%).^{165,170} Two poisoned patients reached peak plasma glyphosate concentrations within 4 hours of ingestion, the concentrations being almost undetectable by 12 hours.¹⁷¹ Severe poisoning is associated with plasma glyphosate concentrations exceeding 1000 mg/L,¹⁷¹ and occasionally, concentrations as high as 1600 mg/L have been encountered.¹⁷²

Only a small proportion of glyphosate is metabolized to aminomethylphosphonic acid (AMPA): the ratios of glyphosate to AMPA in serum at 8 and 16 hours after ingestion were 126:1 and 147:1, respectively.¹⁷³

Absorption after inhalation does not appear to have been studied but would not be expected to be significant.

Clinical Features

Regardless of the route of exposure, most reports of human poisoning with severe features generally involve concentrated formulations containing 41% glyphosate as the isopropylamine salt and 15% polyoxyethyleneamine. Accidental exposure usually causes only mild, transient features.

INGESTION

Nausea, vomiting, and diarrhea are the only likely features following ingestion of glyphosate ready-to-use amateur formulations. Up to 30 mL of the 41% glyphosate plus 5% to 15% polyoxyethyleneamine formulations may also cause these symptoms, together with burning in the mouth and throat and hypersalivation, but has not caused severe systemic effects in adults.^{155,156} Ingestion of more than 85 mL of the 41% glyphosate plus 5% to 15% polyoxyethyleneamine formulations is likely to cause significant toxicity in adults,¹⁵⁵ including gastrointestinal corrosive effects with mouth, throat, and epigastric pain and dysphagia.^{156,174} The corrosive damage is predominantly gastric and esophageal rather than duodenal.¹⁷⁴ Patients with grade 2 or 3 (multiple ulcerations with necrosis) esophageal lesions were more likely to have ingested more than 200 mL of glyphosate concentrate and to manifest severe systemic sequelae, including gastrointestinal hemorrhage, hypotensive shock (not always in association with hypovolemia), or aspiration pneumonia. The latter complication is particularly likely if laryngeal corrosive injury occurs during ingestion.¹⁷⁵

Lower gastrointestinal corrosive injury is rare,¹⁵⁵ but small bowel infarction has been reported, probably secondary to hypotension.¹⁷⁶ A 44-year-old man developed acute colitis 1 week after consuming glyphosate-contaminated wine.¹⁷⁷

Aspiration of glyphosate-containing products contributes to ventilatory insufficiency in severely poisoned

patients,¹⁵⁶ but noncardiogenic pulmonary edema is the underlying pathologic process in some cases.^{155,176} Acute bronchospasm, followed by pneumomediastinum, tension pneumothorax, and subcutaneous emphysema, has been described in a man who ingested 500 mL of a glyphosate-containing product.¹⁷⁸

Renal and hepatic impairment (increased aminotransferase and transaminase activities) and impaired consciousness are not uncommon in more severe cases^{154,176} and usually reflect reduced organ perfusion, although a direct toxic effect of glyphosate or surfactant may contribute. Similarly, hypovolemia is an important factor in cases complicated by cardiogenic shock or acidosis, although direct toxicity, may contribute.¹⁷⁹ Glyphosate- or surfactant-induced myocardial depression may also occur.¹⁸⁰

Other reported features include dilated pupils,^{156,179,181} convulsions,¹⁵⁶ confusion, coma, fever,¹⁵⁴ neutrophil leucocytosis,^{154,155} increased serum amylase activity,¹⁵⁵ metabolic acidosis,¹⁵⁴ and ECG abnormalities.^{154,158} In a recent case,¹⁷⁶ broad complex tachycardia (140 beats/minute) was a presenting feature after ingestion of 1 L of glyphosate concentrate; it may be relevant that the patient also had a marked metabolic acidosis (pH, 7.25; HCO₃⁻, 13 mmol/L) and a serum potassium concentration of 8.2 mmol/L. Bradycardia and ventricular arrhythmias may occur as preterminal events.^{155,156,179,181}

Table 78-3 lists proposed criteria for classification of severity of poisoning resulting from glyphosate formulation ingestion.

There is a reasonable correlation between the amount of glyphosate ingested, the severity of damage,¹⁵⁵ and the likelihood of serious systemic sequelae^{155,156} or death.^{154,156} When a large quantity is ingested, death typically ensues within 72 hours.¹⁵⁴ Not surprisingly, not all cases conform to these prognostic criteria.^{155,181} Other features significantly more likely in patients who die include the presence of respiratory distress, impaired consciousness, pulmonary edema, infiltration on chest x-ray, shock, arrhythmias, and renal failure requiring hemodialysis.¹⁵⁴ The triad of pulmonary edema, metabolic acidosis, and hyperkalemia is also a poor prognostic indicator,¹⁷⁶ as is advancing age.^{154,156}

SKIN EXPOSURE

Skin contact with glyphosate formulations can cause irritation,¹⁸² and contact dermatitis has been reported occasionally.¹⁸³ Severe skin burns are rare.¹⁸⁴ Transfer by contaminated hands to the face may lead to swelling, paresthesias, and periorbital edema.¹⁸¹ Generalized pompholyx was reported in a man who was accidentally drenched with horticultural-strength glyphosate-containing product.¹⁸¹ Although photosensitivity to glyphosate was claimed to have developed in a 64-year-old man,¹⁸⁵ the authors later concluded that the responsible agent was not glyphosate but the coformulant.¹⁸⁶

INHALATION

Inhalation is a minor route of exposure to glyphosate,¹⁸⁷ but spray mist may cause oral or nasal discomfort, an unpleasant taste in the mouth, tingling, and throat

TABLE 78-3 Proposed Criteria for Classification of the Severity of Poisoning Resulting from Ingestion of Glyphosate Formulations

GRADE OF SEVERITY	CRITERIA
Asymptomatic	Absence of symptoms and abnormal clinical or laboratory findings
Mild	Short-lived (<24 hr) buccal or alimentary tract features
Moderate	<i>At least one of the following:</i> Buccal ulceration Endoscopically confirmed esophagitis Alimentary tract features lasting > 24 hr Gastrointestinal hemorrhage Transient hypotension Transient oliguria Transient renal impairment Transient acid–base abnormalities Transient hepatic damage
Severe	<i>At least one of the following:</i> Hypotension requiring intervention Loss of consciousness Recurrent convulsions Renal failure requiring replacement therapy Respiratory abnormalities requiring endotracheal intubation Cardiac arrest Death

Based on Talbot AR, Shiaw M, Huang J, et al: Acute poisoning with a glyphosate-surfactant herbicide ("Round-up"): a review of 93 cases. *Hum Exp Toxicol* 1991;10:1; and Tominack RL, Yang G, Tsai W, et al: Taiwan national poison center survey of glyphosate-surfactant herbicide ingestions. *J Toxicol Clin Toxicol* 1991; 29:91.

irritation. A single case of acute pneumonitis alleged to be due to inhalation of Roundup in a warm, confined space over a 4-hour period has been reported.¹⁸⁸ Whether the features were due to glyphosate including polyoxyethyleneamine or to some other cause was subsequently debated but not resolved.^{189,190}

EYE EXPOSURE

Eye contact may lead to mild conjunctivitis, and superficial corneal injury is possible if irrigation is delayed or inadequate. One man who accidentally rubbed glyphosate into one eye developed chemosis, palpitations, raised blood pressure, headache, and nausea.¹⁸¹ Permanent eye damage is most unlikely.¹⁹¹

Management

INGESTION

Management is symptomatic and supportive. Because ingestion of ready-to-use amateur products is unlikely to cause systemic toxicity, gut decontamination is unnecessary. Gastric lavage may be considered if a life-threatening amount of a concentrated glyphosate formulation has been ingested within 1 hour (unless there is evidence of buccal irritation or burns), but there

is no evidence that this procedure reduces absorption of either glyphosate or polyoxyethyleneamine. Alternatively, if there is no buccal irritation or burns, oral activated charcoal, 50 to 100 g for an adult, may be considered.

Hypotension secondary to fluid loss should be treated conventionally. Dopamine or dobutamine may be required in severe cases. Early upper alimentary endoscopy should be considered in patients with features suggesting significant gastrointestinal corrosive effects.

Intubation and mechanical ventilation are likely to be required in the most severely poisoned patients. Significant acidosis that persists despite adequate oxygenation and perfusion should be corrected by intravenous sodium bicarbonate. An ECG should be performed in all symptomatic cases.

SKIN EXPOSURE

Thorough skin decontamination is the priority with removal of contaminated clothing, and washing with soap and water. Management is otherwise symptomatic and supportive. Severe lesions should be managed as burns.

INHALATION

Removal from exposure is the priority. Management is otherwise symptomatic and supportive.

EYE EXPOSURE

Eye contamination should be managed as a chemical exposure, with attention particularly to adequate irrigation.

TRIAZINE HERBICIDES

The triazine herbicides are a class of compounds based on a symmetric six-member ring containing three carbon and three nitrogen atoms. Some 15 different triazines have been marketed and are still used widely as amateur and professional herbicides, often formulated with other pesticides. The Spanish Poison Control Centre found that 9% of all enquiries relating to occupational exposure to pesticides involved triazines.¹⁹²

Clinical Features

Serious toxicity has not been reported,¹⁹³ except in one case in which it is probable that the observed features were due to other constituents of the formulation.¹⁹⁴ Any features directly attributable to triazines are likely to be nonspecific. Exposure to dusts or sprays may cause mucous membrane and eye irritation. Contact dermatitis may develop in sensitized individuals.¹⁹⁵⁻¹⁹⁷

Management

Gastric lavage and activated charcoal administration are unnecessary. Management is symptomatic and supportive. The possibility of features developing due to coformulated pesticides or from other constituents, most notably solvents, should be considered. In one case, the

clearance of atrazine by hemodialysis was 250 mL/min over 4 hours, and the dialysance was 76%.¹⁹⁴

UREA HERBICIDES

Substituted urea compounds are used as pre-emergence and postemergence herbicides and as soil sterilants and generally are referred to as urea herbicides. Those that have caused clinical illness include diuron (1-[3,4-dichlorophenyl]-3,3 dimethylurea), monolinuron, and metobromuron (Fig. 78-5). They are often marketed in formulations containing other active ingredients. The toxicity of these compounds is probably due to their metabolism to aniline derivatives, which can cause methemoglobinemia. They also induce microsomal enzymes in animals.¹⁹⁸

During the 10-year period from 1994 to 2003, 716 exposures to urea herbicides were reported to the AAPCC. There were no fatalities, but 46 cases were classified as being of moderate severity, and 3 were life threatening.^{104-108,153,199-202} Release into the atmosphere of an estimated ton of isoproturon did not cause adverse effects in the inhabitants of a nearby residential area, probably because biomonitoring revealed that exposure was below the acceptable daily intake.²⁰³

Toxicokinetics

Diuron is absorbed from both the gastrointestinal and respiratory tracts. It undergoes hydroxylation, dealkylation, or both of the terminal nitrogen atom, the urea moiety generally remaining unchanged. Several metabolites have been identified in humans after suicidal ingestion of diuron²⁰⁴⁻²⁰⁶ and are excreted in the urine with low concentrations of diuron.²⁰⁴ Similarly, several metabolites were detected in the plasma and urine of a patient who had ingested metobromuron.²⁰⁷

Clinical Features

Urea herbicides are generally of low acute toxicity, and serious poisoning is only likely after ingestion of large quantities; four deaths have been recorded (Table 78-4). However, it is unlikely that three of these can be attributed to the urea herbicide. One was almost certainly

FIGURE 78-5 Chemical structure of two urea herbicides.

TABLE 78-4 Deaths from Formulations Containing Urea Herbicides

ACTIVE INGREDIENTS*	ESTIMATED DOSE OF UREA HERBICIDE	AGE AND SEX	MAIN FEATURES	METHEMOGLOBIN (%)	REFERENCE
Monolinuron (14%) + paraquat (10%)	40 mg/kg bw	59 M	Central cyanosis, renal, respiratory, and hepatic failure	52	Casey et al (1994) ²⁰⁸
Diuron	Several grams	77 ?	Severe sedation	Unknown	Verheij et al (1989) ²⁰⁴
Diuron + parathion	Unknown	38 F	Coma	Unknown	van Boven et al (1990) ²⁰⁵
Diuron + atrazine + aminotriazole + propylene glycol	200 g	35 M	Metabolic acidosis	3	Brinquin et al (1993) ²⁰⁹

*Urea herbicide in bold.

due to the paraquat coingested,²⁰⁸ one to the solvent (propylene glycol) in the formulation,²⁰⁹ and one to parathion.²⁰⁵

Nausea, vomiting, diarrhea, and abdominal pain are the initial features. Later, as the aniline-related metabolites appear, hemoglobin is oxidized to methemoglobin, accumulation of which is the principal cause of urea herbicide toxicity. The onset of clinically detectable methemoglobinemia may be delayed for 6 to 10 hours.²¹⁰ It was present in 5 of the 10 published cases.^{207,208,210-212} Significant intravascular hemolysis followed in four.^{207,210-212} For that reason, Heinz body formation, reticulocytosis, a positive Schumm's test, and brownish discoloration of the plasma and urine due to the presence of free hemoglobin may be observed. Plasma lactate dehydrogenase activity may be increased. Acute renal failure and metabolic acidosis may ensue.

A slate-gray color of the skin not reversed by supplemental oxygen may be seen when methemoglobin concentrations exceed 10% to 15%. The patient often appears unduly well for the degree of "cyanosis." As methemoglobin concentrations increase, features of hypoxia develop, with headache, fatigue, weakness, dizziness, syncope, tachycardia, dyspnea, and increasing respiratory distress. Methemoglobin concentrations in excess of 60% are life threatening, with coma, convulsions, cardiac arrhythmias, and cardiorespiratory arrest.

Chest discomfort and cough have been reported after heavy occupational inhalation of a mixture of diuron and 2,4-D,²¹⁴ but there are no reports relating to a urea herbicide alone. Similarly, there are no reports of toxicity after topical exposure, although skin may be irritated.

Management

Although gastric lavage may be considered if a life-threatening amount of a urea herbicide has been ingested within 1 hour, there is no evidence that it reduces absorption. The same is true of oral activated charcoal, although administration of 50 to 100 g to an adult may be considered in the same situation. Patients should be observed for several hours if substantial exposure is suspected because the onset of toxicity may be delayed. Arterial blood gas tensions and methemoglobin concentrations should be measured.

Methylthionium chloride (methylene blue), 1 to 2 mg/kg given intravenously, is indicated if the methemoglobin concentration exceeds 30%. The plasma potassium concentration should be monitored frequently if hemolysis develops, and hyperkalemia is treated conventionally. Red blood cell transfusion should, if possible, be avoided until the toxic metabolites have been eliminated. Plasmapheresis may have a role in removing circulating free hemoglobin and red blood cell fragments. Renal function will also need to be monitored and failure treated conventionally.

BENTAZON (BENTAZONE)

Bentazon (bentazone) is a selective contact herbicide with the chemical structure shown in Figure 78-6.

Mechanisms of Toxicity

Its mechanism of action in humans is unknown, although the clinical features of poisoning suggest that bentazon may uncouple oxidative phosphorylation. It is likely that coformulants will be responsible for some of the toxic effects of some products.

Toxicokinetics

What little is known of the toxicokinetics of bentazon in humans indicates that it is rapidly and extensively absorbed after oral administration and excreted largely unchanged in urine. A possible hydroxylated metabolite was present in the blood of a farmer who died after ingestion of bentazon, the concentration of the parent compound in plasma being of the order of 1500 mg/L.²¹⁵ In another case, the postmortem blood concentration of bentazon was 625 mg/kg.²¹⁶

**FIGURE 78-6** Bentazon.

Clinical Features

The three reported cases of acute poisoning in humans involve ingestion. Analytic confirmation of the presence of bentazon was present in two,^{215,216} but not in the third case.²¹⁷ The emerging pattern of bentazon poisoning is that the time required for onset of features may be less than 1 hour and that death may result within as little as 2 hours. Upper and lower gastrointestinal irritation is common, and although bentazon is said not to cross the blood-brain barrier in rats, drowsiness, agitation, talking nonsense, and loss of consciousness in these patients suggest that it may do so after consumption of very large amounts. Other features include sweating, hyperpyrexia, increased heart rate, tachypnea, and difficulty in breathing. Limb rigidity was a prominent feature in two patients, and one had clear evidence of rhabdomyolysis and several other features; those who cared for him proposed that acute bentazon poisoning mimicked neuroleptic malignant syndrome.²¹⁷ Leucocytosis and minor disturbances of liver and renal function have been reported.²¹⁷

Management

The management of acute bentazon poisoning is symptomatic and supportive. Gastric lavage or oral activated charcoal (100 g for an adult) may be employed, although there are no data to indicate that they might be effective. Indeed, it is unlikely that they would be effective because absorption is so rapid. Liver and renal function and the ECG should be monitored. Dantrolene may be indicated if muscle rigidity is a problem.²¹⁷ Respiratory and renal failure should be managed conventionally. Antiemetics may be given if vomiting persists.

79 *Rodenticides*

HOLLY E. PERRY, MD

At a Glance...

- All rodenticides possess some human toxicity when taken in overdose.
- High-toxicity rodenticides include thallium, sodium monofluoroacetate, strychnine, aluminum and zinc phosphide, vacor, naphthylthiourea (ATNU), and cholecalciferol. Low-toxicity agents include superwarfarins and red squill.
- Originating from multiple classes of compounds, the rodenticides produce a broad range of toxicities.
- The treatment of rodenticide overdose is generally supportive. For select agents, such as vacor and superwarfarins, specific therapies are available.

Competition between humans and lower animals for food and shelter, whether real or imagined, is a constant struggle. In an attempt to gain the ecologic upper hand, humans have endeavored to develop ways to curb rodent populations. The rodenticides encompass a diverse group of chemicals with a wide variety of actions. Whether organic or inorganic, mildly or highly toxic, all these agents are designed to kill in a cost-effective manner. A problem arises when humans or nontarget animals come into contact with these chemicals.

Rodenticides are designed to kill rodents considered a nuisance, such as rats, mice, gophers, moles, voles, ground squirrels, and prairie dogs. These animals damage crops in the field and foods in storage, host human diseases, bite people, and are capable of causing material damage by gnawing. It makes sense from both an economic and health perspective to attempt to control populations of these animals.^{1,2}

Historically, a wide variety of inorganic and organic compounds have been used as rodenticides. Early rodenticides were agents derived from plant material such as strychnine and red squill or were inorganic chemicals such as arsenic trioxide and thallium. Newer agents tend to be synthetic organic compounds. Regardless of type, virtually all rodenticides are referred to as “rat poisons” by the lay public.

Some substances used as rodenticides proved to be nearly as dangerous to humans and other animals as they are to rodents. Thallium and vacor are no longer marketed in the United States because of severe toxicity. Efforts have been made to lessen the risk of using rodenticides by restricting the use of some substances and by requiring premarketing studies of potential new products. Still, all rodenticides are toxic if misused.¹

The many chemical agents used as rat poisons are listed in Table 79-1. When possible, the container label should be used to identify a particular product. Even labeling can be a problem if not read carefully. For example, bromethalin, a neurotoxin, can be confused

with bromadiolone or brodifacoum, which are long-acting anticoagulants. It is generally worth the effort to find the container and positively identify the ingredients in order to know what effects might be expected and how to approach treatment.

Rodenticides are regulated by the U.S. Environmental Protection Agency (EPA) in accordance with two acts. The Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) of 1947 regulates distribution, use, and sale of these products within the United States. In 1972, the Federal Pesticide Control Act was passed as an amendment to the FIFRA. This is the act that most pesticide legislation is based on. According to this act, licensed exterminators must undergo a rigorous application procedure as well as ongoing training. This act also regulates labeling of pesticides. All pesticides must have a signal word clearly displayed on the front panel that reflects the highest possible toxicity of the product. The signal word “Danger” is indicative of a product that has an LD₅₀ of 0 to 50 mg/kg; “Warning” indicates LD₅₀ of 50 to 500 mg/kg; “Caution” indicates an LD₅₀ of 500 to 5000 mg/kg. Under this categorization, a taste (one seventh of a teaspoon) of a rodenticide with signal word “Danger” would be enough to kill 50% of children weighing 10 kg. The corresponding lethal dose for a rodenticide with the signal word “Warning” would be 1 teaspoon.³ There are a variety of ways that rodenticides may be classified, but for the purposes of this chapter, they are classified according to the severity of their toxicity.

HIGHLY TOXIC RODENTICIDES (SIGNAL WORD: “DANGER”)

Thallium

AVAILABLE PRODUCTS

No thallium rodenticides are sold in the United States, but they are available in Mexico. Exposures rarely still occur in the United States as a result of homicide attempts,^{4,5} from contaminated herbal preparations,⁶ and from illicit drugs.⁷

DESCRIPTION

Thallium sulfate is a tasteless and odorless powder. Exposure can occur by absorption through intact skin, inhalation, or ingestion. It was introduced in the United States as a rodenticide in the 1920s.^{8,9} The use of thallium as a pesticide was restricted in the United States to commercial exterminators in 1965^{8,9} and was completely banned in 1975 because of continued accidental exposures. The LD₅₀ in humans is 8 to 12 mg/kg.¹⁰ Thallium is rapidly absorbed. Cell membranes do not differentiate between thallium and potassium because

TABLE 79-1 Alphabetical List of Rodenticides by Trade Name and Type of Agent*

TRADE NAME	ACTIVE INGREDIENTS	TYPE OF RODENTICIDE
Acme Mole and Gopher Killer	Zinc phosphide	Phosphides
Anchor Rat and Mouse Bait Packet	Warfarin	Warfarin
Assault Rat Pellets	Bromethalin	Bromethalin
Assault Rat Place Pack	Bromethalin	Bromethalin
Assault Rat WR	Bromethalin	Bromethalin

ANTU, α -naphthyl-thiourea.

*Many trade names sound similar. Package labels should always be checked to verify the type of rodenticide when possible.

their ionic radii are similar: 1.47 Angstroms versus 1.33 Angstroms. Thus, thallium is distributed to tissues with a high potassium concentration such as the nervous system, muscle, and liver. Elimination is primarily by feces,¹¹ with significant enterohepatic circulation.¹² Its volume of distribution is estimated to be 3.6 L/kg.¹³

Thallium poisoning causes a distinct constellation of symptoms. Immediately after exposure, patients experience gastrointestinal (GI) symptoms, including vomiting, abdominal pain, or constipation. Within 24 to 48 hours, exquisitely painful paresthesias of the hands and feet occur. Alopecia begins by 10 days after the exposure and is complete within 1 month, although facial hair, axillary hair, and the inner one third of the eyelashes may be spared.¹⁴ The amount ingested determines the severity of symptoms and the rapidity of onset. The GI symptoms tend to be relatively mild in comparison to other heavy-metal intoxication, unless the ingestion was large. Other symptoms that occur within days of an exposure include autonomic instability, cranial nerve palsies, and altered mental status—specifically confusion, delirium, and psychosis. Optic neuritis and Mees' lines may be late findings. Patients are at risk for sudden cardiac death for many weeks after an exposure.¹⁵ Persistent neurologic sequelae such as impaired memory and weakness are common.¹⁴

MANAGEMENT

Agreement on a treatment protocol is lacking. Gastric lavage should be considered if exposure is recent unless

the patient has vomited. A dose of activated charcoal should be given immediately. Thallium undergoes enterohepatic circulation; therefore, multiple doses of an absorbent should be continued. Prussian blue is the preferred decontamination strategy based on animal data¹⁶⁻²⁰ and in vitro models.^{21,22} The safety and efficacy of Prussian blue in humans have not been systematically tested, although no adverse effects have been recorded. The release of cyanide ions is negligible.²³ The recommended dose for adults is 3 g orally three times a day and for children 2 to 12 years old is 1 g orally three times a day. The recommended duration of treatment is 6 weeks.²⁴ Prussian blue (Radiogardase) was not available in the United States until 2003, when it was approved by the U.S. Food and Drug Administration (FDA), because of concerns of terrorists deploying "dirty bombs." Radiogardase is approved for use in decontamination of patients exposed to radioactive cesium, radioactive thallium, and nonradioactive thallium. (For information: 1-888-CALL-FDA.) If it is not available, laboratory reagent grade Prussian blue may be used. Activated charcoal has also been shown to bind a significant amount of thallium²¹; therefore, multi-dose activated charcoal may be an acceptable alternative.

Other treatment modalities are of questionable benefit. In the past, forced potassium diuresis had been used and was shown to decrease the half-life of thallium from 30 days to 8 to 10 days.²⁵⁻²⁷ However, potassium diuresis was noted to worsen symptoms in humans^{4,28-31}

and increase central nervous system (CNS) toxicity and lethality in animals.^{15,32} The use of hemoperfusion or hemoperfusion alternating with hemodialysis may enhance the elimination of thallium to some degree^{25,33,34} and may be useful in certain patients such as those with renal insufficiency or if combined with other therapies.

Sodium Monofluoroacetate and Fluoroacetamide

DESCRIPTION

Sodium monofluoroacetate is a white powder that is usually mixed with a black dye when used as a rodenticide. Its use is restricted to commercial exterminators. It is odorless, tasteless, and highly water soluble and remains stable for a long period of time. It is readily absorbed through the GI tract, respiratory tract, mucous membranes, and abraded skin. In humans, doses of 0.5 to 2 mg/kg should be considered highly dangerous, and 5 mg/kg is estimated to be the lethal dose.³⁵ The fluoroacetate metabolite, fluorocitric acid, inhibits aconitase, a necessary cofactor in the Krebs cycle, resulting in lactic acidosis, accumulation of citrate in the cells, and chelation of serum calcium.³⁶ It has recently received more attention because of its potential use in biochemical warfare. Its lethality was highlighted in 2004 when it was implicated in the mass poisoning of zoo animals in São Paulo, Brazil.

There is a latent period before symptoms develop because sodium monofluoroacetate must first be metabolized to fluorocitrate for toxicity to occur. Typically, the lag time is between 30 and 180 minutes, but symptoms can be delayed for up to 20 hours.³⁷ Fluoroacetamide has essentially the same actions as fluoroacetate but is less toxic.¹ It has a slightly higher fatal dose (13–14 mg/kg) and a more delayed onset.³⁸

The clinical effects are variable, although nausea, vomiting, and abdominal pain occur in most patients.³⁹ CNS effects and cardiac effects predominant. CNS effects include agitation, muscle spasm, stupor, and seizures. Apprehension, auditory hallucinations, and facial paresthesias often precede seizures. Cardiac effects include ectopic beats, ventricular tachycardia, ventricular fibrillation, and sudden cardiac arrest. Hypocalcemia, hypokalemia, and acidosis are frequent metabolic aberrations. Most deaths occur within hours of ingestion and are due to ventricular tachycardia or fibrillation; all fatalities occur by 72 hours.³⁹ In survivors, delayed effects include renal dysfunction, liver dysfunction, cerebellar degeneration, and cerebral atrophy. Paresthesia, neuropathies, and weakness may be permanent sequelae.³⁶

MANAGEMENT

Treatment of sodium monofluoroacetate and fluoroacetamide toxicity is supportive. A dose of activated charcoal should be given if the exposure is recent. The patient should be placed on a continuous cardiorespiratory monitor and monitored for hypocalcemia, hypokalemia, and acidosis. Seizures should be treated with benzodiazepines. Arrhythmias may respond to

procainamide or calcium. Asymptomatic patients should be observed for at least 24 hours.

There is no known antidote, but a number of potential therapies have been studied. Ethanol, which is metabolized to acetate, has been shown to be an effective antidote in animals but has not been studied in humans.³⁶ Glycerol monoacetate (monacetin), which acts as an acetate substrate in the Krebs cycle, has been used experimentally in monkeys.⁴⁰

Strychnine

DESCRIPTION

Strychnine is a plant alkaloid found in the seeds of *Strychnos nux-vomica*, a tree native to India. It was first used as a rat poison during the 16th century in Germany and is still used worldwide today.⁴¹ Strychnine-impregnated bait is also used to control pests such as pigeons, rabbits, porcupines, and wild carnivores. Strychnine is available to the public in concentrations ranging from 0.3% to 0.5%. Licensed exterminators may obtain preparations that are 5% strychnine by weight. For the past 5 years, there have consistently been more than 100 exposures reported to the American Association of Poison Control Centers Toxic Exposures Surveillance System (AAPCC-TESS).⁴²⁻⁴⁶ Strychnine has also been reported to be an adulterant in both cocaine and heroin.⁴⁷⁻⁴⁹

The mechanism of strychnine poisoning is well understood. Strychnine blocks uptake of glycine, an inhibitory neurotransmitter. Inhibition occurs primarily at the level of the postsynaptic spinal cord motor neurons and to a lesser extent in the brainstem and higher centers.⁵⁰ Thus, strychnine poisoning causes an increase in motor impulses reaching the spinal cord.

Toxic amounts are rapidly absorbed,⁵¹ with convulsions occurring within 15 to 20 minutes. Because strychnine's effects occur primarily at the level of the spinal cord, the patient typically is awake both during and after the convulsions. In massive ingestions, the patient may be unconscious.⁵² Characteristic convulsions are trismus or facial grimacing (*risus sardonicus*) and extensor spasm or frank opisthotonus. Convulsive episodes are brief but very painful. They can be precipitated by any sensory stimuli. Convulsions generally decrease within 12 to 24 hours. Respiratory arrest secondary to spasm of respiratory muscles is the usual fatal event.⁵⁰ Animal studies have shown that artificial ventilation protects from otherwise fatal doses of strychnine. Other complications of strychnine poisoning are due to the violent muscle activity. Profound lactic acidosis, rhabdomyolysis, hyperthermia, and compartment syndrome have been reported.⁵⁰

MANAGEMENT

The primary goals are prevention or control of convulsions^{41,53-55} and ensuring adequate ventilation. Because any stimulation may precipitate convulsions, the patient should be placed in a nonstimulating environment and given benzodiazepines prophylactically. Large amounts of benzodiazepines (>1 mg/kg) may be needed to control seizures. If seizures are not controlled by these measures, pentobarbital or a neuromuscular blocking

agent should be considered. Gastric lavage is not recommended because strychnine is rapidly absorbed and stimulation can precipitate convulsions. If symptoms are minimal or absent, activated charcoal should be considered. The patient should be monitored for lactic acidosis and rhabdomyolysis. The prognosis is generally favorable if the patient can be supported for the first 24 hours.⁴⁷

Aluminum Phosphide, Zinc Phosphide

DESCRIPTION

Phosphides are used throughout the world to protect stored grains from rodents and other pests.⁵⁶ They are also available as mole and gopher killers. Phosphine gas is rapidly formed when zinc or aluminum phosphide comes in contact with dilute acids or with water⁵⁷ and is thought to be primarily responsible for their toxicity.⁵⁶⁻⁶⁰ The exact mechanism of action is unclear, but phosphine is thought to produce toxicity by blocking cytochrome-*c* oxidase, which inhibits oxidative phosphorylation and eventually results in cell death.⁵⁶ Phosphine is heavier than air and has an odor of rotten fish, which can be detected at levels of 2 ppm.^{56,61} Unfortunately, odor cannot be relied on as either a warning sign or diagnostic aid because toxicity can occur below the olfactory threshold.⁶¹ Oral exposures to phosphides have become more numerous, with more than 100 exposures being reported to the AAPCC-TESS in 2001 and 2002.^{45,46} Phosphides are reported to be a common suicidal agent in northern India.^{56,62-64} The lethal dose in humans is not known, but patients ingesting zinc phosphide have died after ingesting as little as 4 to 5 g and have survived ingestion of 25 to 50 g. Toxic exposures to phosphine gas by inhalation have been reported.^{58,59,65} The threshold limit value for phosphine gas is 0.3 ppm.⁶¹

Phosphides cause severe GI irritation. Nausea and vomiting with epigastric pain is universal and occurs within 10 to 15 minutes⁵⁶ in the case of aluminum phosphide and within 20 to 40 minutes for zinc phosphide.⁶³ Other frequent symptoms include hypotension, tachypnea, metabolic acidosis, palpitations, and hypocalcemic tetany. Pulmonary edema, jaundice, and widened QRS on the electrocardiogram occasionally occur.⁶⁴ Except for the universal occurrence of anxiety and restlessness, CNS symptoms are not prominent, although convulsions and coma have occurred in fatal cases.^{59,60} Most deaths occur about 30 hours after ingestion but may be delayed up to 14 days. Death is most likely due to myocardial damage.⁶¹

MANAGEMENT

Treatment is symptomatic and supportive. A dose of activated charcoal is given if the exposure is recent. The patient should be placed on a cardiorespiratory monitor. Electrolytes and calcium should be followed closely and treated as necessary. Renal and liver function tests should be monitored daily. Phosphine can be off-gassed from emesis, feces, or lavage solution, and these fluids should be cleaned up immediately and disposed of properly.

The prognosis for patients with severe cardiovascular and pulmonary problems is grave.

Phosphorus

DESCRIPTION

Elemental phosphorus exists in two forms. The red form, used in manufacturing matches, is not absorbed and is nontoxic. In contrast, the yellow (also called white) form is a highly toxic protoplasmic poison and is available as a rat or roach paste.⁶⁶ The acute lethal dose has been reported to be about 1 mg/kg.⁶⁷

Symptoms have classically been divided into three stages. In stage I occurring minutes to hours after the ingestion, severe oral burns, vomiting, stomach pain, garlic-like odor on the breath, and diarrhea may be noted. The feces or vomitus may appear phosphorescent in a darkened room, and hence phosphorus poisoning has been called the *smoking stool syndrome*.⁶⁸ Death in stage I has been attributed to ventricular dysrhythmia and cardiovascular collapse.⁶⁸ If the patient survives, a quiescent period of several weeks ensues (stage II). The third stage represents systemic toxicity caused by phosphorus. Organ systems primarily affected are the GI tract, liver, heart, kidneys, and CNS.⁶⁹

MANAGEMENT

Treatment is primarily directed toward removing and preventing absorption of the phosphorus, as well as symptomatic and supportive care of patient. Emesis should be avoided. Dilution with milk is not recommended because digestible fat increases the absorption of phosphorus. Gastric lavage with 1:5000 potassium permanganate or a 2% solution of hydrogen peroxide may be useful if begun before onset of symptoms; these solutions oxidize phosphorus to the less harmful phosphate. Care must be taken to protect both the patient and caregivers from contact with phosphorous, which may be present in emesis or feces.

The patient should be observed for damage to the GI tract, liver, kidneys, heart, and cardiovascular system. Hypoglycemia, hypoprothrombinemia, and clotting abnormalities may be noted with liver damage, and clotting studies should be performed in seriously affected patients. Hypocalcemia has been reported. Asymptomatic patients should be monitored for 24 to 36 hours.

Arsenic

DESCRIPTION

Although more commonly used as a pesticide or herbicide, arsenic finds some limited use as a rodenticide. Arsenites are salts of arsenous acid (from arsenic trioxide). Arsenites are more soluble and have a faster onset of toxicity than other forms of arsenic, thus making them likely choices for rodenticides, herbicides, and pesticides.¹

For effects and treatment of exposure to arsenic, see Chapter 74.

Barium Carbonate

DESCRIPTION

Barium carbonate is one of several soluble barium salts, including sulfide, chloride, chlorate, and nitrate. All are highly toxic. On the other hand, barium sulfate, an insoluble salt, is harmless and is used in medicine as a radiopaque contrast medium. In the past, rodenticides were used that contained 20% to 25% barium carbonate. No barium rodenticides are currently in use, although other forms used for poisoning are available.^{70,71} The lethal dose is estimated to be 2 g. Acute toxicity may occur with 200 mg.¹

Barium apparently produces a depolarizing neuromuscular blockade resulting in weakness of striated, cardiac, and smooth muscle. Hypokalemia, often profound, may occur. Symptoms include paresthesias around the mouth; this may spread to the hands and feet. Vomiting and diarrhea with colicky abdominal pain may ensue 1 to 8 hours after ingestion. Tightness in the throat, dysarthria, headache, muscle twitching, general weakness, and paralysis may be noted. Paralysis can range from weakness of one limb to complete paralysis with respiratory failure.⁷¹ Many of the reported cases have resulted from contamination of food. In such cases, the rapidity of onset and absence of eye signs can help rule out botulism.⁷¹

MANAGEMENT

Treatment should start with emptying the stomach by emesis or lavage unless substantial vomiting has already occurred. A lavage solution of magnesium or sodium sulfate (30 g in 250 mL of water) should be used to precipitate the barium as insoluble barium sulfate. The patient's fluids and electrolytes should be monitored. Hypokalemia is common and should be treated aggressively.^{72,73} Muscle tone and respiratory effort should be followed closely and mechanical ventilation instituted as needed.

The prognosis is favorable if patients are stabilized and are maintained for 24 hours. Recovery is usually complete.

Pyriminil (Vacor, PNU)

DESCRIPTION

This agent was released in 1975 as a one-feeding, acutely toxic rodenticide. Because of its severe toxicity, it was withdrawn as a general-use pesticide in 1979. The manufacturer asked for return of unsold packages but did not request a general recall of packages sold to the public. As a result, rare exposures continued to occur as recently as 2002.⁴⁶

Pyriminil destroys the β cells of the islets of Langerhans in the pancreas, resulting in inadequate production of insulin. Patients may present within hours of exposure with diabetic ketoacidosis. Death may result from dysrhythmias or diabetic ketoacidosis. Sequelae are significant and includes brittle diabetes mellitus; postural hypotension, which can be difficult to control; and sensory and motor neuropathies.⁷⁴⁻⁷⁶ Death has been reported with a dose of 780 mg, and symptoms have been noted after ingestion of as little as 390 mg (5.6 mg/kg).⁷⁶

The exact mechanism of action of pyriminil is not known, but in animals, it seems to act as a niacinamide

antagonist, interfering with the pentose phosphate shunt, particularly in liver, brain, and islet cells, and resulting in defects in RNA production.

MANAGEMENT

A dose of activated charcoal is given if the exposure is recent. Although niacinamide (nicotinamide) may be an antidote, it is no longer available, and therefore niacin (nicotinic acid) has been substituted. Of note is that the vasodilation caused by niacin may exacerbate the existing postural hypotension. The recommended dose is 500 mg administered intravenously (slow push), followed by 100 to 200 mg every 4 hours for 48 hours. If symptoms of poisoning are present, the dosing interval should be decreased to every 2 hours.

Monitoring should include glucose, ketones, electrolytes, and liver function tests. Diabetic ketoacidosis should be treated with insulin and fluid as necessary.

MODERATELY TOXIC RODENTICIDES (SIGNAL WORD: "WARNING")

α -Naphthyl-Thiourea (ANTU)

DESCRIPTION

ANTU produces pulmonary edema and pulmonary effusion in adult Norway rats. Young Norway rats, roof rats, and most other animals except dogs are resistant to its effects.¹

Animal studies suggest the lethal dose for humans may be between 0.5 and 5 mg/kg.⁷⁷ Expected effects after ingestion include vomiting, dyspnea, cyanosis, and pulmonary rales or edema. Exposures are rare but continue to be reported. There have been no recorded human fatalities.

MANAGEMENT

Treatment is supportive. Routine decontamination should be performed. The patient should be monitored for pulmonary edema and treated symptomatically if it occurs.

Cholecalciferol

DESCRIPTION

A rodenticide first marketed in 1984, cholecalciferol (vitamin D₃) takes advantage of the fact that rodents are extremely sensitive to small percentage changes in the calcium balance in their blood. Cholecalciferol causes hypercalcemia both by mobilizing calcium from bone and by increasing absorption of calcium by the gut. The hypercalcemic state results in calcification of the organs, blood vessels, and soft tissue. It may also lead to nerve and muscle dysfunction as well as cardiac rhythm disturbances.⁷⁸

Cholecalciferol is commonly used by the general public as well as licensed exterminators. Pellets are available in 30-g packs and in bulk containers. Each pellet contains 0.0577 mg, or 2308 IU, of vitamin D.⁷⁹ There is wide individual variation in the amount of

cholecalciferol required to produce hypervitaminosis D in humans, with most reported poisonings a result of chronic excess of vitamin D. Continued ingestion of 50,000 IU or more per day can cause toxicity.⁸⁰ No serious toxicity or death has been reported from the rodenticide form of D₃. However, there are several reports of toxicity due to hypervitaminosis D₃ when added in error to milk⁸¹ and nutritional supplements⁸² or when industrial concentrates of vitamin D₃ were used as a cooking oil.^{83,84} No information is available on acute exposures. Because of the long elimination half-life (>30 days), however, a very large single dose might produce the same effects as long-term exposures.

Symptoms of hypercalcemia are common with levels above 11.5 to 12 mg/dL. These include anorexia, weight loss, weakness, fatigue, disorientation, vomiting, polyuria, and constipation.⁸¹ Levels exceeding 13 mg/dL may produce seizures and renal insufficiency. Calcification in the kidneys, skin, vessels, lungs, heart, and stomach also may occur at this level. In children, one episode of moderately severe hypercalcemia may result in growth retardation. Six months or more may pass before growth resumes.⁸⁵

MANAGEMENT

Several bait pellets or a small amount of the mouse seed should not be toxic, and no treatment is necessary. Patients who have ingested a single large dose of cholecalciferol should be given a dose of activated charcoal. Serum calcium levels must be monitored for 24 to 48 hours after ingestion. Normal serum calcium by 48 hours excludes significant toxicity. Serum potassium and magnesium levels should also be monitored frequently.

Hypercalcemia should be treated aggressively. Forced diuresis using normal saline and furosemide increases the elimination of calcium. Prednisone (5–15 mg every 6 hours by mouth) is effective in vitamin D intoxication to lower calcium levels. Calcitonin (4–8 IU/kg subcutaneously or intramuscularly every 12 hours) may significantly lower calcium levels over the course of hours. In severe hypercalcemia (>15 mg/dL), or for those patients not responding to other measures, the use of mithramycin should be considered. All patients should be placed on a low calcium diet.

LOW-TOXICITY RODENTICIDES (SIGNAL WORD: "CAUTION")

Warfarin and Long-Acting Anticoagulants (Second-Generation Anticoagulants, Superwarfarins)

DESCRIPTION

Warfarin and the long-acting anticoagulants (brodifacoum, bromadiolone, difenacoum, and chlorophacinone) act by inhibiting vitamin K epoxide reductase and vitamin K reductase. However, the long-acting anticoagulants differ from warfarin in two important ways: they are more potent, and they have longer half-lives. They thus have advantages as rodenticides in that they are

effective in single or limited feedings (warfarin requires repeated feeding for 4 to 5 days), and they are effective against animals that are resistant or more tolerant to warfarin.⁵ Since their introduction during the mid to late 1970s as a second generation of anticoagulants, these agents have essentially replaced the older warfarin-containing products.

The long-acting anticoagulants are responsible for more than 80% of the human rodenticide exposures reported in the United States. Most of these exposures are reported in children younger than 6 years as a consequence of exploratory behavior.⁴⁶ Significant clinical toxicity has never been shown in this subset of patients.⁸⁶⁻⁹¹ In contrast, both single ingestions of a large amount and multiple ingestions of small amounts either through occupational exposure^{92,93} or surreptitious exposure⁹⁴⁻⁹⁶ can result in toxicity with symptoms lasting for months.

For effects and treatment of warfarin and the long-acting anticoagulants, see Chapter 66.

Bromethalin

DESCRIPTION

Bromethalin is one of the newer rodenticides, having entered the market in 1985 but not widely available until the late 1990s with significant numbers of exposures only reported in 2001.⁴⁵ Bromethalin acts as a neurotoxin. It is metabolized to desmethylbromethalin, which has much more potent neurotoxic activity.⁹⁷ The CNS effects appear to be secondary to the uncoupling of mitochondrial oxidative phosphorylation. A resultant decrease in the production of adenosine triphosphate causes the development of fluid-filled vacuoles between the myelin sheaths covering the central nerves. Increased CNS pressure and pressure on nerve axons result in decreased nerve impulse conduction. Resulting paralysis is followed by eventual death.⁹⁸ Bromethalin is a nonselective mammalian poison. All animals, including humans, are vulnerable to its toxic effects. Its effectiveness as a rodenticide is based on smaller rodents consuming larger quantities per kilogram of body weight than larger animals.⁹⁹ One possible exposure has been reported in which the patient presented unconscious with severe myoclonic jerks when touched. This patient had almost complete neurologic recovery within 48 hours.¹⁰⁰

Treatment of a bromethalin ingestion should be symptomatic and supportive.^{99,101-103} Effects in animals are typically noted within 2 to 4 hours but may be delayed up to 12 to 24 hours. Therefore, massive ingestions should be observed for at least 12 hours.

Red Squill

DESCRIPTION

Red squill is a botanic rodenticide derived from the red variety of *Urginea maritima*, or sea onion. Red squill contains two cardiac glycosides, scillaren A and scillaren B.¹⁰⁴

Red squill is very bitter and has a powerful emetic action; hence, much of the material may be spontaneously removed from the stomach before it is

absorbed. The scillaren A and B produce effects similar to digitalis, and treatment is the same as for digitalis toxicity, including the use of Digibind (see Chapter 68). A polyclonal assay for digoxin may confirm a significant ingestion. However, signs and symptoms may exceed what would be predicted from the level because the assay does not have equivalent cross-reactivity for all cardiac glycosides.¹⁰⁵

Norbromide

DESCRIPTION

Norbromide is selectively toxic to Norway rats, in which it acts to produce smooth muscle constriction. Death is a result of intense peripheral vasoconstriction.¹⁰⁶ Other rats, rodents, and animals, including humans, are resistant because they do not have the receptor for this compound in their blood vessels. Human volunteers given 20 to 300 mg had no symptomatic complaints but at the higher doses demonstrated slight decreases in temperature and blood pressure. Lowest values were seen 1 hour after ingestion, and values returned to normal by 2 hours.

MANAGEMENT

After large exposures, activated charcoal should be given. Treatment is rarely needed but would be symptomatic and supportive.

CONCLUSION

A number of groups of persons are poisoned by rodenticides. Children are especially at risk. Of 20,507 calls about rodenticides recorded by members of the AAPCC-TESS in 2002, 85% involved children younger than 6 years.⁴⁶ Other exposures occur in suicide attempts, victims of attempted homicide, exterminators and others putting out rodenticides, intoxicated individuals, psychiatric or mentally impaired patients, and people who accidentally eat rodenticides that are stored in containers normally used for edible products.

At a Glance...

- Fumigants exist in the gaseous state as nonselective pesticides. They pose significant risks to humans when conditions of safe use are not observed.
- Some fumigants may be explosive as well as toxic. Depending on their molecular weight, they may be heavier or lighter than air, and thus tend to accumulate in corresponding (low or high) areas of confined spaces
- Phosphine has been responsible for numerous human poisonings. Patients may complain of headache, dizziness, tremors, cough, chest pain, shortness of breath, nausea, vomiting, and abdominal pain. Clinical signs include depressed mental status, pulmonary edema, hypotension, cardiac dysrhythmias. Seizures have been reported.
- Methyl bromide is a neurotoxicant and may cause status epilepticus. It is also a potent vesicant.
- Sulfuryl fluoride may cause bronchospasm, mucosal irritation, nausea, vomiting, and abdominal pain, as well as paresthesias, refractory seizures, and coma. Fluoride toxicity may result in profound shock, life-threatening cardiac dysrhythmias, and pulmonary edema.

Fumigants are chemical pesticides that exist as gases at specific ambient temperatures and atmospheric pressures. In their gaseous state, these chemicals are able to easily penetrate into treated agricultural product stores as well into the crevices of structural materials that would be difficult to reach with conventional liquid spray techniques. Fumigants are generally not selective with regard to target pests, and human exposure to these agents may under specific circumstances result in significant human morbidity. Individuals who use these chemicals must have special training in how to work with these chemicals safely before becoming certified fumigators.

This chapter summarizes the chemical and biomedical characteristics of the fumigants currently available for use in the United States. In addition, several fumigants no longer approved for use are discussed because important lessons have been learned from their prior use.

1,3-DICHLOROPROPENE (CAS: 542-75-6) (TELONE II)

1,3-Dichloropropene (DCP) is a chlorinated aliphatic hydrocarbon with a strong chloroform odor. Its chemical formula is $C_3H_4Cl_2$. Used as a soil fumigant, it is useful as a fungicidal and nematocidal agent in vegetable and tobacco crops. At room temperature, this chemical is a yellow liquid, which is applied by injection into soil. After injection, it quickly vaporizes.

Data regarding human exposure to 1,3-dichloropropene are limited. A study of commercial fumigant applicators in the potato fields of the Netherlands revealed no nephrotoxicity or hepatotoxicity after 117 days of exposure to an 8-hour time-weighted average (TWA) of 2 ppm.¹ The current TWA standard of the Occupational Safety and Health Administration (OSHA) is 1 ppm for dermal exposure.²

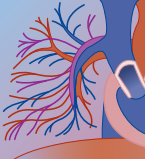

Animal studies have demonstrated that DCP is metabolized in the liver by the glutathione transferase enzyme. A study of DCP in rats showed that the main excreted product in the urine is *N*-acetyl-S-(cis-3-chloro-2-propenyl)-L-cysteine, a mercapturic acid metabolite.³ Human studies involving biologic monitoring of commercial applicators have used this same mercapturic acid metabolite as a marker of exposure to DCP.⁴

Symptoms of acute exposure are primarily the result of mucosal irritation and include eye burning, tearing, coughing, difficulty breathing, and skin rashes.⁵ There are also reports of contact dermatitis arising from chronic use of this product.⁶ Treatment is primarily supportive after decontamination measures appropriate for the route of exposure have been completed. Pulmonary edema, acute renal and hepatic failure, and adult respiratory distress syndrome have been described after ingestion of this product. Activated charcoal may be beneficial after oral ingestion. Copious irrigation using normal saline solution or water is recommended for ocular and dermal exposures.^{7,8}

DCP has been listed as a possible human carcinogen by the U.S. Environmental Protection Agency (EPA). Multiple animal studies showed an increase in tumors of the stomach, liver, lung and bladder.⁹

PHOSPHINE (CAS 7803-51-2) (PH₃)

Phosphine gas is produced when pellets of aluminum, calcium, magnesium, or zinc phosphide are exposed to water vapor. Aluminum phosphide is used primarily to treat grain and tobacco stores. Its formulation as pellets lends itself for use in treating transport containers. Phosphine gas is described as having a garlic or rotten fish odor. The OSHA threshold limit value (TLV) for phosphine gas is 0.3 ppm. The odor is detectable at a concentration of 2 ppm. However, this odor threshold does not give adequate warnings regarding possible dangerous gas concentrations. For this reason, manufacturers of aluminum phosphide include ammonia-producing agents in the pellets as the more noxious ammonia odor may allow for better detection of possible phosphine gas release. This gas is highly explosive, and additives are placed within the pellets to slow the rate of gas formation to reduce the risk for explosion.

Multiple mechanisms of action have been proposed for phosphine gas. Animal studies demonstrated inhibition of the mitochondrial cytochrome oxidase system as well as interference with amino acid incorporation into proteins. Small vessels appear to be affected to a greater degree than the major vessels, which may explain the extensive third spacing and profound cardiovascular collapse that may occur with phosphine poisoning.¹⁰ Numerous cases have been reported of human exposures both as accidental exposures in a commercial fumigation setting and as reports of these agents being used in suicidal gestures. One *in vitro* study showed that phosphine induces the formation of excess superoxide radicals in red blood cells. This resulted in the production of denatured hemoglobin aggregates (Heinz bodies) in the erythrocyte in the course of a hemolytic anemia.¹¹ Another case report of a 25-year-old man who ingested 6 g of aluminum phosphide pellets describes the development of methemoglobinemia (32%) occurring 32 hours after ingestion.¹²

Numerous deaths have been reported when stowaways attempt to use grain cars on trains and ships as transportation, not realizing that these containers have been treated with one of the phosphide chemicals to prevent pest and fungi destruction of the grain during transport. One report described three adults who became ill and a 12-year-old boy who died after spending 18 hours in a railroad boxcar containing lima beans that had been fumigated with aluminum phosphide. At time of discovery, the child was dead, and the adults were complaining of nausea, vomiting, abdominal pain, headache, and dizziness. Another report describes the discovery of a 23-year-old man who was found dead after he had broken the plastic seal in a rice-filled boxcar in order to gain entry. Postmortem toxicologic analysis of this individual showed phosphine levels in all tissue samples taken.¹³

Clinical findings in acute phosphine poisoning may include depressed mental status, pulmonary edema, hypotension, cardiac dysrhythmias, liver and kidney failure, and severe gastritis.¹⁴ Inhalation of low levels of phosphine gas may produce symptoms of headache, dizziness, tremors, cough, chest pain, shortness of breath, nausea, vomiting, and abdominal pain. Seizures have been reported.

OSHA exposure limits for phosphine gas are 3 ppm for an 8-hour TWA; exposure to 500 ppm for 30 minutes is expected to be fatal, whereas only "a few breaths" of phosphine at a concentration of 1000 ppm can be lethal.¹⁵ Treatment for phosphine toxicity includes removing the victim from the source of exposure and supportive care. Patients must be closely observed for the development of hypoxia due to pulmonary edema or methemoglobinemia. Patients who develop hemolytic anemia may require the administration of blood products. The electrocardiogram may show nonspecific ST-T changes, but no one pattern is pathognomonic for phosphine toxicity. One study done on rats showed some improvement in cardiovascular status and overall survival after administration of *N*-acetylcysteine.¹⁶

Tachycardia, both supraventricular and atrial fibrillation, has been reported, as well as ST changes and

various conduction delays and blocks. Reports of patients who manifested electrocardiographic changes due to their phosphine exposure show that these changes resolve within 25 days if the patient survives the first 24 hours after exposure.¹⁷ There are also reports of hypokalemia after acute exposure; serum magnesium levels may also be elevated or decreased. Although blood phosphine levels have been studied, they are not routinely used to manage patients. One author examined blood phosphine levels in 40 cases of oral ingestion and found that blood phosphine levels correlated with severity of clinical symptoms. This study demonstrated that patients with a blood phosphine concentration of 1.067 mg/dL or less survived the ingestion.¹⁸ Anger and colleagues were able to detect elevated levels of both aluminum and phosphorous in blood and tissue samples of a 39-year-old man who committed suicide by ingestion of aluminum phosphide.¹⁹ The authors were unable to detect any phosphine in the blood or urine samples; however, the phosphine was present in tissue samples from the brain, liver, and kidney.

Decontamination for oral ingestion may include the use of activated charcoal. Patients who vomit may risk exposing hospital staff to phosphine by means of off-gassing from the vomitus. Emesis should be suctioned and placed in sealed containers as soon as possible. Overdose victims also run a significant risk for chemical pneumonitis if they aspirate.^{7,8}

Phosphine gas is not listed as a possible carcinogen with the International Agency for Research on Cancer. However, there are studies suggesting that fumigators who have chronic exposure to phosphine may have an increased risk for non-Hodgkin's lymphoma. One investigation found consistent chromosomal abnormalities in the pesticides applicator group as compared with the nonexposed control group.²⁰

METHYL BROMIDE (CAS 74-83-9)

Methyl bromide is a colorless and odorless liquid that quickly volatilizes. The gaseous form is heavier than air. It is used for pest control in agriculture and home fumigation. A lacrimating agent, chlorpicrin, is usually added to provide some warning of exposure. Methyl bromide has a TLV of 5 ppm, and the concentration which is immediately dangerous to life and health (IDLH) is 2000 ppm. Aside from use as a fumigant, this chemical has also been used in the past in fire extinguishers. The primary route of exposure is by inhalation, although dermal absorption may also result in significant morbidity.

Methyl bromide is a severe vesicant. Dermal exposure to the gas can result in severe blistering of the skin. It can irritate the mucosa of the oropharynx; coughing may be sufficiently intense to produce post-tussive emesis. The central nervous system is the most profoundly affected in cases of methyl bromide poisoning. Early neurologic symptoms of an acute exposure may vary from tremors, headache, ataxia, blurred or double vision, and vertigo

to grand mal seizure, status epilepticus, and coma. The onset of symptoms after an acute exposure may be delayed up to 24 hours. Both acute and chronic exposures may result in psychosis, hallucinations, or delirium.²¹ Chronic exposures of methyl bromide are associated with extremity paresthesia, hearing or vision loss, balance disturbances, and syncopal episodes. One study found symmetric midbrain and cerebellar lesions on magnetic resonance imaging of a 30-year-old man who worked in a warehouse that was regularly fumigated with methyl bromide. His presenting complaints were foot paresthesia and a gait disturbance.²²

Exposures to methyl bromide occur under a variety of circumstances. Some cases are the result of fumigators who did not follow proper procedures or had faulty protective equipment. Other reports involve use of the chemical in an area that had previously unknown venting sources. Underground sewer pipes and other similar conduits have been implicated in several deaths. In Norway, a newborn infant was killed when the methyl bromide that was used to fumigate a house in another part of the housing subdivision leaked into the victim's home through the sewer pipes.²³ In the United States, there is a case report of a 36-year-old woman who died from methyl bromide exposure. This woman lived in a guesthouse that was connected to the main house by eight hidden conduit pipes of which the property owner was unaware. Aside from these abandoned pipes, the guesthouse was not structurally connected to the main house. The property owner had the main house fumigated with methyl bromide, and that evening, the woman told friends she felt ill. The next morning, she was found in status epilepticus, which persisted despite multiple anticonvulsants and being placed on a pentobarbital infusion. She remained in a persistent vegetative state until she died 19 days after fumigation. At autopsy, the heart showed areas of edema and hemorrhage, the lungs had severe edema with infiltrates of neutrophils and macrophages, the liver had areas of centrilobular necrosis, and the brain had bilateral hippocampal necrosis which was thought to be consistent with status epilepticus and anoxia. All tested tissue samples, blood, bile, liver, and adipose tissue had detectable levels of methyl bromide.²⁴

Several mechanisms have been postulated for the severity of the neurotoxic effects of methyl bromide. Its overall toxicity is believed to be the result of alkylation of sulfhydryl groups of numerous enzymes involved in routine physiologic functioning. Methyl bromide is metabolized into methyl glutathione by the enzyme glutathione transferase. The methyl glutathione is then converted into the neurotoxic metabolites of methanethiol and formaldehyde. Animal studies have shown that those species with decreased glutathione stores manifest lesser neurotoxic effects when exposed to methyl bromide.²⁵ This may be one of the few instances when treatment with *N*-acetylcysteine may be detrimental.

Treatment of methyl bromide exposure consists of thorough decontamination and supportive care. Seizures should be treated aggressively with anticonvulsants, benzodiazepines, and barbiturates if needed. Although it

is possible to obtain blood and urine methyl bromide levels, these assays are not routinely used and have little bearing on the management of the patient. Serum bromide levels may be used as a marker for exposure. Methyl bromide is not listed as a possible carcinogen.

Under the Clean Air Act passed in 1993, methyl bromide was declared to be an ozone-depleting agent. Therefore, manufacture and importation of this substance was set to be phased out by 2001. However, in 2003, the EPA announced the phase-out would not be completed until 2005. Methyl bromide may still be used under a critical use exemption as alternative fumigants are still being investigated. Unfortunately, methyl bromide has been an effective agricultural fumigant for more than 30 years, and some of its uses have no good alternative treatments at this time. It is expected that total cessation of methyl bromide use will be met with some resistance, and the phase-out is expected to take longer than expected.²⁶

SULFURYL FLUORIDE (CAS 2699-79-8)

Sulfuryl fluoride gas is colorless, odorless, and heavier than air. It has a threshold limit value of 5 ppm for an 8-hour TWA, a 15-minute short-term exposure limit (STEL) of 10 ppm, and an IDLH value of 1000 ppm.²⁷ Aside from agricultural uses, it is also used to eradicate termites. The mechanism of action of sulfuryl fluoride was shown in a termite study that revealed excretion of inorganic sulfate when these insects were exposed to a nonlethal dose.²⁸ This is consistent with signs and symptoms of fluoride toxicity seen in sulfuryl fluoride exposure across many different species. Fluoride is rapidly absorbed in the body and quickly binds any available calcium ion, resulting in profound hypocalcemia, which can precipitate cardiac dysrhythmias.

Exposure to this substance can cause severe bronchospasm, which is why it is shipped as a compressed gas. Symptoms of exposure begin with mucosal irritation, nausea, vomiting, and abdominal pain. Clinical symptoms then shift to its central nervous system effects, which may then predominate with paresthesias, refractory seizures, and coma. Finally, effects of the fluoride toxicity itself may result in profound shock, life-threatening cardiac dysrhythmias, and pulmonary edema. Sulfuryl fluoride exposure in some animal studies has resulted in symptoms consistent with parasympathetic toxidromes, including salivation, lacrimation, vomiting, and diarrhea.²⁹

This gas leaves behind a large amount of residue of sulfuryl fluoride on the foods it was used to fumigate. When heated, this residue may give off dangerous gases, such as hydrofluoric acid.³⁰

Treatment of ingestion of this substance includes gastric lavage with a 0.15% calcium hydroxide solution or with any available calcium salt to bind the fluoride ion before it is absorbed. In cases of inhalational toxicity or after absorption for ingestion, the mainstay of treatment is to be aggressive with calcium replacement to prevent the life-threatening cardiac dysrhythmias that may result

if a hypocalcemic state is untreated. Calcium may be replaced with a calcium gluconate solution through a peripheral intravenous line, whereas calcium chloride may only be administered through a central venous catheter because of the irritation it may cause when delivered into a small blood vessel. Because the fluoride ion is excreted primarily in the urine, fluid resuscitation should be delivered to maintain a steady urine output.^{7,8}

METHYL ISOTHIOCYANATE (CAS 556-61-6)

Methyl isothiocyanate (MITC) has a solid crystalline structure at room temperature, which sublimates directly to a gaseous state. It has a sharp horseradish odor and is a severe skin irritant.

Although it has been restricted from use as a pesticide or a fumigant since 1992, this agent is still encountered in a variety of sources. It is only available as MITC as a wood preservative at this time. This compound should not be confused with methyl isocyanate (MIC), which was involved in the Union Carbide disaster in Bhopal, India. MITC is a breakdown product of two pesticides that are still in use: metam sodium, and dazomet.³¹ This substance has been described as a breakdown product of many of the carbamate pesticides.³² MITC was noted in 30 name-brand cigarettes after the company discovered strange odors appearing to originate from the filters. This finding launched a recall of more than 8 billion cigarettes in the U.S. market starting in 1995. The Centers for Disease Control and Prevention could not definitively link this finding as a causative agent in complaints regarding respiratory symptoms made by 72 consumers.^{33,34} Also, Italian wine producers were discovered placing MITC in their products to prevent secondary fermentation during shipping.³⁵

MITC is metabolized through glutathione pathways, and animal studies in rats and mice show the major excretion product is a mercapturic acid derivative found in the urine.³⁶ Clinical signs of exposure are skin and mucosal irritation from the vesicant effects. MITC can also produce severe bronchospasm. Exposure to metam sodium results in similar symptoms of mucosal and dermal irritation. There are reports of blistering, papular eruptions, and skin discoloration, which responded to topical corticosteroids.³⁷ There are no minimal exposure limits for MITC, and it is unknown whether this compound is carcinogenic. The treatment of exposure to MITC is primarily supportive.^{7,8}

MITC was first registered in 1987 as a preventative treatment for wood-destroying fungi. It is currently under restricted use for this purpose. This substance may only be handled by those who have been certified in its use. MITC had been used as a soil fumigant until 1992, when the producer voluntarily withdrew this application from its registration. This withdrawal allowed 1 year for the remaining stocks to be destroyed and for retailers to use up the stock they already had on hand.³¹

At a Glance...

- Most organochlorine insecticides are widely restricted or banned.
- The major effect of acute toxicity is central nervous system excitation.
- Chronic exposure may result in persistent neurologic disability.
- Treatment of acute toxicity centers on supportive care and control of seizure activity.

INTRODUCTION AND RELEVANT HISTORY

Organochlorine insecticides (sometimes referred to as *chlorinated hydrocarbon insecticides*) were introduced in the 1940s with Paul Müller's effective demonstration of dichlorodiphenyltrichloroethane (DDT).¹ Before this time, available insecticides were limited to arsenicals, petroleum oils, nicotine, pyrethrum, rotenone, sulfur, hydrogen cyanide gas, and cryolite.² The organochlorine insecticides proved to be nonvolatile, inexpensive to manufacture, environmentally stable, and relatively less toxic than previous insecticides. These properties led to the widespread use of this class of insecticides.

Utilization of DDT has had a tremendous impact on human health. DDT was used in worldwide mosquito abatement programs and is credited for saving millions of lives from malaria and typhus. This success led to the development of other organochlorine insecticides.

However, although these organochlorine compounds were very effective as insecticides, there were subsequent ecological repercussions that developed from their use. In 1962, Rachel Carson, in her book *Silent Spring*, described the reduction of the eagle and osprey population as result of DDT's persistence in the environment and its ability to bioconcentrate within certain animals.³ These properties eventually led to a ban on DDT in the United States, and subsequent bans on other organochlorine insecticides that demonstrated these properties of environmental persistence and bioconcentration. The 2001 Stockholm Convention on Persistent Organic Pollutants (POPs) targeted a number of pollutants, including many organochlorine pesticides, and recommended a worldwide ban on these compounds. This agreement became legally binding on May 17, 2004.⁴

EPIDEMIOLOGY

Because organochlorine insecticides are strictly restricted or banned in North America and Europe, exposures to them are rare in these regions. In 2003, of about 2.4

million exposures reported to U.S. poison centers, only 1435 exposures involved chlorinated hydrocarbon insecticides. There were only 13 major outcomes, and no reported deaths.⁵ However, because organochlorine insecticides are very effective and cheap, they are still widely used in developing countries, despite the Stockholm Convention agreement. In 2002, evidence of continued poisoning episodes with organochlorine insecticides in developing countries occurred in India where, due to food contamination, 36 people were poisoned by endosulfan, resulting in the deaths of three children.⁶

Although chlorinated hydrocarbons are no longer in agricultural use in the United States, the organochlorine γ -hexachlorocyclohexane, better known as *lindane*, is still used for medicinal purposes, as a scabicide. As a result, in the United States, lindane is probably the most common source of toxicity from a chlorinated hydrocarbon insecticide. As safer agents for scabies treatment have been developed, lindane has become a second-line agent. The U.S. Food and Drug Administration (FDA), in 2003, issued a public health advisory regarding the risk for potential toxicity from treatment with lindane by misuse or therapeutic use. The FDA also required a boxed warning, product size limitation, and distribution of a medication guide with each prescription. In 2001, California banned the use and sale of lindane in the state. Texas poison control centers found that accounts of lindane exposure declined from 132 to 75 between 1998 and 2002 as newer, safer therapies became available and regulations on lindane increased.⁷

STRUCTURE AND STRUCTURE–ACTIVITY RELATIONSHIPS

Organochlorine insecticides represent a diverse group of compounds that contain carbon, hydrogen, and chlorine. However, unlike the volatile chlorinated hydrocarbons found in solvents, organochlorine insecticides have higher molecular weights and are consequently less volatile.

Organochlorine insecticides belong to four distinct structural classes: diphenyl aliphatics (e.g., DDT and related compounds), cyclodienes (e.g., aldrin, dieldrin, endrin, endosulfan, heptachlor), cyclohexanes (e.g., γ -hexachlorocyclohexane, known more commonly as lindane), and polychloroterpenes (e.g., toxaphene). The organochlorine pesticides chlordecone and mirex are also called *cage compounds*; they do not fall into a distinct category, although they are sometimes classified with the cyclodienes.

The activity and toxicity of these insecticides do not necessarily correlate with structure. In fact, some structurally similar compounds can have vastly different

activities and toxicities. For instance, the γ -isomer of hexachlorocyclohexane has insecticidal properties and will cause central nervous system excitation, whereas other isomers have no insecticidal properties and will cause central nervous system depression.⁸

PHARMACOLOGY

Pathophysiology

In general, the primary means by which organochlorine insecticides kill insects is through their neurotoxicity. As such, when toxic to humans, the predominant system affected is the nervous system. The mechanism of toxicity, however, varies among the different organochlorine insecticides.

Simplistically, DDT acts on the central nervous system by interfering with the movement of ions through neuronal membranes. There appear to be multiple mechanisms by which DDT affects this ion movement. DDT delays the closing of the sodium ion channel and prevents the full opening of potassium channels.⁹ It also appears to affect a specific neuronal adenosine triphosphatase (ATPase) involved in sodium, potassium, and calcium movement through the nerve membrane.¹⁰ DDT may inhibit the neuron's ability to transport calcium ions by binding to calmodulin and affecting a Ca/Mg ATPase; however, this theory has not been confirmed.¹¹

The combined effect of these actions would lead to sustained depolarization of the neuronal membrane, resulting in continued release of neurotransmitters and central nervous system excitation.

There is also some evidence to suggest that DDT may also have the effect of increasing serotonin and norepinephrine breakdown as well as increasing levels of aspartate and glutamate in the central nervous system.¹²⁻¹⁴ Because serotonin and norepinephrine modulate (and sometimes inhibit) central nervous system activity, and aspartate and glutamate act as excitatory transmitters, the subsequent imbalance that results may lead to central nervous system excitation.

Lindane and the cyclodienes, although structurally different, seem to have a similar mechanism of neurotoxicity, further demonstrated by the development of cross-tolerance between these two classes of organochlorines in insects.¹⁵ Both lindane and cyclodienes inhibit γ -aminobutyric acid (GABA) activity by interacting with the picrotoxin binding site of the GABA_A receptor-ionophore complex and subsequently blocking the influx of chloride through the complex.¹⁶⁻²⁸ As a result of this action, a major inhibitory neurotransmitter is antagonized. Toxaphene seems to antagonize GABA at the GABA_A receptor-ionophore complex as well.²⁹

Although chlordecone antagonizes the GABA receptor at the picrotoxin binding site in cockroaches,³⁰ it does not appear to do the same in humans. The mechanism of chlordecone neurotoxicity in humans is poorly understood.

Organochlorines cause sensitization of the myocardium to endogenous catecholamines and predispose test animals to dysrhythmias, presumably in a fashion similar to the chlorinated hydrocarbon solvents.

Pharmacokinetics

In varying degrees, the absorption of organochlorine insecticides occurs after ingestion, inhalation, or dermal absorption. The efficiency of dermal absorption is variable. Lindane and most of the cyclodienes are well absorbed across the skin, whereas DDT and its analogs, along with toxaphene and mirex, have low dermal absorption.

Most of the solid organochlorines are not highly volatile; however, inhalational exposure can still occur with pesticide-laden aerosol or dust particles. They can then become trapped in respiratory mucus and subsequently swallowed, leading to significant gastrointestinal absorption.

Once absorbed, some organochlorines are stored in adipose tissue as the unchanged parent compound; however, the degree to which this occurs is variable. Those compounds that undergo slow metabolism tend to be stored in body fat to a greater extent than those compounds that undergo rapid metabolism. As a result, the organochlorines that are metabolized slowly are likely detected in breast milk because of their lipophilic nature.

Most organochlorines are metabolized to some degree, being dechlorinated, oxidized, and then conjugated. The primary mode of elimination is through biliary excretion, although nearly all organochlorines yield measurable urinary metabolites. Because many of the unmetabolized pesticides are excreted into the bile, these organochlorines often undergo enterohepatic and enteroenteric circulation, substantially retarding fecal excretion.³¹ The kinetics of elimination after lindane ingestion appear to have two phases: a rapid distributive phase and a slower elimination phase. The second phase parallels the elimination seen with dermal exposure. These pharmacokinetics may be due to ingestion that results in more rapid absorption and is followed by a distributive phase that is not seen with dermal administration.³²

Special Populations

Children are particularly susceptible to toxicity from organochlorines, as highlighted by an episode of mass endosulfan poisoning that recently occurred in India. Although 36 victims of all ages became ill from the exposure, the illness first became manifest in children. Children were also more severely ill and accounted for the only fatalities; only children had electroencephalogram abnormalities, although their serum endosulfan concentrations were comparable to adults.⁶ Children may also be more susceptible to developing toxicity from topical application of lindane, presumably because of their less keratinized, more permeable skin.

Elderly people may also be predisposed to toxicity from topical application of lindane, as highlighted by seizures that developed in 3 of 19 geriatric patients who were being treated with topical 1% lindane. These victims may have been given greater than the normal dose and received their applications following hot baths. Atrophic skin and age-related sensitivity may have had a role as well.³³

Pharmacologic Agents

The only pharmacologic agent among the organochlorine insecticides that has been approved by the FDA for medicinal use is lindane.

Drug Interactions

Organochlorines have been shown to induce hepatic microsomal drug-metabolizing enzymes.³⁴ Although this liver enzyme induction will accelerate the metabolism of the insecticide itself, other theoretical consequences include the enhanced metabolism of certain drugs. However, there are a few anecdotal case reports describing this and no definitive reports of enhanced metabolism of therapeutic drugs or adverse reactions because of microsomal enzyme induction in humans.

TOXICOLOGY

Clinical Manifestations

Most victims of acute ingestion of organochlorines develop nausea, vomiting, and abdominal pain. There may be evidence of dermal irritation if the exposure is cutaneous.

The major acute effects of organochlorine pesticides are primarily related to central nervous system stimulation. These effects manifest primarily as convulsions; motor overactivity may be limited to myoclonic jerking but is often expressed as seizures, which is sometimes the only clinical manifestation of organochlorine toxicity. Other less severe signs of neurologic toxicity include paresthesias, tremor, ataxia, and hyperreflexia. Seizures are more characteristic of acute toxicity to lindane and the cyclodienes. DDT and its analogs, as well as chlordecone, tend to cause neurosensory and mild motor abnormalities.

The clinical effects of chronic exposure to chlordecone have been well described after the “Hopewell epidemic” that came to light during the summer of 1975.³⁵⁻³⁸ Because of poor industrial hygiene, more than 100 employees at a chlordecone manufacturing plant were chronically exposed to chlordecone during its synthesis. Patients with prolonged exposure developed toxic effects that included tremors, weight loss, arthralgias, skin rashes, chest pains, mental changes, opsochonus, muscle weakness, ataxic gait, incoordination, and slurred speech. Patients characteristically had an intention tremor and, in severe cases, a resting tremor.³⁸ Although

the hands were chiefly involved, fine tremors of the head and trembling of the entire body were also noted. This condition was termed “Kepone shakes” by the workers. An exaggerated startle response was also observed in some severely affected patients. Other prominent features included visual difficulties with an inability to fixate and focus, and bursts of erratic movements of the eye. Personality changes were also observed, with irritability, poor short-term memory, and mild depression being the most common. In a few cases, frank disorientation was also observed.³⁵ Nerve biopsies have demonstrated that chlordecone causes degenerative nerve changes predominantly affecting the unmyelinated and smaller myelinated fibers.³⁷

There has been an increased interest in the potential hazards posed by certain substances that may affect the endocrine system because of the ability of these chemicals to mimic or block endogenous hormones; such agents are known as *environmental endocrine disruptors*. In vitro assays have demonstrated that a number of organochlorine insecticides have estrogen-like activity.^{39,40} As a result of this characteristic of organochlorines, they have been examined very closely for potential associations with certain developmental and reproductive disorders as well as cancers of reproductive organs—breast, testicular, and prostate.

Although some case-control studies have implicated organochlorines as having a possible etiologic role in the development of breast cancer,⁴¹⁻⁴³ more recent studies have found no increased risk due to organochlorine exposure.^{44,45} The International Agency for Research on Cancer (IARC) reviewed DDT and its metabolite DDE as a potential carcinogen, and although evidence for carcinogenesis was found in a murine model, there is no convincing evidence that these compounds are carcinogenic in humans.

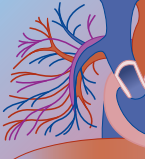

Adverse Effects

Organochlorine insecticides have been associated with a number of other adverse effects. A small number of case reports have associated lindane and chlordane with certain hematologic disorders, including aplastic anemia and megaloblastic anemia.⁴⁶⁻⁴⁹ Disseminated intravascular coagulation has also been reported in association with chlordane ingestion.⁵⁰ Rhabdomyolysis and profound lactic acidosis have been described with lindane ingestion.⁵¹ Although not definitive, there may also be an association between organochlorine insecticides and the development of chronic motor neuron diseases, such as amyotrophic lateral sclerosis.⁵²

DIAGNOSIS

Laboratory Testing

Gas chromatography analysis of biologic specimens can be used to identify organochlorine levels.⁵³ However, such testing is usually not necessary for the management

of acute toxicity. Because many of the organochlorines are stored in lipids, adipose tissue biopsies and human breast milk have been used to measure organochlorine residues. The value of measuring organochlorine concentrations in these tissues is primarily to confirm past exposure.

Other Diagnostic Testing

There are no other specific biomarkers that confirm organochlorine exposure. Certain laboratory testing may be helpful to help rule out other causes of a patient's clinical manifestations, or to evaluate for possible sequelae of toxicity from organochlorines. This evaluation may include determination of complete blood count, renal function, serum electrolytes, creatine phosphokinase, urine myoglobin, lactic acid, computed tomography of the brain, electroencephalograms, and coagulation studies.

Differential Diagnosis

The diagnosis of organochlorine toxicity should be made primarily by history because there are no pathognomonic features. The common presenting symptoms after acute exposures include nausea, vomiting, abdominal pain, agitation, irritability, dizziness, drowsiness, lethargy, and seizures. However, these are fairly nonspecific. Other potential toxic agents that can produce similar neurologic symptoms include any toxin that produces central nervous system excitation, such as strychnine.

Other medical causes are numerous and include underlying seizure disorder, meningitis, encephalitis, trauma, electrolyte derangements, cancer, and hypoglycemia.

MANAGEMENT

Supportive Measures

Initial supportive measures include airway protection, ventilatory support, and maintenance of adequate circulation. Meticulous attention to these supportive measures is likely the only intervention needed for treatment of the acute manifestations of organochlorine toxicity because these symptoms are usually self-limited.

If needed, seizure control can be achieved by the administration of GABA agonists such as benzodiazepines and barbiturates. The use of benzodiazepines or barbiturates is rational, given that the underlying mechanism of neurotoxicity of many of the organochlorines revolves around the antagonism of GABA.

Phenytoin, in general, is not a first-line agent for toxicant-induced seizures. In fact, for lindane-induced seizures, phenytoin may worsen seizures. However, phenytoin has been shown in experimental models to decrease DDT-induced tremor.^{13,54} This makes mechanistic sense because DDT will keep a sodium channel open, leading to sustained or repetitive nerve firing, and phenytoin acts as a sodium channel blocker. In the same model, phenytoin administered to rats

exacerbated the neurologic symptoms in those who were dosed with chlordecone or lindane.⁵⁴

Decontamination

For dermal exposures, contaminated clothing should be removed and the skin decontaminated with copious amounts of soap and water.

Gastric lavage may be considered after ingestion if the patient presents in a timely manner. As organochlorine insecticides are often found in a liquid form, nasogastric aspiration of stomach contents may be less traumatic to the patient. However, all precautions should be taken to avoid aspiration because a chemical pneumonitis may develop, particularly because the insecticides are often formulated in a hydrocarbon vehicle.

Activated charcoal can be administered after an acute ingestion in an effort to decrease absorption. However, there is some evidence that suggests activated charcoal does not adsorb to organochlorine insecticides well.^{55,56}

Cholestyramine has been found in a murine model to adsorb lindane, decreasing absorption better than activated charcoal.⁵⁶

Laboratory Monitoring

There are no standard laboratory tests to monitor. However, measurement of creatine phosphokinase, blood cell counts, renal function, liver function, and coagulation studies should identify evidence of the serious sequelae that have been associated with organochlorine toxicity.

Antidotes

No specific therapies have been reported effective in blocking the toxicities of organochlorine insecticides. Treatment centers primarily on supportive care and prevention of future exposures.

Elimination

Because organochlorine insecticides are highly lipophilic and undergo extensive tissue distribution, methods to enhance elimination through extracorporeal techniques, such as hemodialysis, hemoperfusion, exchange transfusion, and peritoneal dialysis, are unlikely to be efficacious.

However, for certain organochlorines that undergo enterohepatic and enteroenteric recirculation, prolonged administration of cholestyramine may be helpful in enhancing the fecal elimination and subsequent decrease in body burden. This was demonstrated during the Hopewell epidemic, when cholestyramine (16 g/day) was administered to adult patients who were heavily exposed to chlordecone. In this setting, cholestyramine was associated with a sevenfold increase in the fecal excretion of chlordecone, a significant decrease in the half-life of the compound in the body, subsequent improvement of neurologic symptoms, and increased motile sperm.³⁶ Cholestyramine has also been found to be effective in

adsorbing to lindane in the murine model and may potentially have a role in the enhanced elimination of this compound, but this has not been well investigated.⁵⁶

Disposition

Patients who are exposed to an organochlorine insecticide, either through ingestion or inhalation, should develop symptoms immediately because these compounds are absorbed very quickly. After an observation period of several hours, asymptomatic patients can be discharged home safely.

SECTION I

ENVIRONMENTAL, INDUSTRIAL, AND HOUSEHOLD PRODUCT TOXICOLOGY

82 *Occupational Toxicology*

MICHAEL G. HOLLAND, MD

At a Glance...

- Occupational diseases from toxicant exposures often mimic or present as common nonoccupational conditions.
- Occupational diseases and illnesses are underreported because of poor recognition.
- The occupational history is the crucial part of a workup for any patient presenting with new onset of symptoms.
- Occupational toxicants primarily affect the skin and respiratory tract.
- Soluble irritant gases cause primarily upper airway irritation, whereas poorly soluble gases can lead to alveolar injury.
- Systemic absorption following dermal or respiratory exposures can lead to other end-organ toxicities.
- Electronic databases and Poison Control Centers are valuable resources for information on the toxicity of the more than 70,000 chemicals in commercial use.
- Passage of the Occupational Safety and Health Act of 1970 has greatly reduced the incidence of occupational poisonings in the United States.

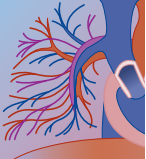

The U.S. Bureau of Labor Statistics (BLS) reported 5559 occupational fatalities in private industry for the year 2003, most due to physical hazards, accidents, homicides, and falls. However, 9.0% were due to exposure to harmful substances or environments, and 4% were due to fires and explosions.¹ The BLS report for the year 2003 (most current year available) reveals there were about 269,500 newly reported cases of nonfatal occupational illnesses in private industry, of which 4.9%, or 43,400, were skin disorders; 2.2%, or 19,000, were listed as respiratory conditions; and 0.4%, or 3900, were due to poisoning.² These numbers may be misleading because illnesses or exposures requiring only first-aid treatment are not generally reported. Also, the connection between work and the illness is often missed because of latent onset of symptoms or disease; thus, the actual incidence is probably much higher.

On a global scale, the World Health Organization (WHO) estimates more than 200 million workers are affected by occupational diseases worldwide.³ The overwhelming majority of these diseases are seen in developing nations, where workers often do not wear personal protective equipment (PPE) and where regulatory bodies to ensure worker safety often do not exist or are grossly underfunded and understaffed. In addition to the human suffering involved, economic costs of these occupational diseases constitute a significant percentage of each country's gross national product.⁴

There are millions of chemical substances in existence and more than 70,000 in common commercial use. About 3300 of these are designated high-production-volume (HPV) chemicals by the U.S. Environmental Protection Agency (EPA), signifying that they are produced in excess of 1 million tons per year. These HPV chemicals are listed by the EPA as part of the Inventory Update Rule of the Toxic Substances Control Act of 1986, and the list is revised every 4 years.⁵ Given these large numbers of potential toxicants, it is not surprising that relevant toxicology data regarding human health effects are not available for most of these chemicals. As an example, the Hazardous Substances Data Bank (HSDB) operated by the National Library of Medicine's (NLM) Toxicology Data Network (TOXNET) has comprehensive data on less than 4800 chemicals. Therefore, treating physicians need to know what available resources can help when confronted with exposures to chemical hazards with which they are not familiar. Often, toxicity must be extrapolated from the knowledge of familiar chemicals with known toxicities that may share similar properties or structure–activity relationships with the new chemical.

HISTORICAL PERSPECTIVES

Physicians have long recognized the connection between workplace and environmental exposures and disease

states. Georgius Agricola described the diseases associated with mining as early as the 16th century.⁶ Bernardo Ramazzini, generally regarded as the father of occupational medicine, in 1713 recognized the connection of disease to work in many occupations, noting that the route of exposure was usually inhalational. He also described numerous occupational diseases, including lead and mercury poisoning. He emphasized the critical need to delve into the work history when evaluating a patient's symptoms.⁷ Alice Hamilton was the first American physician who dedicated her career to industrial medicine. She described the effects of lead poisoning in workers, as well as "phossy" jaw of matchmakers, and hematologic effects of benzene exposure.⁸

Occupational medicine became a recognized specialty of the American Board of Medical Specialties in 1955. With the passage of the Occupational Safety and Health Act in 1970, the specialty experienced remarkable growth. With the creation of the Occupational Safety and Health Administration (OSHA) and the National Institute of Occupational Safety and Health (NIOSH), the United States has since witnessed a marked decrease in classic occupational diseases and deaths. However, developing nations are experiencing dramatic increases in some of these classic occupational diseases. In any event, workers everywhere will continue to be exposed to chemicals and toxicants, and knowledge of the health effects of these exposures is important not only in occupational medicine but also in primary care and other medical specialties.

RECOGNITION OF OCCUPATIONAL DISEASES

The diagnosis of industrial poisoning is important not only for the care of the patient but also because accurate diagnosis makes it possible to identify potential workplace hazards that may affect the patient's coworkers or the community at large. Emergency physicians and primary care specialists should maintain a high index of suspicion for the possibility of industrial poisoning, familiarize themselves with industrial processes and toxic substances used locally, maintain an adequate reference library or have on-line access to toxicology databases, and obtain occupational histories from their patients. In addition, potential hazardous releases can be prevented if inadequate engineering controls are identified.⁹ However, there are problems with recognition and diagnosis of occupational diseases for numerous reasons, discussed next.

Similarity to Common Diseases

Many occupational illnesses caused by toxic exposures will mimic or duplicate nonoccupational diseases. Unless a proper history is taken, along with the knowledge that similarly exposed workers were experiencing similar effects, the connection of the disease to the work exposure might be missed. An example is occupational asthma, by far the most common occupational disease in the United

States. Asthma is also a very common condition in the general population. Exposures to certain industrial chemicals (toluene diisocyanate [TDI], maleic anhydride) can cause occupational asthma. Knowing the job a patient performs and the chemicals used there (e.g., polyurethane foam manufacturing and TDI use) may help identify the cause as occupational in origin.

Latency

Recognition of industrial poisoning may be obvious when the acutely ill person is transported directly from the workplace where an unprotected exposure to a known toxic substance has occurred. However, many toxicants have a latent period between the time of exposure and the onset of clinical illness. This can involve several hours for acute effects, such as acute lung injury from phosgene or oxides of nitrogen exposure, to weeks for the peripheral neuropathy seen after exposure to hexacarbons like *n*-hexane and methyl-*n*-butyl ketone, to years for dust exposure and pneumoconioses like silicosis and asbestosis.

Toxicants That Exist as Mixtures or Are Contaminated with Other Chemicals

If there are multiple or unknown potential toxicants, recognition of the link to work may be missed or underestimated. For instance, methyl ethyl ketone (MEK), a widely used industrial solvent, does not produce peripheral neuropathy. However, when MEK is mixed with small amounts of *n*-hexane, a peripheral neurotoxicant, it potentiates the effects of the *n*-hexane. Also, some toxicants may be present only as contaminants of the chemical in use, and therefore are not listed on ingredient labels. The herbicide mixture 2,4-dinitrochlorophenoxyacetic acid (2,4-D) and 2,4,5-trinitrochlorophenoxyacetic acid (2,4,5-T) was known as Agent Orange because of the color of the containers in which it was shipped to Vietnam. This mixture contained a significant amount of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, or simply "dioxin"). Dioxin was previously an unknown contaminant produced when manufacturing the 2,4,5-T component of the mixture (but not 2,4-D). Because of the chloracne caused by dioxin in 2,4,5-T manufacturing workers, and other alleged health effects in exposed soldiers in Vietnam, the use of 2,4,5-T in the United States has been discontinued.

Unavailable Information Regarding the Chemical in Use

As mentioned previously, comprehensive toxicologic information is available for only a small fraction of chemicals in use. Also, many chemical mixtures are patented, proprietary mixtures. As such, the ingredients may not be listed on the material safety data sheet (MSDS), and manufacturers may be hesitant to release this information. Also, the fear of litigation may prevent an employer from admitting to using a hazardous

chemical, that proper engineering controls were not in place, or that personal protective equipment was not provided to their exposed employees.

Other Nonoccupational Conditions That May Affect the Response to Industrial Toxicants

Certain nonoccupational conditions or ingestions can exacerbate or ameliorate the effects due to occupational exposures. For example, degreaser's flush only occurs after exposure to trichloroethylene and subsequent ethanol ingestion. Conversely, it has been demonstrated that smokers have a decreased incidence of hypersensitivity pneumonitis after exposures to appropriate antigens when compared with nonsmokers, possibly owing to effects on cytokine populations and antigen handling.¹⁰

Inadequate Physician Training Regarding Occupational Illnesses

Medical schools have very few courses or electives in occupational health and other preventive medicine disciplines. This is true in American,¹¹ British,¹² Australian, and New Zealand medical schools.¹³ In addition, most primary care residency programs lack formal rotations in occupational medicine, and sadly, the number of residents and programs in occupational medicine in the United States is declining.¹⁴

CLASSIFICATION OF HAZARDOUS MATERIALS

The U.S. Department of Transportation requires all shipping papers to have classifications as well as identification numbers.⁸ This classification and numbering system is used by many other regulatory agencies and authorities for identifying potentially hazardous substances⁹ (Box 82-1).

The National Fire Protection Association (NFPA) Committee on Fire Hazards of Materials developed a hazard signal system: NFPA-704¹⁰ (Fig. 82-1). This includes a numeric rating scale to identify the degree of hazard in the categories of health, fire, and reactivity (Box 82-2). This system is frequently used for labeling by chemical manufacturers; however, this system is rarely employed for chemicals in transport. Under this system, the term *health hazard* refers specifically to the capacity of a material to cause personal injury from contact with or absorption into the body of a chemical. In fire fighting or other emergency conditions, the term *health hazard* refers to a single exposure, which may vary in duration from a few seconds to 1 hour. It is not applicable to the situation of an industrial worker who is exposed on a routine basis. The NFPA-704 system's use of the five ratings of the degree of hazard of a specific chemical is defined as follows:

BOX 82-1

LABELING AND CLASSIFICATION SYSTEMS

US Department of Transportation

1. Class A explosives
2. Class B explosives
3. Blasting agent
4. Poison A
5. Flammable gas
6. Nonflammable gas
7. Nonflammable gas (chlorine)
8. Nonflammable gas (oxygen, pressurized liquid)
9. Flammable liquid
10. Combustible liquid
11. Flammable solid
12. Flammable solid (dangerous when wet)
13. Oxidizer
14. Organic peroxide
15. Poison B (nonflammable gas—fluorine)
16. Radioactive material
17. Corrosive material
18. Irritating material

United Nations Classification Numbers

1. Explosives
2. Gases
3. Flammable and combustible liquids
4. Flammable solids, spontaneous combustion substances
5. Oxidizers and organic peroxides
6. Poisonous materials
7. Radioactive materials
8. Corrosives
9. Miscellaneous hazardous materials

- 0—Materials that on exposure under fire conditions would present no hazard beyond that of ordinary combustible materials
- 1—Materials that on exposure would cause irritation but only minor residual injury even if no treatment were given
- 2—Materials that on intense or continued exposure could cause temporary incapacitation or possible residual injury unless prompt medical treatment is given
- 3—Materials that on short exposure could cause serious temporary or residual injury even if prompt medical treatment is given
- 4—Materials that on very short exposure could cause death or major residual injury even if prompt medical treatment is given

The MSDS contains detailed information about specific chemicals and their toxicity. Because of their standard format and availability, these sheets have become required by many fire department HAZMAT (hazardous materials) units and in right-to-know ordinances. Since 1986, OSHA has required that an MSDS be readily available for any chemical used in the workplace. It is the responsibility of the importer or manufacturer of each chemical to prepare these forms in a standardized format. In 29CFR1910.120, OSHA defines what min-

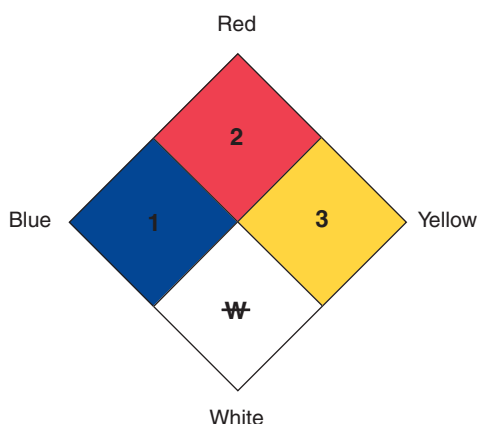

FIGURE 82-1 Symbol of the National Fire Protection 704 Hazard Signal System. See Box 82-2 for explanation.

imum information must be included in these sheets. The employer is required to provide an MSDS to the treating physician when an employee is involved in an acute exposure. The quality of the medical treatment guidelines of an MSDS varies widely, but in general is poor, because these documents are generally produced without input by physicians or toxicologists. However, they contain useful information regarding the chemical content of the material and its reactivity and explosive nature, and advice on the proper method to be used for decontamination, environmental cleanup, and fire control.

BOX 82-2 NFPA HAZARD SIGNAL SYSTEM "704"

Flammable (Red)

- 4—Extremely flammable
- 3—Ignites at normal temperatures below 37.8° C (100° F)
- 2—Ignites at temperatures below 93.3° C (200° F)
- 1—Must be preheated to burn
- 0—Will not burn

Health Hazard (Blue)

- 4—Too dangerous to enter vapor or liquid
- 3—Extreme danger
- 2—Hazardous
- 1—Slightly hazardous
- 0—Normal material

Reactivity (Yellow)

- 4—May detonate
- 3—Shock and heat may detonate
- 2—Violent chemical change
- 1—Unstable if heated
- 0—Stable

Specific Hazard (White)

- OXY—Oxidizer
- ACID—Acid
- ALK—Alkali
- COR—Corrosive
- W—Use no water
- —Radiation hazard

OCCUPATIONAL HISTORY

Obtaining a detailed occupational history on every patient presenting to an emergency department or primary care office may not be practical and often is too time consuming for use as a screening instrument. Goldman and Peters developed a systematic approach (Fig. 82-2) for evaluating hazardous exposures.¹⁵ The algorithm begins with a quick survey that can be performed routinely on all patients. The clinician may then proceed to a more detailed line of questioning to follow any indications of toxic exposure.

Routine Survey

The first step includes asking questions about three essential topics that are easily incorporated into routine history taking: (1) current and past job titles; (2) known exposure to fumes, chemicals, dusts, or radiation; and (3) any temporal relationship of the chief complaint to work activities or other contributory factors. The work and exposure history acts as a broad screen to elicit potentially hazardous exposures at home or work. When conditions with short latency periods are under evaluation, such as occupational asthma, the emphasis should be on the current job and exposures. For conditions of longer latency, such as asbestosis, the history must focus on jobs and exposures in the past. Allergic responses to agents may develop even after years of asymptomatic exposure.

A temporal relationship between the onset of symptoms and work or home activities can provide an important clue to recent sources of exposure. In general, symptoms that recede on the weekend or at vacation time and return at the start of the workweek indicate some current job-related exposure. For example, acute systemic solvent toxicity, which includes the symptoms of headache, gastrointestinal disturbances, and lightheadedness, usually occurs within a short time of exposure and lessens within hours after removal from exposure. The expression of toxic symptoms also is influenced by the use of medications, preexisting medical diseases, and exposure to other hazardous substances. In addition, some personal habits (e.g., the use of tobacco or alcohol) represent significant environmental exposures that may interact with or add to occupational exposures.

If, after the initial screening survey, there appears to be a possible link between the illness and work exposures, further investigation is necessary. This will consist of a comprehensive occupational and environmental history as well as an in-depth past medical history.

Current Occupation

In assessing the likelihood of the workplace as a source of toxic exposure, the physician should obtain a complete description of all jobs that the patient has had, beginning with the current job and working backward in time to prior jobs. Necessary information includes the chemicals used, the products manufactured, and the processes involved. Many workers are well informed

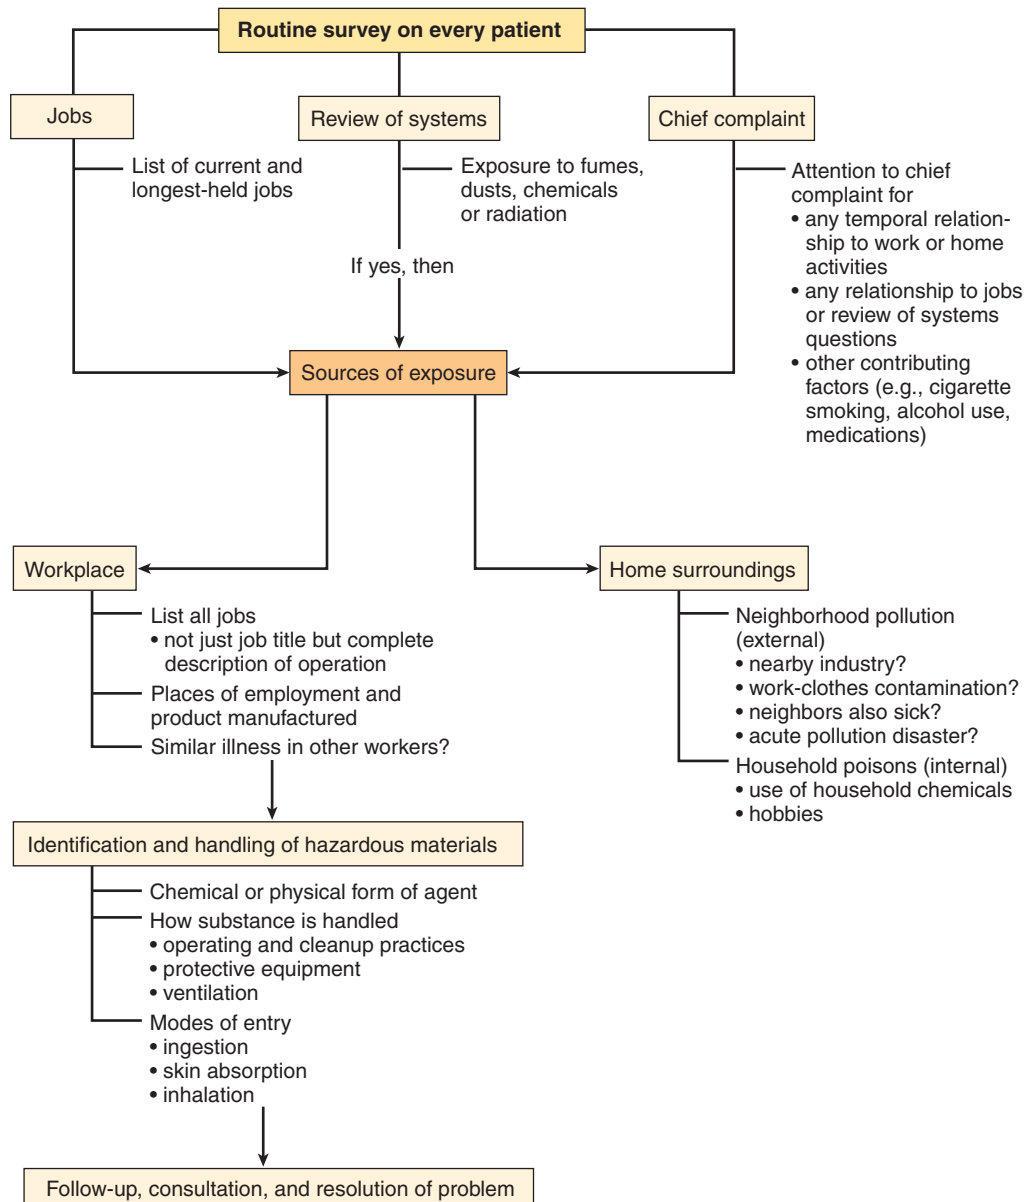

FIGURE 82-2 Systematic approach to history taking and diagnosis of occupational illness. (From Goldman RH, Peters JM: The occupational and environmental health history. *JAMA* 1981;246:2831–2836. Copyright 1981, American Medical Association.)

about specific exposures at the workplace, and the information that they provide is sufficient for documentation. Often, however, obtaining an exposure history requires further detective work for identification of specific components of products and for documentation of exposure levels. Most jobs have their own jargon for processes performed and materials used. Patients may know the chemical only by its trade name or process name (e.g., “blanket wash” for ink press solvent cleaner) and do not know the generic or chemical name. Whenever possible, workers should be urged to bring the MSDS for all chemicals with which they work to the emergency department or clinic visit. Many times a simple phone request from the treating physician to the worksite will prompt the MSDS to be faxed to the clinical site. In the case of multiple casualty incidents, prehos-

pital medical care personnel or HAZMAT team members may be helpful in locating chemical labels, manifest sheets, MSDS, shipping papers, or knowledgeable personnel who can identify the agent involved.

Patients should be asked whether fellow workers have similar complaints; the cluster of symptoms among employees may be the first clue to identifying the presence of an occupational hazard, and Hill’s criteria require that similarly exposed workers should have similar medical conditions.²⁷ The workplace industrial hygienist, occupational medicine physician or nurse, or plant manager can often provide the most useful information on working conditions and chemicals in use, as well as PPE employed and the extent of engineering controls employed. In addition, OSHA requires that the employer provide a copy of the MSDS.

Prior Occupations

Many occupational illnesses have long latency periods. Sensitizer-induced asthma takes at least several months of exposure to develop, whereas the latency for pneumoconiosis is often 2 to 3 decades. Therefore, it is important to obtain a detailed occupational history from the start of employment up to the present time. Self-employed persons must be carefully questioned because OSHA does not regulate this type of work, and recommended or required exposure limits or regulations often are not followed. Prior occupational history must include questions regarding work as a child, such as on a family farm, and part-time, seasonal employment, as well as prior military service. Tailor the questioning of past exposures as they relate to the current symptoms, such as prior irritant and allergen exposures in the case of possible pulmonary disease.

Environmental History

In addition to occupational sources, the treating physician needs to be aware of possible sources of contamination in the home. Home renovation projects have become quite commonplace in recent years, and these activities have resulted in lead poisoning of family members.¹⁷ The patient should be asked about neighborhood environmental exposure, such as a nearby factory or chemical waste dump, because community poisonings have occurred in those living in close proximity to certain industrial plants.¹⁸ An obvious source of external pollution is dust or chemicals carried into the home on work clothes. The literature contains numerous reports of children with excessive blood lead levels caused by parents bringing home the toxicant on the hands and clothing¹⁹⁻²¹; workers involved in small businesses such as radiator repair shops have caused lead poisoning in multiple family members.²² Many toxic industrial chemicals are readily available for home use; these include pesticides, solvents, cleaning fluids, rust removers, and disinfectants. A dangerous situation may arise when two common household substances are mixed together in the hope of producing a more potent compound (e.g., chloramine, a soluble irritant gas, is produced when ammonia and household bleach [sodium hypochlorite] are mixed; chlorine gas is produced when acid toilet bowl cleaners and bleach are mixed).

The growth and diversification of hobbies have introduced a multitude of hazardous substances into the household. Artists are generally self-employed, and their studios exist in their homes, placing them and their families at risk for exposure to toxic chemicals, metals, and dusts. Artists and craftspeople, depending on their medium of choice, can face daily exposure to diverse toxic substances such as solvents, paints, inks, and thinners^{23,24}; lead, cadmium, and other metals in pigments, pottery glazes, copper enamels, solders, and other metalworking materials²⁵; and dusts such as silica and asbestos in clays, talcs, and glazes.²⁶ Further compounding this problem is the inadequate labeling of many art materials and the relative naiveté of the artists to the potential risks they face.

The Agency for Toxic Substances and Disease Registry (ATSDR) publishes a didactic case study entitled "Taking an Exposure History," which is an excellent source for a comprehensive environmental history form, and is available on-line from the ATSDR.²⁷

Assessing Causation

Many occupational diseases are clearly caused by work, and the diagnosis is obvious upon initial presentation in most cases. For example, few would dispute the fact that irritant contact dermatitis of the hands in a patient who uses solvents regularly without gloves is an occupational skin disease. Similarly, a patient exposed to unventilated engine exhausts presenting with nausea and headache and a carboxyhemoglobin level of 15% is clearly carbon monoxide poisoned at work. However, in our increasingly litigious society, the treating physician is frequently asked to assign causation on a patient's initial visit. Employers may pressure the physician to deem the condition not work related, thereby saving money by avoiding premium increases from their worker's compensation insurance. Conversely, many temporary or part-time workers are not offered health insurance through their employers. Many employees covered by health insurance have seen their coverage reduced and are assigned larger co-pays. Therefore, employees not adequately covered by personal health insurance may pressure the physician to ascribe the health effects as being caused by work, so that their medical bills and prescription costs are covered.

Occasionally, a patient presents with a constellation of signs and symptoms that do not readily point to a specific diagnosis, and the clinician is asked to determine whether this condition represents an occupational illness. Sir Austin Bradford Hill wrote a landmark article in 1965 regarding assessing causation of a disease. It is helpful to keep these principles in mind when evaluating a patient for a suspected work-related illness when the cause is not clearly evident.¹⁶ Among the criteria are seven basic principles:

1. *Strength of association:* The rate of increase in a disease in the exposed population over that seen in the unexposed, and disease seen in specific organ systems of the exposed population.

As an example, nylon flock worker's lung is seen only in random-cut flock workers at two plants using this process, not in other flock workers exposed to precision-cut flocking process, and not in other nylon workers.^{28,29}

2. *Consistency:* The relationship is seen in multiple studies of workers with similar exposures at other locations studied by different investigators.

Workers with similar exposures should have similar effects. This is why it is especially helpful to survey an individual patient's coworkers to determine whether similar symptoms or physical findings are present. In the example cited earlier, nylon flock workers in the other random-cut plant had similar findings, and rat studies

had revealed pulmonary toxic effects due to the nylon particles.³⁰

3. *Specificity*: The exposure causes a specific disease or related group of diseases, not a constellation of unrelated, vague, multisystem symptoms.

Symptoms such as cough and dyspnea and chest tightness after exposure to animal dander at work, along with measurable decrements in FEV₁ on pulmonary function testing, is excellent presumptive evidence for diagnosing occupational asthma. However, vague, multisystem symptoms such as headache, fatigue, mental fogging, and body aches in an office worker are more difficult to definitively diagnose as an occupational illness.

4. *Temporality*: Exposure must precede the disease.

This seems obvious, but often a review of a patient's past medical history and old charts reveals that similar symptoms preceded the exposure. This emphasizes the need for a comprehensive past medical history in all patients suspected of having an occupational illness.

5. *Dose–response, or the biologic gradient*: The risk for the disease increases as the dose of the exposure increases.

As an example, low-level toluene vapor exposures can cause eye and upper respiratory tract irritation. As exposures become more intense, central nervous system (CNS) effects such as lightheadedness and dizziness can be seen. Higher exposures can cause frank ataxia and CNS impairment (feeling drunk or “high”), and overwhelming exposure such as that which occurs in an unventilated confined space can cause loss of consciousness. The biologic effect exhibits a definable, recognizable dose–response relationship.

The dose–response criterion is also subject to the experimentation test: reducing the exposure causes a concomitant reduction in the disease. As a historical example, carbon disulfide, a volatile organic solvent, is used in the viscose rayon industry. In the early 1900s, levels in the workplace were so high that workers experienced acute CNS effects, ranging from mood changes to frank delirium and psychosis. Workplaces even had to have bars across windows to prevent affected employees from jumping out. Through the efforts of pioneers like Dr. Alice Hamilton, much of the process was contained with engineering controls to greatly reduce workplace exposure levels (i.e., dose reduction), so that this effect of carbon disulfide is no longer seen. As a more recent example, reduction of TDI levels by the use of engineering controls has reduced the incidence of occupational asthma in polyurethane foam production workers.

6. *Biologic plausibility*: The associated disease and the exposure make sense (i.e., it is plausible); the subjective and objective findings are explained by the exposure. The association should be analogous to other well-characterized diseases.

For example, suppose that a new organic solvent comes into use, and a worker develops a peripheral neuropathy after using it for several months. If you find that this solvent has a metabolite with a gamma diketone structure, it is plausible that this new solvent could be the causative agent. Known peripheral neurotoxicants *n*-hexane and methyl *n*-butyl ketone both have the common gamma diketone metabolite 2,5-butanedione. Knowledge of this structure–activity relationship makes it biologically plausible that this exposure could cause this disease.

Conversely, attributing neuropsychiatric symptoms in workers to toxigenic fungi and molds found growing on wallboard in an office building with indoor air quality issues is not biologically plausible, given the known scientific facts of mold growth, mycotoxin production, and bioavailability through the inhalational route.^{31–34}

7. *Coherence*: The association is consistent with other established scientific evidence regarding the disease and the toxicant and requires that other known common causes of the disease not be ignored.

For instance, a known clinical syndrome caused by mycotoxin ingestion is alimentary toxic aleukia (ATA), which was seen in Russia in the 1930s when people ate overwintered wheat that had been contaminated by mold growth of *Fusarium* species that produced the trichothecene mycotoxin T-2. This syndrome consisted of bone marrow suppression and gastrointestinal hemorrhage and resulted in thousands of deaths. Similarly, aflatoxins are contaminants found in food products and are produced by *Aspergillus* species. Aflatoxins are known acute hepatotoxins at high doses, and at lower doses are carcinogens contained in the human diet, with daily exposure limits set by regulatory bodies. All these effects are seen with ingestion of the mycotoxins, none by inhalation.

However, ascribing the vague symptoms seen in some sick building syndrome evaluations to mycotoxin exposure due to indoor fungi is not coherent with the known scientific evidence regarding mycotoxins. Mycotoxins are not produced to any significant quantity when growing on environmental surfaces, and because the contaminated wallboard and carpeting are not ingested, employees cannot receive any measurable dose of mycotoxin from inhalational exposure in the workplace.^{32,33} In other words, this association is not consistent with known established scientific evidence regarding the toxins and the diseases they produce. Other factors that can cause these symptoms, such as elevated volatile organic compounds, poor air exchange levels (as evidenced by high ambient CO₂ levels), high job dissatisfaction, and high work stress levels would have to be ignored.

Exposure Characterization

In characterizing the health effects of a chemical exposure, it is important to determine not only the generic ingredients of the compound involved but also

its physical state and the process employed at the time of exposure. For example, chlorinated hydrocarbon solvents or chlorofluorocarbon refrigerants are simple asphyxiants, which can cause CNS depression and may precipitate cardiac arrhythmias when inhaled in sufficient concentrations. However, when these compounds are heated or burned, such as in torch cutting or welding activities, phosgene is produced.³⁵ This low-solubility irritant gas can then cause acute lung injury and adult respiratory distress syndrome.³⁶ Knowledge of processes occurring near the patient's workspace is important because gases can diffuse and travel to other areas of the worksite. In the previous example, phosgene has a vapor density that is 3.4 times the density of air, and as such will settle in low areas. Therefore, employees working below the welder and unaware of the inadvertent production of phosgene can nonetheless be poisoned.

In addition to the character of an exposure, the quantity and concentration as it exists is often a crucial determinant of toxicity. As Paracelsus taught centuries ago, the "dose makes the poison." Simply being at a workplace where a certain chemical is used does not imply poisoning. If the process is completely contained or if the material is not in an absorbable form, then toxicity is not likely. Whenever possible, engineering controls and personal protective equipment should be used to reduce exposures. Workplace monitoring of chemical levels will determine exposure risks and dictate the need for personal protective equipment.

Workplace Exposure Levels and Monitoring

Many employers using potentially hazardous chemicals will have exposure monitoring programs in place. These include general workplace air monitoring and personal breathing space monitoring. Air monitoring is also performed because certain toxicants have OSHA-regulated permissible exposure limits (PELs). These air-monitoring samples are taken during normal work processes and are irrespective of PPE being worn. Those that do not have OSHA-mandated PELs often have NIOSH-recommended exposure limits (RELs), which employers can use as a guide to reduce exposures. In addition, the American Conference of Governmental Industrial Hygienists (ACGIH) develops threshold limit values (TLVs) and biologic exposure indices (BEIs) that can also be helpful (see later). Workplace air monitoring is performed using various methods for a specified time period, and then expressed as an 8-hour time-weighted average (TWA). The goal of setting exposure limits is to find a level to which it is safe to be exposed for 8 hours per day, 40 hours per week.

With the passage of the Occupational Safety and Health Act of 1970, the U.S. Congress created two new federal agencies, OSHA, the regulatory arm, and NIOSH, the research and training arm. OSHA has published mandatory PELs for a number of chemical agents. These are available at the OSHA website.³⁷ Several hazardous substances also have their own standards regarding PELs,

action levels, and medical monitoring requirements. These are listed in the Code of Federal regulations, CFR 1910 subpart Z, and are available at the OSHA website.³⁸ For most of these chemicals, workplace air monitoring must be performed to determine the exposure level. If the airborne concentration is above the mandated "action level," then compliance with airborne monitoring, employee biologic monitoring, and necessary PPE is required. Many of these regulations also mandate pre-exposure and periodic medical examinations, as well as when biologic monitoring indicates excess employee exposure or absorption (e.g., elevated blood lead level).

OSHA levels are a balance between recommended safe levels and practicality of achieving these levels, and the cost and industry lobbying efforts. However, NIOSH recommended levels, like the ACGIH TLVs, are levels that are believed to be safe based on best available science and toxicologic data, and are not particularly influenced by economic or political concerns. This explains the frequent discrepancy whereby the NOISH RELs or ACGIH TLVs are lower than the OSHA PELs.

The ACGIH, formed in 1938, publishes the TLVs on 642 chemical substances and physical agents, and BEIs on 38 different chemicals. The ACGIH developed their TLVs and BEIs as guidelines to assist in the control of health hazards, not to be used as legal standards, and ACGIH does not advocate their use as such. The TLVs and BEIs represent conditions under which ACGIH believes that nearly all workers may be repeatedly exposed without adverse health effects.³⁹

NIOSH publishes the *NIOSH Pocket Guide to Chemical Hazards (NPG)*, which is intended as a source of general industrial hygiene information for workers, employers, and occupational health professionals. The *NPG* presents key information and data in abbreviated tabular form for 677 chemicals or substance groupings (e.g., manganese compounds, tellurium compounds, inorganic tin compounds) that are found in the work environment. The current version contains information on all substances for which NIOSH has recommended exposure limits (RELs) and those for which OSHA has established PELs.⁴⁰

NIOSH has also defined exposure levels that are considered immediately dangerous to life or health. The current NIOSH definition for an immediately dangerous to life or health (IDLH) condition is a situation "that poses a threat of exposure to airborne contaminants when that exposure is likely to cause death or immediate or delayed permanent adverse health effects or prevent escape from such an environment." It is also stated that the purpose of establishing an IDLH is to "ensure that the worker can escape from a given contaminated environment in the event of failure of the respiratory protection equipment." These levels are published in the *NPG* as well as at the NIOSH IDLH home page.⁴¹

Exposure Route

The normal routes of exposure in the occupational setting are inhalation and dermal. The most common effects are the dermatoses, consisting mainly of irritant

contact dermatitis and allergic contact dermatitis. Most of these effects are confined to the skin and are not usually an acute problem. Systemic absorption may occur and cause systemic effects when large skin areas are exposed, or when prolonged contact occurs, such as when clothing becomes soaked and is not removed, or when the skin is not decontaminated. Certain toxicants, such as phenol, are very well absorbed dermally, and significant systemic toxicity from skin spills can occur in these cases.⁴²

Inhalation exposures to toxic fumes, vapors, and gases pose the greatest danger to life and health. Irritant gases cause airway and pulmonary injury depending on the length of exposure and the water solubility of the gas. Simple asphyxiants displace oxygen from ambient air and cause hypoxia due to decreased F_{iO_2} . Systemic asphyxiants cause toxicity either by interfering with hemoglobin's ability to carry oxygen (CO, methemoglobin-forming agents), or interfering with mitochondrial ability to utilize molecular oxygen (CN, H_2S , azides). Also, in the case of gaseous releases, the potential to affect many people simultaneously is very real, both in the industrial setting and after a hazardous chemicals (HAZMAT) incident. See Chapter 9 for more detailed description of inhalational toxicity of specific agents and recommended management.

Accidental or intentional toxic ingestions occur much less commonly in the occupational setting. However, eating or smoking in the workplace may put the worker at increased risk for absorption of toxicants, such as metallic dusts (lead, cadmium). Smoking at work when fingers are contaminated with certain chemicals can cause systemic effects, like polymer fume fever in the case of polytetrafluoroethylene (PTFE, Teflon).

PATHOPHYSIOLOGY OF WORKPLACE EXPOSURES

The pathologic effects that may occur with exposure to a specific hazardous substance include direct injury, sensitization, asphyxiation, or systemic toxicity. Effects such as carcinogenesis, mutagenesis, and teratogenesis have long latency periods and thus are not considered in the category of toxicologic emergencies.

Dermal Exposures

Irritant contact dermatitis is the most common occupational skin disorder and is associated with a wide variety of chemical and physical agents. The chemical agents involved may be acids, alkalis (caustics), certain metal compounds, detergents, or solvents. Strong corrosives may incite an acute injury that manifests as a vesicular (blistering) or ulcerative injury. Milder irritants, such as soaps, detergents, and solvents, remove surface lipids and cause dryness and cracking of the skin. Chronic exposure to these agents can result in the skin becoming thickened (lichenified) along with erythema, dryness, and fissuring due to the chronic irritation. Workers commonly affected are metalworkers who use

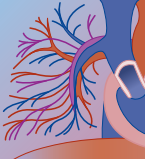

degreasing solvent and metalworking fluids, as well as printers using ink solvents. Mechanical irritation, heat, cold, and low humidity are important contributing factors in many cases. An example is the hand dermatitis seen in health care workers in northern states that occurs during the winter months as a result of the frequent hand washing and the associated low-humidity winter air. Exposures predominantly to oils and greases can incite acneiform lesions as well. After avoidance and corticosteroid treatment, most workers can resume work with the substance as long as barrier creams or gloves are used to minimize future contact. Specific toxicants are addressed in their respective chapters of this textbook.

Allergic contact dermatitis is a delayed type IV, cell-mediated hypersensitivity reaction. The prototypical, common example of this type of reaction is ivy poison dermatitis due to urushiol resins found in poison ivy, poison oak, and poison sumac. Chemicals commonly associated with allergic contact dermatitis include permanent hair dyes (*p*-phenylenediamine), epoxy resins, and rubber accelerants, which can occur with both natural and synthetic rubber gloves and products. Allergic contact dermatitis requires prior sensitization, which takes a minimum of a few days of contact to occur, but can occur even after years of asymptomatic exposures. The reaction in sensitized individuals takes place within 1 to 2 days after contact with the allergen and manifests as intensely pruritic erythema followed by papular lesions and vesicles. Treatment consists of drying the weeping areas, and topical corticosteroids can be helpful. Rarely, systemic glucocorticoids are necessary when large areas are involved. Contact urticaria can occur in sensitized individuals using natural rubber latex gloves and may progress to systemic anaphylaxis (see later).

The amounts of toxic chemicals absorbed systemically from dermal exposure of intact skin are usually minimal. Exceptions include chlorinated hydrocarbons, warfarin, organophosphates, organic mercury, tetraethyl lead, and dimethylsulfoxide.²⁰ However, systemic effects can occur under certain circumstances, and because of recent improvements in airborne toxicant reductions and respiratory protection, the relative importance of dermal exposure has increased. Certain toxicants are listed by the regulatory bodies of several countries as having skin designation in addition to their allowable airborne exposure levels. The most common systemic poisoning from dermal exposure is cholinergic excess, occurring in the agricultural setting as a result of carbamate and organophosphorus pesticide exposures. Significant effects can also be seen after dermal contamination by aromatic amines, chlorinated hydrocarbons, and polycyclic aromatic hydrocarbons.⁴³ Concentrated hydrofluoric acid can cause systemic fluoride poisoning from even relatively small body surface area burns. Topical phenol can cause systemic poisoning as mentioned above.

Inhalation Exposures and Pulmonary Toxicity

Highly water-soluble irritant gases cause upper airway burning immediately, and if exposure continues, they

can cause lower airway and alveolar injury as well. Low-solubility gases such as phosgene and oxides of nitrogen cause little upper airway burning, so that workers tolerate prolonged exposures, only to suffer delayed acute lung injury hours later. Late effects can include reactive airway dysfunction syndrome/irritant-induced asthma, bronchiectasis, bronchiolitis obliterans fibrosa, and pulmonary fibrosis (for a more in-depth discussion, see Chapter 9).

Hypersensitivity reactions are caused by repeated exposure to specific organic and inorganic agents. Occupational asthma can occur after exposure to various high-molecular-weight antigens encountered in the workplace, most commonly animal and plant antigens such as bird feathers, animal excreta, and serum proteins. Plant antigens include wheat flour proteins, natural rubber latex, and wood dusts.

Most recently, latex allergy has become a significant problem among health care workers. Exposures to natural rubber latex have increased since 1980 because of increased glove use for protection from blood-borne pathogens. This has caused many workers to become sensitized, with an estimated prevalence of 2% to 17%. Natural rubber latex gloves can induce an immediate type I hypersensitivity reaction to the protein allergens, or a type IV delayed hypersensitivity reaction to the chemicals used to process the rubber gloves. Cornstarch powders used as donning agents act as vectors to increase inhalation and mucosal exposures to the allergens, and gloves with higher protein contents correlate with higher allergenicity. The use of powder-free, low-protein gloves has been shown to be effective in reducing symptoms and decreasing markers of systemic sensitization. As a minimum, all latex gloves in use should be low protein and powder free. Whenever possible, nonlatex gloves, such as those made of nitrile or vinyl, should be used. Use of these safer products will likely decrease the incidence of latex sensitization in health care workers.⁴⁴

Certain low-molecular-weight antigens can induce occupational asthma as well, most notably isocyanates and trimellitic anhydride. The basic mechanism involved is type I, immunoglobulin E-mediated hypersensitivity reactions. Low-molecular-weight antigens and chemicals (TDI, TMA) can also cause occupational asthma. They sensitize by acting as a hapten and combining with serum proteins to become a complete antigen.

Hypersensitivity pneumonitis, also known as *extrinsic allergic alveolitis*, is an immunologic reaction probably involving type I and type IV mechanisms, and occurs after exposures to various antigens in the occupational setting. The most common is the prototypical disease Farmer's lung, caused by exposure to the antigens from thermophilic actinomyces from moldy hay (see Chapter 9).

Numerous gases encountered in the workplace act as asphyxiants. Simple asphyxiants exert their toxic effects by decreasing available oxygen concentration of inspired air. These include carbon dioxide, methane, propane, chlorinated hydrocarbons, and the noble gases. This usually occurs in confined spaces. The hydrocarbons also carry significant explosive risks as well. Chemical asphyxiants cause systemic poisoning by either

disrupting natural hemoglobin's ability to carry oxygen (methemoglobin-forming agents such as nitrites; carbon monoxide causing carboxyhemoglobin) or by interfering with cellular utilization of oxygen (cytochrome oxidase poisoning by cyanide, hydrogen sulfide, or azide).

Inhalation absorption of toxicants is very rapid owing to the huge alveolar absorptive surface and the rich pulmonary capillary blood supply. In fact, inhalational absorption approaches the rapidity of intravenous administration. Once an agent has been absorbed, the clinical manifestations depend on many factors, including the inherent toxicity of the chemical, the total dose, and the duration of exposure. Exposure to other agents such as alcohol or drugs may modify the response (Table 82-1). The clinical spectrum is accordingly very broad.

OTHER ORGAN-SPECIFIC TOXICITY

Hepatotoxicity

The liver is the primary organ involved in the detoxification of xenobiotics, both from orally ingested drugs and toxicants and from inhaled or dermally absorbed toxicants. Hepatic enzyme systems metabolize lipid-soluble xenobiotics through phase I biotransformation reactions, usually through oxidation and reduction or hydration. Phase II reactions involve conjugation with glucuronides or glutathione, causing them to become more polar and excretable in the urine. In some instances, the oxidation system converts inactive chemicals to highly reactive electrophiles that can then cause hepatocellular necrosis (carbon tetrachloride). The most potent hepatotoxicants are chlorinated hydrocarbons (e.g., CCl_4 , CHCl_3), white phosphorus, and dimethylformamide. Table 82-2 lists the common occupational hepatotoxicants.

Renal Toxicity

The kidneys will be exposed to most excreted toxicants because they receive 20% of the cardiac output. There are numerous P-450 metabolic enzymes present in renal tissue, and therefore certain toxicants can cause nephrotoxicity through reactive intermediates. Because renal excretion is the major elimination pathway, the kidneys will have significant exposure to these reactive species. The most common nephrotoxicants are metals and chlorinated solvents, but any agent that produces rhabdomyolysis or hemolysis can induce acute renal failure by pigment precipitation in the renal tubules. In such cases, adequate intravenous fluids and diuretics as needed to maintain high urine flow rates, as well as urinary alkalization with intravenous sodium bicarbonate to prevent precipitation, can prevent renal injury. Table 82-3 lists industrial toxicants that can cause renal toxicity.

Cardiac Toxicity

Numerous industrial chemicals can cause cardiovascular toxicity. The most common acute toxicity is from in-

**TABLE 82-1** Factors that Modify Risk for Occupationally Related Illness

MODIFYING FACTOR	KNOWN OR PROBABLE EFFECT
General	
Age	Youth—latency for cancer; elderly—more susceptible to toxicity
Sex	Sex differences exist for some toxicity states; reproductive effects
Smoking status	
Current smoker	Confers additive risk in some situations
Smoker at time of exposure	Confers synergistic risk in some situations
Smoking during exposure	Modifies toxic exposure in some situations, such as polymer fume fever
Family history	Hereditary conditions or predispositions may be exacerbated or triggered, such as in cancer-prone families
Exercise	
Conditioning	Fitness may reduce susceptibility in some situations
At time of exposure	Generally increased susceptibility
Metabolic states	Activity of certain enzyme systems involved in activation, detoxification, and adaptation to toxic exposures may modify response bout within range of normal
Medical	
Generally, any debilitating condition may enhance clinical susceptibility	
Atopy	
Asthma	Tendency toward easy sensitization
Eczema	Increased bronchial reactivity
Chronic respiratory disease	
Respiratory insufficiency	Diminished pulmonary reserve
Bronchitis	Increased bronchial reactivity; exacerbated bronchial irritation
Chronic cardiovascular disease	
Cardiac insufficiency	Increased susceptibility
Coronary artery disease	Angina in some situations, such as carbon monoxide, methylene chloride exposure
Infection	
Acute viral illness	Increased susceptibility to bronchial irritation; possibly synergistic effect
Exposure to infectious agents	Certain exposures may depress host defenses
Immune deficiency states	
Hereditary	Increased susceptibility to infections
Immunosuppressive therapy	
Renal disease	
Renal insufficiency	Additive or synergistic effects may occur with exposure to nephrotoxic agents
Chronic renal disease	Increased susceptibility to toxic agents excreted via renal route
Neurologic conditions	
Diminished mental capacity	Immunodeficiency; increased susceptibility to toxic effects
Neurologic disease	May affect judgement and response to exposure situation
Seizure disorder	Toxic effects may be additive; increased clinical susceptibility
Impaired perceptive ability (visual or hearing impairment, anosmia)	Certain toxic exposures may alter threshold Impaired ability to avoid hazard
Dermatologic conditions	
Skin rashes	may increase dermal absorption; may condition response
Substance abuse	
Concomitant alcohol and drug abuse	may have additive or synergistic effects in some situations
Hepatic insufficiency	
Increased susceptibility to toxic agents detoxified by liver; increased susceptibility to hepatotoxic agent; reduced hepatic reserve	
Systemic conditions	
Malnutrition (general)	Increased susceptibility to toxic effects
Vitamin deficiency (selective)	Diminished host defenses against toxic effects
Inborn errors of metabolism	Selective susceptibility (depending on abnormality)
Genetic diseases	Certain genetic diseases associated with increased susceptibility to mutagenic effects
Mental status	
Stress	may increase susceptibility to some toxic exposure. Stress, affective disorders, neuroses, or psychoses may mask, mimic, or subtly modify the clinical presentation

(From Occupational and Environmental Health Committee of the American Lung Association of San Diego and Imperial Counties: Taking the occupational history. *Ann Intern Med* 1983;99:641–651.)

halation of hydrocarbons, especially halogenated hydrocarbons. They can sensitize the myocardium to endogenous as well as exogenous catecholamines, and ventricular arrhythmias can result. Historically, occupational toxicology studies showed carbon disulfide to be atherogenic, but newer data have called this effect into question.⁴⁵ Chronic exposure to nitrates can precipitate angina in workers when they withdraw from the chronic vasodilatory effects. Any systemic asphyxiants (H₂S, CO,

CN, methemoglobin formers) can precipitate acute coronary syndromes in workers with preexisting atherosclerotic disease.

Neurotoxicity

Any of the simple asphyxiants can cause CNS depression and even death by displacing oxygen from the inspired air. Very high concentrations can cause rapid uncon-

ILLNESS	AGENT	USE/OCCUPATION/INDUSTRY
Pulmonary injury ALI, ARDS, RADS/IIA, BOF Degree of injury, injury type, and sequelae, depend on exposure duration and agent. See text for discussion.	Irritant gases <i>Soluble</i> HCl, HF, H ₂ SO ₄ , HNO ₃ , NH ₃ , and other alkali and acid mists SO ₂ Tear gas Isocyanates <i>Insoluble</i> Phosgene Ozone NO ₂ <i>Medium solubility</i> Chlorine Acrolein Smoke inhalation Pesticides Organophosphates (OP), carbamates, type II pyrethroids, dinitrophenol, pentachlorophenol (wood preservative), paraquat Metals and metal compounds Cd, Hg, Mn Nickel carbonyl—Ni(CO) ₄	Acid, alkali production workers; manure pits (NH ₃ + H ₂ S) Sulfuric acid production; air pollutant Law enforcement Polyurethane industry, firefighters Polymer industry, welders—burning chlorinated metal degreasers Any worker exposed to air pollution: city workers, bus drivers, cab drivers, etc. Silo fillers, high temp arc welders, nitric acid workers Water purification, paper pulp, swimming pool workers Polymer industry, firefighters (component of smoke) Firefighters Farmers, exterminators, crop dusters, pest control workers, lumber industry Smelters, welders Mond process of nickel refining
Occupational asthma (see Chapter 9 for expanded detail)	High-molecular-weight antigens Animal proteins (danders, feathers, excreta, serum) Plant proteins Natural rubber latex Wheat flour Low-molecular-weight antigens Certain antibiotics, drugs Metals: Cr, Co Ni, Pt, various others Chemicals: Inorganic Ammonium persulfate Fluoride Chemicals: Organic Plicatic acid (Western red cedar) Abeitic acid (colophony: pine rosin) Isocyanates: TDI, MDI Many others	Animal handlers, lab workers, farmers, many others Health care workers Bakers (Baker's asthma) Pharmaceutical industry Metal plating, metal workers, others Beauticians Aluminum pot-room workers Lumberjacks, sawmill workers Polyurethane foam workers See Chapter 9 Microwave popcorn workers Nylon flock workers in random-cut factories Asbestos miners, shipbuilders, insulators, brake linings Coal miners Miners, sandblasters, foundries, quarries, stone carvers, ceramics
Popcorn worker's lung Nylon flock worker's lung Pneumoconioses Lung cancer ^{vi} (IARC Class I carcinogens)	Diacetyl from artificial butter flavor Random-cut nylon flock Asbestos fibers: asbestosis Coal dust: coal workers' pneumoconiosis Silica: silicosis Mica: combination of asbestosis and silicosis Asbestos Arsenic (mainly arsenic trioxide) Beryllium Cadmium Chloromethyl ethers <i>bis</i> (chloromethyl) ether (BCME) and chloro- methyl methyl ether (technical grade) Chromium (Cr VI) Crystalline silica Environmental tobacco smoke (ETS)	Miners Asbestos miners, shipbuilders, insulators, brake linings, vermiculite miners Smelting lead, copper, gold, others; Arsenical pesticides; coal burning Beryllium extraction and processing; aircraft and aerospace industries; electronics and nuclear industries; jewelers Cadmium-smelter workers; battery production workers; cadmium-copper alloy workers; dyes and pigments Production; chemical intermediate; alkylating agent laboratory reagent; plastic manufacturing; ion- exchange resins and polymers Chromium mining, chromate production Granite and stone industries; ceramics, glass, and related industries; foundries; and metallurgical industries; abrasives; construction; farming Bartenders, waitresses, etc.; other workers exposed to ETS

TABLE 82-2 Occupational Illnesses, Selected Associated Agents, and Associated Uses and Occupations and Industries^{i-v,*}—(Cont'd)

ILLNESS	AGENT	USE OCCUPATION INDUSTRY
Lung cancer (IARC Class 1 carcinogens) <i>cont'd.</i>	Ionizing radiation	Radiologists; technologists; nuclear workers; radium-dial, painters; plutonium workers; cleanup workers following nuclear accidents; aircraft crew
	Mustard gas	Mustard gas production; used in research laboratories; military personnel
	Nickel	Nickel refining
	Polycyclic aromatic hydrocarbons (PAHs)	Fossil fuel burning, exhaust smoke
	Radon	Uranium miners, other underground mining
	Talc (containing asbestos fibers)	Manufacture of pottery, paper, paint, and cosmetics
Acute toxic encephalopathy	Wood dusts	Loggers, carpenters, sawmills, etc.
	Acrylamide monomer	Wastewater treatment, grouting
	Azides	Lab reagent, preservative, weed control; inflates automobile air bags
	Carbon disulfide	Viscose rayon workers, rubber manufacture*
	Carbon monoxide	Any exposure to incomplete burning, improper ventilation, or exhaust: garage workers, firefighters; paint strippers (methylene chloride)
	Cyanide (CN)	Metal plating, jewelers, firefighters (smoke inhalation)
Seizures	Hydrogen sulfide	Farmers (manure pits), sewer workers, petroleum refineries
	Mercury	Chlor-alkali workers (electrolytic production of chlorine and caustic soda), manufacturing mercury-containing instruments, fungicide users, topical antiseptics*
	Simple asphyxiant gases (CO ₂ , CH ₄ , propane)	Gas production, various industries with confined space issues
	Toluene, xylene, other hydrocarbon solvent vapors	Painters, chemical production, solvent use (confined space)
	Metals	
	Arsenic	Smelting lead, copper, gold, others; arsenical pesticides
	Copper	Coal burning, leather tanning, pesticides
	Lead	Copper smelters, miners Lead-acid battery, HAZMAT site cleanup, automobile radiator repair, lead reclamation, solder
	Manganese	Mn miners, chemical industry, metal refining
	Nickel carbonyl	Model nickel refining process
	Pesticides	
	Organochlorines* (lindane, cyclodienes, DDT)	Farmers, agriculture, forestry, landscapers, pest control
Organophosphates		
Paraquat, Diquat (herbicides)		
Pentachlorophenol (PCP)		
Dinitrophenol		
Chlorophenoxyacetic acid herbicides		
Rodenticides* (thallium, SMFA, strychnine, Zn phosphide, As, methyl bromide)	Rodenticide users: graineries, longshoremen, exterminators (many of these rodenticides are no longer in use in the United States)	
Phosphine, methyl bromide (fumigants)	Grain workers	
Any general CNS depressant producing hypoxia		
Toxic inhalants (CN, H ₂ S, CO)	See Acute Toxic Encephalopathy, above	
Simple asphyxiants (hydrocarbons, CO ₂ , He, N ₂ , etc.)		
See also Toxic Encephalopathy, above		
Chlorinated HC solvent vapors		
Peripheral neuropathy	Acrylamide monomer	Wastewater treatment, grouting
	Arsenic	Smelting lead, copper, gold, others; arsenical pesticides; coal burning, leather tanning, pesticides
	Carbon disulfide	Viscose rayon, rubber manufacturing
	Lead	Lead-acid battery, HAZMAT site cleanup, automobile radiator repair, lead reclamation, solder
	Mercury	Chlor-alkali workers (electrolytic production of chlorine and caustic soda), manufacturing mercury-containing instruments, fungicide users, topical antiseptics*
	Methyl bromide	Fumigation
	<i>n</i> -Hexane, methyl <i>n</i> -butyl ketone	Solvent users, glues
	Organophosphates	Pesticide users
	Thallium	Rodenticide users
	Trichloroethylene	Solvent, degreasers

TABLE 82-2 Occupational Illnesses, Selected Associated Agents, and Associated Uses and Occupations and Industries^{1-v,*}—(Cont'd)

ILLNESS	AGENT	USE OCCUPATION INDUSTRY	
Cyanosis	Methemoglobin-forming agents: organic amino and nitro compounds* CNS depressants causing hypoventilation and hypoxia	Synthetic dyes, leather and shoe industry, fabric dyeing* Various industries; see Toxic Encephalopathy, above	
Hyperthermia/fever	Pentachlorophenol (wood preservative) Nitrophenol pesticides	Lumber production, landscaping Exterminators, pest control, agriculture, farmers, forestry workers	
Hematologic toxicants	Chlorophenoxyacetic acid herbicides Inhalational fever syndromes	Landscapers See Fume Fever Syndromes, below	
	Methemoglobin (MetHgb) producers Aniline, nitroaniline, <i>p</i> -chloroaniline dyes Toluidine Naphthalene Paradichlorobenzene Nitrates Trinitrotoluene (TNT)	Rubber industry, dye manufacturing, dye users, pharmaceuticals Dyes Clothing fumigant (mothballs) Clothing fumigant (mothballs) Fertilizers Explosives	
	Hemolytic agents Any methemoglobin-producing agent (above) in G6PD-deficient workers, or with large exposures in normal workers	As above	
	Arsine (AsH ₃), stibine (SbH ₃)	Dopant gases for n-type semi-conductors in the microelectronics industry; zinc smelting	
	Chlorate salts (MetHgb unresponsive to methylene blue antidote, denatures hemoglobin)	Match and explosive production, dye manufacture, paper pulp bleach manufacturing (ClO ₂), pesticides, herbicides	
	Organic nitro and amino compounds Toxic porphyrias (acquired) Hexachlorobenzene 2,4-D, 2,4,5-T herbicides (? due to TCCD contaminant)	Synthetic dyes, leather and shoe industry, fabric dyeing Herbicide (accidental ingestion) Herbicide	
	Lead (when whole blood level > 60 µg/dL)	Lead-acid battery, HAZMAT site cleanup, automobile radiator repair, lead reclamation, soldering	
	Vinyl chloride monomer	PVC production	
	Bone marrow toxicants Leukemogen Benzene (acute myelogenous leukemia AML) Ionizing radiation	Chemical intermediate, glues, solvents, inks, paints; components of gasoline-petrochemical workers Military exposures, uranium miners, nuclear power personnel	
	Ethylene oxide (possible leukemogen)	Health care industry gas sterilizers; chemical intermediate	
	Multiple myeloma (increased risk suggested, causation not proven) Benzene Ionizing radiation	Chemical intermediate, glues, solvents, inks, paints; component of gasoline-petrochemical workers Military exposures, uranium miners, nuclear power personnel	
	Myelodysplastic syndromes (implicated toxicants); Benzene Ionizing radiation	Chemical intermediate, glues, solvents, inks, paints; component of gasoline-petrochemical workers Military exposures, uranium miners, nuclear power personnel	
	Chemotherapeutic agents (association seen, risk not proved)	Nurses, oncologists, pharmacists	
	Rhabdomyolysis	Any agent causing seizures (see above) Any agent causing hyperthermia associated with hypermetabolic state such as pentachlorophenol, dinitrophenol, chlorophenoxy herbicides CO (direct cellular toxicity) Any CNS depressants causing coma and thereby inducing rhabdomyolysis from pressure	See above Farmers, lumber industry, pest control, exterminators Any exposure to incomplete burning, improper ventilation, or exhaust: garage workers, firefighters; paint strippers (methylene chloride) See Toxic Encephalopathy, above

TABLE 82-2 Occupational Illnesses, Selected Associated Agents, and Associated Uses and Occupations and Industries^{1-4,*}—(Cont'd)

ILLNESS	AGENT	USE OCCUPATION INDUSTRY
Fume fever syndromes	Metal fume fever: Zn, Cu Polymer fume fever (PTFE)	Welders (galvanized metal), foundries, smelting, metal refining Welders (cutting through Teflon coatings or polymer pipes), polymer workers
Organic dust toxic syndrome (ODTS) and other inhalation fevers	ODTS: Bio-aerosols of fungi, bacteria, exotoxins Moldy hay, moldy silage, compost Sewage sludge Grain dust Cotton dust Animal confinement buildings Other inhalation fevers Contaminated humidifiers Contaminated water cooling systems, spas, fountains Contaminated wood dusts/chips/bark (moldy wood chip exposure)	Farmers (silo-unloader's disease) Sewer workers, plumbers Grain mills ("grain fever") Cotton mills ("mill fever") Veterinary, laboratory workers Any building with contaminated humidifiers (humidifier fever) Any building with contaminated cooling system or fountain (Pontiac fever) Sawmills, pulp and paper mills, landscapers (wood trimmer's disease)
Hypersensitivity pneumonitis (HP)	Organic antigen exposures Moldy hay Moldy compost Contaminated humidifiers, dehumidifiers, HVACs Bagasse (moldy pressed sugarcane) Animal products (excreta, serum, feathers, dander) Chemicals Trimellitic anhydride (TMA), phthalic anhydride Diisocyanates Plicatic acid (red cedar) Pyrethrum insecticides Sodium diazobenzene-sulfonate (Pauli's reagent)	Farmers (farmer's lung) Mushroom workers (mushroom worker's lung) Office workers (any contaminated building)—humidifier lung Sugarcane workers (bagassosis) Animal handlers, etc. (pigeon breeder's disease, duck fever) Painters, epoxy resin users Polyurethane foam industry Red cedar workers, lumber industry, carpenters Exterminators, pest control, insecticide manufacturing Chromatography
Cardiovascular disease (atherosclerosis, myocardial infarction, and ischemia)	Many others (see Chapter 9) CO: acute MI and/or angina due to carboxyhemoglobin formation Methylene chloride (metabolized to CO) Carbon disulfide (CS ₂) (recent evidence weak) Organic nitrates: Ethylene glycol dinitrate	Varied industries Jobs with exposure to exhaust or poorly ventilated combustion: miners, forklift operators, mechanics, firefighters, etc. Paint strippers, solvent use Viscose rayon workers,* rubber industry workers, chemical intermediate Explosive industry (TNT)
Cardiac arrhythmias Tachydysrhythmias	Chlorinated HC Hydrocarbon (HC) solvents CO	Mechanics, degreasers, dry cleaners Printers, painters, mechanics, degreasers, dry cleaners Paint strippers (CH ₃ Cl), jobs with exposure to exhaust or poorly ventilated combustion: miners, forklift operators, mechanics, firefighters, etc.
Bradydysrhythmias Nephrotoxicants	Organophosphates, carbamates Arsine, stibine (due to massive hemolysis) Halogenated hydrocarbon solvents (CCl ₄ , CHCl ₃ , ethylene dichloride, trichlorethylene, tetrachloroethane, others) Vinylidene chloride Ethylene glycol ethers Ethylene chlorohydrin Toluene (ATN) White phosphorus Any agent associated with rhabdomyolysis Beryllium (granulomatous renal disease, only seen with concomitant lung disease) Cadmium Lead	Farmers, pest control applicators Semiconductor industry Dry cleaning, degreasers, plastics industry, other solvent use Monomer used in polymer industry Solvents, paints, coatings Solvent, chemical intermediate; penetrates skin readily Painters Match production (historical); military exposures See above Beryllium extraction and processing; aircraft and aerospace industries; electronics and nuclear industries; jewelers Cadmium-smelter workers; battery production workers; cadmium-copper alloy workers; dyes and pigments, welders Lead-acid battery, HAZMAT site cleanup, automobile radiator repair, lead reclamation, soldering

TABLE 82-2 Occupational Illnesses, Selected Associated Agents, and Associated Uses and Occupations and Industries^{i-v,*}—(Cont'd)

ILLNESS	AGENT	USE OCCUPATION INDUSTRY
Acute hepatotoxicants ^{vii}	Mercury	Chlor-alkali workers (electrolytic production of chlorine and caustic soda), manufacturing mercury-containing instruments, fungicide users, topical antiseptics*
	Anesthetic gases (halothane)	Anesthesiologists, nurses
	Hydrazine (steatosis)	Rocket fuels
	Halogenated hydrocarbons: CCl ₄ , CBr ₄ , CHCl ₃ , bromobenzene, others	Mechanics, degreasers, dry cleaners, plastics industry, solvents
	White phosphorus	Match production (historical); military exposures
	Methylene dianiline (MDA): cholestatic "Epping jaundice"	Epoxy resins
	Trinitrotoluene (TNT)	Explosives
	Dimethylacetamide	Textile workers
	Dimethylformamide (DMF)	Solvents, chemical manufacturing
	2-Nitropropane	Painters
Chronic hepatotoxicants	Cirrhosis	Smelting lead, copper, gold, others; arsenical pesticides; coal burning, leather tanning, pesticides
	Arsenic	Chemical intermediate
	CCl ₄	Solvent
	Tetrachloroethane	Explosives
	Trinitrotoluene	
Granulomatous hepatic disease	Beryllium (only seen with concomitant lung disease)	Beryllium extraction and processing; aircraft and aerospace industries; electronics and nuclear industries; jewelers
Hepatic carcinogens	Copper	Copper smelting, production workers
	Arsenic: hepatic angiosarcoma, hepatocellular carcinoma	Smelting lead, copper, gold, others; arsenical pesticides; coal burning, leather tanning, pesticides
	Vinyl chloride monomer: hepatic angiosarcoma	Polyvinyl chloride industry
	Dimethylnitrosamine: hepatocellular carcinoma	Rocket manufacturing
Skin disorders		
	Chloracne	Chlorinated herbicides (2,4-D, 2,4,5-T) PCBs TCDD ("dioxin")
Occupational acne	Lubricating oils Petroleum oils Vegetable oils	Metalworkers, mechanics Refinery workers, highway workers Fry cooks
Contact dermatitis	Irritant contact dermatitis	
	Solvents, oils	Solvent users, metalworkers, mechanics
	Soaps, frequent hard washing	Health care workers, food workers
	Allergic contact dermatitis	
	Biocides	Water treatment, pool workers
	Chromate	Inks, dyes, paints, corrosion inhibitors
	Epoxy resins	Epoxy resin manufacturers
	Formaldehyde	Formaldehyde workers, pathologists, deniers, morticians
Skin cancer	<i>p</i> -Phenylenediamine (hair dye)	Beauticians, rubber workers, rubber workers
	Para-aminobenzoic acid (PABA) sunscreens	Outdoor workers
Reproductive toxicants	Arsenic	Smelting lead, copper, gold, others; arsenical pesticides; coal burning, leather tanning, pesticides
	Ionizing radiation	Radiologists; technologists; nuclear workers; radium-dial, painters; plutonium workers; cleanup workers following nuclear accidents; aircraft crew
	Polycyclic aromatic hydrocarbons	Coal tar workers, petroleum products, chimney sweeps
	Ultraviolet radiation (sunlight)	Outdoor workers
Female reproductive system	Chemotherapeutic agents	Health care workers, nurses, anesthesiology
	anesthetic gases	
	Chlorinated hydrocarbon solvents	Solvent users
	Ionizing radiation	Radiologists; technologists; nuclear workers; radium-dial, painters; plutonium workers; cleanup workers following nuclear accidents
	Environmental tobacco smoke (ETS)	Bartenders, waitresses, etc.; other workers exposed to ETS
	Mercury	Chlor-alkali workers (electrolytic production of chlorine and caustic soda), manufacturing mercury-containing instruments, fungicide users, topical antiseptics*
	Lead	Lead-acid battery, HAZMAT site cleanup, automobile radiator repair, lead reclamation, soldering

TABLE 82-2 Occupational Illnesses, Selected Associated Agents, and Associated Uses and Occupations and Industries^{i-v,*}—(Cont'd)

ILLNESS	AGENT	USE OCCUPATION INDUSTRY
Male reproductive toxicants	Carbon disulfide	Viscose rayon workers,* rubber industry workers, chemical intermediate
	Dibromochloropropane (DBCP)	Nematocide users, applicators; DBCP production workers
	Ionizing radiation	Radiologists; technologists; nuclear workers; radium-dial, painters; plutonium workers; cleanup workers following nuclear accidents; aircraft crew
	Lead	Lead-acid battery, HAZMAT site cleanup, automobile radiator repair, lead reclamation, soldering
	Pesticides (chlordecone, carbaryl, 2,4-D, ethylene dibromide)	Farmers, pest control applicators

*Many of the chemicals/toxicants may no longer be used or manufactured in the United States but still are in common use in other parts of the world. U.S. industries with modern IH practices have limited or eliminated many exposures to industrial toxicants, but workers in developing nations may remain at substantial risk.

sciousness. Numerous volatile hydrocarbons, both aliphatic and aromatic, as well as halogenated hydrocarbons, can have general anesthetic effects when inhaled, leading to CNS depression and even to coma in high doses. Lower doses cause dizziness, lightheadedness, or a drunk or “high” feeling. Chemical asphyxiants cause CNS depression by interfering with oxygen transport or utilization (discussed previously).

Peripheral neuropathies can be induced by *n*-hexane and methyl *n*-butyl ketone, which share the common toxic metabolite 2,5-hexanedione. This effect is potentiated when these hexacarbonyls exist in mixtures containing MEK. Acrylamide monomer can induce both CNS effects in high concentrations and a peripheral neuropathy following an acute high-dose exposure or chronic exposure. These hexacarbonyls, as well as carbon disulfide, ethylene oxide, and heavy metals (arsenic, thallium, lead, mercury), are commonly cited as causes of peripheral neuropathy. Certain organic phosphorus compounds (e.g., tri-ortho cresyl phosphate) can induce peripheral neuropathy through inhibition of the enzyme neuropathic target esterase, which is independent of its acetylcholinesterase inhibition.

Reproductive Toxicology

Few toxicants have been definitively shown to adversely affect female reproduction, mainly because few have been adequately investigated. Those that have shown strong associations with an increased incidence of spon-

taneous abortions are environmental tobacco smoke, ionizing radiation, chemotherapeutic agents, mercury, and lead. In addition, chlorinated hydrocarbon solvents, anesthetic gases, and chemotherapeutic agents have been associated with birth defects.

There exists slightly more evidence for male reproductive toxicants. The most notable historically is dibromochloropropane (DBCP), a nematocide. DBCP production workers developed dose-dependent decreased sperm counts, with azoospermia in the highest exposure groups. Lead can cause oligospermia and decreased libido. Other reproductive toxicants include carbon disulfide, ionizing radiation, and other pesticides (chlordecone, carbaryl, 2,4-D, ethylene dibromide).

LABORATORY EVALUATION

The current role of the clinical laboratory in the medical management of industrial poisoning is to help provide effective supportive care (e.g., arterial blood gases, acid-base status, complete blood count). Blood and urine levels of most occupational toxicants are not available acutely and are used primarily to document exposures. Some are obtained as mandatory medical monitoring and, if elevated to a certain level, may require medical removal from further exposure. Twenty-four-hour urine collections and blood levels for some metals can guide the need for chelation therapy. Elevated BEIs can indicate over-exposure in the workplace, or improper use of PPE.

TABLE 82-3 Internet Sources of Information on Toxicologic Properties of Various Chemical Agents

INTERNET SERVICE	WEBSITE COMMON NAME	WEB ADDRESS	DESCRIPTION
Toxicology Data Network The following databases are all included in TOXNET and can be searched individually or simultaneously via TOXNET.	TOXNET	http://toxnet.nlm.nih.gov	Allows searching of nine different databases below all at once
Hazardous Substances Data Bank	HSDB	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?HSDB	Included in TOXNET search; broad scope in human and animal toxicity, safety and handling, environmental fate, and more. Scientifically peer-reviewed.
Integrated Risk Information System	IRIS	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?IRIS	Data from the EPA in support of human health risk assessment, focusing on hazard identification and dose-response assessment.
International Toxicity Estimates for Risk	ITER	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?iter	Provides chemical risk information from authoritative groups worldwide (EPA, ATSDR, Health Canada, IARC, etc.) peer-reviewed.
Genetic Toxicology (Mutagenicity)	Gene-Tox	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?GENETOX	Peer-reviewed mutagenicity test data from the EPA
Chemical Carcinogenesis Research Information System	CCRIS	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?CCRIS	Carcinogenicity, mutagenicity, tumor promotion, and tumor inhibition data from the National Cancer Institute
Toxicology Bibliographic Information	Toxline	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?TOXLINE	Biochemical, pharmacologic, physiologic, and toxicologic effects of drugs, chemicals
Developmental and Reproductive Toxicology and Environmental Teratology Information Center	DART/ETIC	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?DARTETIC	Current and older literature on developmental and reproductive toxicology
Toxica Release Inventory	TRI	http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?TRI	Annual estimated releases of toxic chemicals to the environment—EPA's TRI (Toxics Release Inventory)—reporting years, 1995–2000.
Chemical Identification Plus	ChemID plus	http://chem.sis.nlm.nih.gov/chemidplus/chemidlite.jsp	Numerous chemical synonyms, structures, regulatory list information, and links to other databases containing information about the chemicals.
Haz-Map	Haz-Map	http://hazmap.nlm.nih.gov/	Chemicals and biologic agents in Haz-Map are linked to industrial processes and other activities such as hobbies. Occupational diseases and their symptoms are associated with hazardous job tasks and possible exposure to hazardous agents.
MSDS online	MSDSonline	http://www.msdsonline.com/	On-line access to millions of MSDS
Agency for Toxic Substances and Disease Registry	ATSDR ToxFAQ	http://www.atsdr.cdc.gov/toxfaq.html	Series of summaries about hazardous substances developed by the ATSDR Division of Toxicology
Agency for Toxic Substances and Disease Registry	ATSDR toxicologic Profiles	http://www.atsdr.cdc.gov/toxpro2.html	ATSDR produces "toxicologic profiles" for hazardous substances found at National Priorities List (NPL) sites. Ranked based on frequency of occurrence at NPL sites, toxicity, and potential for human exposure.
National Pesticide Information Center	NPIC	http://npic.orst.edu/	Developed from a priority list of 275 substances. Cooperative effort between Oregon State University and the EPA, offers objective, science-based pesticide information
New Jersey Department of Health	Hazardous Substances Fact Sheets	http://www.state.nj.us/health/eoh/rtkweb/rtkhsfs.htm	Brief fact sheets containing physical, chemical, toxicologic, and medical data on hundreds of substances

EPA, U.S. Environmental Protection Agency.

Acutely, some tests are helpful after inhalation exposures to toxic gases, such as carboxyhemoglobin and methemoglobin levels. Whole blood lead levels can often be obtained acutely, and guide therapy. Central to the evaluation of pulmonary problems are chest radiography and pulmonary function testing. Radiography may reveal aspiration pneumonitis, noncardiogenic pulmonary edema, pleural effusions, or interstitial fibrosis. High-resolution computed tomography of the chest is more sensitive in detecting subtle opacities in many occupational lung diseases, such as hypersensitivity pneumonitis (HP), coal worker's pneumoconiosis (CWP), and other pneumoconioses. A xenon ventilation-perfusion lung scan may be useful in patients with suspected inhalation injury.

Electrocardiography is neither very sensitive nor specific for diagnosing occupational exposures or illnesses. Chemical asphyxiants or arsenic may produce an ECG picture of myocardial ischemia by interfering with cellular respiration, and the ECG may reveal ischemic changes. Both arsine and antimony have been associated with abnormalities of the T waves. Overexposure to phosphorous, hydrofluoric acid (due to subsequent hypocalcemia), or arsenic can cause QT-segment prolongation.

INFORMATION SOURCES

The clinician is often faced with incomplete toxicologic data on which to base treatment. If adequate information on the toxic agent is not available on site or from the manufacturer, the nearest poison control center should be contacted once the chemical has been identified. Poison control centers rely on a wide variety of information sources and specialty consultants to assess toxicity and can offer treatment advice. The Regional Poison Control Center can be accessed by the national toll-free number at 1-800-222-1222.

There is no comprehensive database available anywhere that will have information on every chemical that is in commercial use. Information on the toxicologic properties of chemical agents is available in various forms and from various agencies and organizations. Therefore, the clinician should be familiar with the readily available sources of information for chemicals and how to readily access them. Table 82-3 lists useful websites that have information regarding toxicologic properties of various agents.

SUMMARY

Legislative measures, such as the Toxic Substances Control Act of 1976, alone may not be sufficient to reduce occupational disease significantly. Millions of chemicals exist, about 70,000 chemical substances are in common use, and several hundred new compounds are added by industrial processes each year. Unpredicted health hazards from new processes continue to emerge, and "well-known" occupational exposures still escape

surveillance and control.¹⁵ As a result, any patient presenting with an unusual symptom or group of symptoms should always prompt suspicion of an occupationally related disease. A systematic approach to recording the occupational history serves as a guide to discovering a specific toxic exposure that may be the cause of the presenting symptoms. Even when such a history is unavailable, a thorough physical examination and initial laboratory analysis may suggest a toxidrome that can lead the clinician to an early toxicologic diagnosis.

The predominant route of exposure to toxicants in the occupational setting is through inhalation. Irritant gases, metal dusts or fumes, and chemicals of extreme pH or reactivity may produce mucosal damage to the respiratory tract. The location of injury depends on the water solubility and particle size of the substance. The highly water-soluble gases—ammonia, hydrogen chloride, and hydrogen fluoride—dissolve readily in the moisture associated with the mucous membranes of the eyes, nose, and upper respiratory tract. Inflammation, ulceration, edema, and necrosis may acutely obstruct the upper airway. Recovery may be incomplete, and reactive airways dysfunction syndrome, also known as *irritant-induced asthma*, may result. Gases with a low solubility in water, such as ozone, nitrogen dioxide, and phosgene, reach the lower airway and can produce acute lung injury pneumonitis and pulmonary edema. Potential late effects from the inhalation of these substances include bronchiolitis obliterans fibrosa, bronchiectasis, chronic bronchitis, and varying degrees of pulmonary fibrosis.

Most respiratory irritants are gases or vapors, but they may also exist as particulates (e.g., mist) or may be absorbed onto particulates (e.g., sulfur dioxide).⁴⁶ The particle size largely determines the extent of accessibility to small airways. Particles measuring between 1 and 5 μm can reach the alveoli. Pneumoconiosis is the result of chronic exposure to dusts (e.g., asbestos) and leads to the development of fibrorestrictive disease. Systemic absorption of inhaled occupational toxicants can lead to effects on many other organ systems.

Occupational dermatoses are the most common occupational diseases, with irritant contact dermatitis and allergic contact dermatitis predominating. Dermal absorption can also lead to systemic poisoning, especially with certain toxicants such as phenol, hydrofluoric acids, and pesticides. Table 82-2 lists some common occupational illnesses and their causative agents seen in various industrial and occupational settings.

At a Glance...

- Environmental exposure pathways include the ambient air, water, dust, soil and other solids, and other living organisms.
- In situations of chemical environmental contamination, an obvious and clearcut relationship of an exposure and a health impact is relatively uncommon.
- When the health impact of an environmental exposure is unclear, public health and environmental authorities are the clinician's best source of guidance.
- Risk assessment is the process used to determine the relationship between toxicant exposure and the development of adverse health effects.
- Risk assessment requires: (1) identification of the hazard; (2) assessment of the toxicity of the hazard (e.g., dose–response relationship); (3) characterization of the exposure of the population; and (4) characterization of the risk (e.g., risk quantification).
- Risk management includes plans to separate people from the substances that may harm them.
- Certain federal agencies have developed standards for nonoccupational exposure limits, which represent an estimated daily human exposure below which there is a minimal risk for developing adverse health effects.
- Knowledge of the various environmental and public health agencies and their responsibilities can facilitate the care of patients exposed to environmental contaminants.

Environmental toxicology is the study of adverse effects that occur in living organisms from exposure to hazardous substances or pollutants in the surrounding ecosystem. The impact of these chemicals on human health is one focus of this discipline. Environmental toxicology is defined by context and not by a specific set of toxicants or agents. Toxicology is “environmental” by virtue of the routes, doses, and contexts underlying the exposures. Generally, the term *environmental* is applied to exposures that occur outside the workplace and in the area where a patient lives. Exposures are usually either unavoidable or difficult to avoid.

The concept of environmental toxicology as it relates to humans may be more easily understood from examples: Exposure to silica dust in a facility specializing in finishing quarried stone would be considered “occupational” rather than environmental, since the silica in inspired air can be reduced by adequate personal protective equipment, by a change in work practices, by relocating workers, or by other means. Indeed, one can avoid the exposure entirely by choosing other employment. On the other hand, the airborne mercury exposure of populations located downwind of coal-fired power plants is not easily controlled by the individual. Likewise, where arsenic is present in higher than recommended

levels in finished drinking water or polychlorinated biphenyls (PCBs) are present in fish sold for human consumption, these are exposures in a person's physical surroundings or environment.

Environmental media or exposure pathways include all of the principal classes of substances with which people regularly come in contact and which may convey environmental toxicants. These media include the ambient air (both indoor and outdoor), recreational water and drinking water, dust, soil and other solids, and other living organisms. Food and drink should be considered environmental media unless the toxins or toxicants they may contain are sufficiently familiar for them to be easily identified and avoided. For example, it is possible to avoid exposure to nicotine and to the carcinogens in cigarettes or to abstain from ingestion of ethanol in beer and other alcoholic beverages. Rarely, the clinical, social, and political contexts concerning certain parenteral exposures allow them, too, to be considered “environmental.” Recent concerns about thimerosal in pediatric vaccines fall into this category.¹

HISTORY

Environmental health in the United States arose as an active field of endeavor in the 19th century. Indeed, it was the principal component of public health during that era. However, early environmental health was concerned primarily with the control of infectious diseases. The field was based on the work of such scientists as Joseph Lister, who used disinfectants (carbolic acid or phenol) in medical procedures to decrease the incidence of (and mortality from) wound infection and sepsis.² In 1854, another leader in the environmental control of infections, John Snow, interrupted transmission of cholera in London by identifying and restricting access to a source of contaminated drinking water.³

Based on the work of these and many other public health leaders, the “sanitary revolution” of the late 19th and early 20th centuries transformed the spectrum of health and disease in Europe and North America, resulting in substantial decreases in the deaths of newborns and infants from diarrhea and consequent dehydration.⁴ The availability of pure drinking water was a major contributor to the dramatic increases in overall life expectancy that occurred during this period.⁵

The possible admixture of toxic substances into food, water, and other ingested products has caused public concern since at least the early 20th century. After World War II, however, the continuing increase in the industrialization of North America and the burgeoning use of a wide variety of chemical products brought noninfectious environmental problems to the forefront. Chemical

pollution generated increased concern about water quality. Air pollution, previously a safety concern in the workplace, became a major health concern in the general environment, although concerns about outdoor and indoor air differed. By the late 1970s, the documentation of many instances of extensive land and soil-surface pollution from highly toxic substances located in close proximity to residential areas (as occurred at Love Canal in Niagara Falls, New York) generated worry about human proximity to highly toxic environmental solids.

CLINICAL CONSIDERATIONS

Situational Factors

The special considerations pertaining to toxicants found in the environment are most relevant to physicians attending or consulting on individual cases in two broad sets of circumstances:

1. *Active Community Discussion.* There may be ongoing discussions and concern in the larger community or region about a particular environmental exposure or set of exposures. Such concerns may or may not represent a realistic view of the risks involved.
2. *Individual Concern.* Fears about the consequences of a particular exposure or perceived exposure may be patient specific and independent of any particular community concern about the environment. Patients develop such concerns (a) on their own, (b) based on interactions with other health practitioners, (c) based on findings of laboratories specializing in biomonitoring of various substances, or (d) based on their interactions with advocacy groups.

Under any of these sets of circumstances, the physician should be mindful of the broader set of societal issues that likely constitute the patient's frame of reference. Where an active community discussion exists about a specific environmental exposure or set of exposures, there are typically broader social, economic, and political forces at work. For example, concerns about decreased residential property values may energize assertions of a negative health impact. On the other hand, the threat to bottom line corporate profits may lead a company to disclaim responsibility for any illness. The practitioner should be aware that assertions made on either side of an environmental debate often lack clear-cut scientific support.

To the extent possible, the physician should determine the patient's individual relationship to these larger processes. He or she should attempt to understand how community concerns of all types may serve as stressors or otherwise influence the clinical presentation at hand. It is particularly important for the physician not to prejudge the medical importance of the presenting complaints. A relationship of the symptoms to an environmental exposure should not be assumed, nor should it be summarily discounted. The diagnostic workup should involve a careful history and physical examination, with due weight given to all reasonably possible causes of the

presenting symptoms, whether or not they relate to the community concerns about the environment.

Nor should the clinician assume that the lay press has described a possible environmental exposure or the type(s) of environmental contamination either accurately or completely. Press stories may be unduly influenced by the unverified assertions of interested parties. Where specific data about the environment are needed to properly evaluate the patient, the physician should contact the relevant public health officials or environmental authorities who will likely have detailed and reliable information.

Clear-cut Exposures

There are few doubts about the clinical status of patients who present with a typical history of an exposure and matching clinical findings. However, in situations of chemical environmental contamination, an obvious and clear-cut relationship of an exposure and a health impact is relatively uncommon. It occurs, for example, in the context of abrupt releases of toxic environmental contaminants causing familiar syndromes with short latencies (e.g., the abrupt onset of respiratory findings following chlorine gas exposure due to derailment and rupture of a chlorine-containing tanker car). At such times, the authorities responsible for handling acute contamination events should convey information regarding the nature of the contamination to local health care providers. The means for this notification should be written into local emergency management plans. Ideally, local environmental officials will communicate this information to departments of public health and to relevant health care organizations, including those responsible for emergency medical services and also to the directors of poison control centers in the affected areas. If they do not receive information about the exposure through their hospitals or health care organizations, clinicians may wish to contact environmental or public health officials directly in an emergency.

Less commonly, typical illness from an environmental exposure will emerge over a period of days to weeks (or even months) as an ongoing intoxication epidemic comes to medical attention. Such retrospective identification of an environmentally mediated epidemic occurred in the eosinophilia-myalgia syndrome episode that occurred in the United States in 1989.⁶ More recently, hundreds of residents of Libby, Montana, who did not necessarily have any direct occupational exposure to asbestos were found to have clinical findings consistent with asbestosis, apparently from exposure to asbestos-containing mineral tailings distributed widely throughout the community.⁷

Poorly Defined Exposures

Because of the evident danger to people potentially affected by the environmental exposures with a clear-cut etiologic and demonstrable health impact, such occurrences are typically treated as emergencies. The immediacy of an unambiguous threat prompts an unequivocal call for environmental remediation and for appropriate treatment or management of affected persons.

Commonly, however, the health impact of environmental exposures is less clear. Whether a putative environmental toxicant is capable of causing the reported health complaints may be at issue. Alternatively, there may be questions as to whether a dose sufficient to cause the health effects has actually reached the population that is potentially at risk. There may be inconsistent or contradictory data or assertions regarding the nature of the health impact at a population level. In these and similar circumstances, the appropriate clinical approach to individual patients may be unclear, especially if expert opinion is divided as to whether there are sufficient data of the kinds required to infer a causal link (see Chapter 82). Again, public health and environmental authorities are the clinician's best source of guidance.

Roles of Clinical Toxicologists

With increasing frequency, clinical toxicologists also function as public health officials and may have to balance the competing demands of clinical work and public health. The American College of Medical Toxicology has designated particular individuals as points of contact and referral into the medical toxicologic community for situations in which environmental and health authorities in government need specific clinically based advice. Currently, at least two states (Iowa and Pennsylvania) have given specific physicians the title of State Medical Toxicologist. In some states, entire poison control centers operate in an official or quasi-official manner, representing state, local, or regional health authorities.

Clinical toxicologists filling these roles must be aware that public health officials' responsibilities differ somewhat from those of their clinical colleagues. Public health organizations serve the community as a whole, whereas clinical toxicologists typically act on behalf of their specific patients. Nevertheless, supporting clinical health care professionals is one of the most important duties of public health officers. Clinicians require—and should expect public health officials to provide—up-to-date and accurate information about environmental exposures that may affect their patients.

Clinicians' primary concerns are individual patients, on whose behalf they must advocate. Where available information is inadequate for clinical decision making or for optimal clinical care, they can and should advocate for better information to be obtained or developed. Although clinicians will be best served if they understand the constraints and context within which public health officials operate, they should not necessarily accept those limitations as their own. Where necessary for the benefit of their patients, clinicians should advocate for further studies and for the means to care properly for patients who may have been affected by environmental contamination.

Clinicians also have a duty to oppose the practices of providers and laboratories that exploit current fears regarding environmental contamination. For example, some practitioners use chelating agents extensively with neither a recognized indication nor a proper basis in scientific theory that would stand up to careful scrutiny. When such agents are used for extended periods, they

may be harmful. The overuse of chelating agents and other similar excesses in medical practice tend to undercut the trust of both the public and the medical community in clinical toxicologists who undertake a more judicious and scientifically based approach to the assessment and treatment of the health impacts of environmental agents.

BACKGROUND FOR THE CLINICAL ENCOUNTER

Formal Approach to Risk

In the years following World War II, the U.S. public became sensitized to the potential dangers of long-term low-dose exposure to the many new chemicals being developed, manufactured, and introduced into commerce. Repeated announcements warning of pesticides in food, pollutants in the air, chemical contaminants in drinking water, and toxicants emanating from hazardous waste sites generated increasing levels of concern. In particular, the likelihood emerged—now well established—that environmental chemicals could cause cancer. The practical expression of this concern was legislation to limit the exposure of people to potential chemical carcinogens. The landmark “Delaney clause,” enacted within the Food Additive Amendments of 1958, forbade the use in food of any additives that were “known to cause cancer.”

Implementation of the Amendment was complicated by the fact that established and accepted procedures for distinguishing carcinogens from noncarcinogens did not exist. Nevertheless, following Delaney, science and law developed in parallel. *In vitro* and *in vivo* tests were devised to identify and characterize carcinogens. Based on these tests, regulations were devised, applied, and tested in the courts. Over time, a process for characterizing the danger posed by specific chemicals, now called risk assessment, was developed. The steps involved in both assessing and managing environmental risk are diagrammed in Figure 83-1.

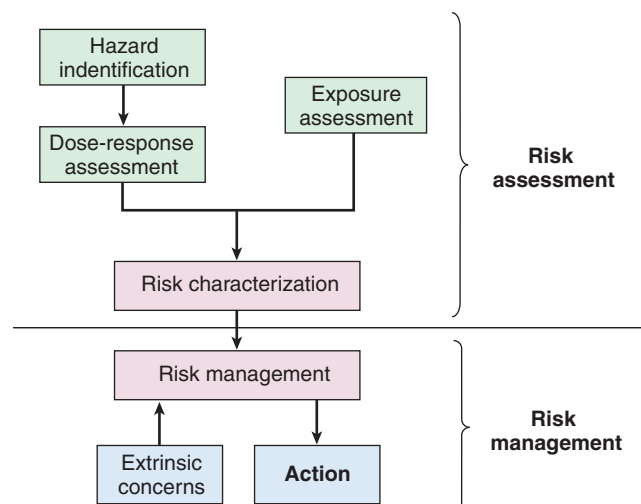

FIGURE 83-1 Outline of current procedures for risk assessment and risk management in regulatory toxicology.

As currently conceived, risk assessment involves the identification of a hazard and then an assessment of the likely human dose response for the impact of concern (e.g., cancer). Hazard toxicity assessment also includes an attempt to identify the threshold dose, or dose below which no adverse effect is observed. Unfortunately, human data are often insufficient, particularly for assessing dose response. Thus, animal studies are required. Procedures have been developed for extrapolation of animal findings to human beings and are widely used. In addition, the risk estimate derived from animal data is modified by uncertainty factors. The final risk assessment must also include a detailed assessment of the exposure. The magnitude, frequency, duration, and routes of exposure have a significant impact on the risk assessment. The final risk characterization, which is based on toxicity and exposure assessments, is a quantitative estimate of the health risk of the hazard. Risk management decisions are made from the results of the risk characterization and other factors.

Of the current sources of systematic reviews and expert judgments on the carcinogenic potential of particular chemical exposures, three stand out:

1. The International Agency for Research on Cancer (IARC), an arm of the World Health Organization (WHO)⁸
2. The Report on Carcinogens (ROC), the development and revisions of which are staffed by the National Toxicology Program (NTP) of the National Institute for Environmental Health Sciences (NIEHS)⁹
3. The Integrated Risk Information System (IRIS) of the U.S. Environmental Protection Agency (EPA).

There are certain features common to each of the three programs.¹⁰ Although the procedures differ for each, all three sources periodically update their conclusions to take into account new information.

The current model for regulating both cancer and other risks maintains a strict distinction between actual management of the risk (actions taken) and assessment of the risk itself (see Fig. 83-1). Risk management decisions involve more than the mere fact or level of risk. In addition, there are logistical, economic, and political considerations. Certain ways of tackling a pollution problem may be more likely than others to succeed. Community values enter into risk management, because some solutions to environmental contamination may be unacceptable to the communities involved. Other aspects of public policy, such as overall land use plans and competing needs for resources, may also modify the actions taken.

Risk management decisions, in their essence, are plans to separate people from the substances that may harm them. This may be done in several ways. Removing or relocating the hazard is generally the most desirable plan from the point of view of those affected. However, it is frequently expensive. Polluting industries, hazardous wastes, and other foci of environmental concern are not very mobile. Thus, techniques to isolate the hazard or diminish the intensity of exposure are used. This may involve the improvement of industrial pollution controls,

barriers to prevent the spread of noxious substances in air and water, or other means. An extreme measure available to the risk manager is the relocation of an entire community. At Love Canal, an exposure situation described in more detail below, many houses were bought so that the owners could move out. At Times Beach, Missouri, the entire town was bought from its owners by the federal government as a risk management measure. The relocation of large numbers of people (or of entire communities) is disruptive to community life and extremely expensive and is a last resort.

Occupational Exposure Limits

In 1946, the American Conference of Governmental Industrial Hygienists (ACGIH) published its first list of 148 exposure limits. In 1956, the ACGIH adopted the term *threshold limit values for chemical substances* (TLV-CS).¹¹ Currently, seven U.S. organizations publish and maintain systematic guidance on toxicant exposures on the basis of which the risk for adverse health effects from specific hazardous substances can be assessed. Measurements of occupational exposures are commonly compared with one or more of three sets of criteria:

1. Permissible exposure limits (PELs), established by the Occupational Safety and Health Administration (OSHA)¹²
2. Recommended exposure limits (RELs), established by the National Institute for Occupational Safety and Health (NIOSH)¹³
3. TLVs, established by the ACGIH¹⁴

In general, workers' risks for experiencing adverse health effects are increased to the extent that their levels of exposure exceed published criteria or standards (see also Chapter 82). The activities of these organizations are described in detail below.

The goal of the criteria for workplace exposures established by these organizations is to prevent adverse health effects in most workers exposed up to 10 hours per day, 40 hours per week for a working lifetime. The emphasis is on a "most workers" basis; the limits are not formulated to protect highly sensitive individuals. Thus, some small proportion of workers may be adversely affected despite adherence to the guidelines. Individual susceptibility, preexisting medical conditions, prescription or illicit drug use, and/or hypersensitivity (allergy) are often cited as examples of factors increasing the susceptibility of workers and leading to toxicity.

To facilitate access to information on occupational exposure limits and supporting material, NIOSH publishes numerous documents and databases that may be useful to clinical toxicologists. Current Intelligence Bulletins, Criteria Documents, and NIOSH Alerts all highlight the current state of knowledge of various chemical and physical toxins. *The NIOSH Pocket Guide to Chemical Hazards* is a comprehensive listing of general industrial hygiene information on several hundred chemicals and chemical classes for workers, employers, and occupational health professionals. Detailed information about chemical exposures may be found in the U.S. version of NIOSH's

International Chemical Safety Cards and the *Occupational Safety and Health Guidelines for Chemical Hazards*.

Occupational exposure limits are sometimes used in the evaluation of community environmental hazards, in part because there are many potential toxicants for which occupational exposure guidance is available but on which guidance on exposures of the general population is lacking. Although sometimes unavoidable, there are pitfalls to this practice because the general population has many more sensitive individuals than the typical workplace. Moreover, a higher level of safety is typically required. Limits for occupational exposure are suggested maximum levels of exposures based on an 8- to 10-hour time-weighted average workday exposure, designed only to protect an ideal “normal, healthy adult.”¹⁵

Nonoccupational Exposure Limits

Certain federal agencies have developed standards for exposures in nonoccupational environments. Like occupational exposure standards, the nonoccupational exposure limits represent an estimated daily human exposure below which there is a minimal risk for developing adverse health effects. Where sufficient human exposure data do not exist to establish exposure limits for a given toxicant, they are typically based on animal studies using a no observed adverse effect level/uncertainty factor (NOAEL/UF) approach. Test animals are exposed to varying concentrations of a toxicant by different routes and over varying periods in order to identify the organ and lowest threshold for toxicity in the most sensitive organ. This level is called the lowest observable adverse effect level (LOAEL). At some exposure level below this, there will be a level at which there is no evidence of an adverse effect, the no observable adverse effect level (NOAEL). Once a NOAEL has been determined among test animals, a standard set of calculations and decision making are used to derive an initial exposure limit based on the NOAEL. To assure protection of vulnerable subpopulations of people (e.g., infants and the elderly) and to account for other points of uncertainty (e.g., establishing a value for the protection of humans on the basis of animal data), the initial NOAEL-based value may be decreased by (divided by) one or more uncertainty factors with values of from 2 to 10, inclusive. Thus, the final value of the minimal risk level (MRL) is often as much as two orders of magnitude lower than the NOAEL.¹⁶

Because of slight differences in their procedures, the different agencies use different terms for their exposure limits. The Agency for Toxic Substances and Disease Registry (ATSDR) derives MRLs. The EPA develops exposure limits termed the *reference dose* (RfD) for oral exposures and the *reference concentration* (RfC) for air. The FDA's guidance values are termed *action levels*.

FEDERAL AGENCIES

Because of the number of persons involved, significant environmental exposures frequently involve environ-

mental and public health authorities, and clinicians should expect to deal with them. At the very least, clinicians will need to understand their deliberations and pronouncements. Interactions with environmental and health authorities can be greatly facilitated by a working knowledge of the various agencies (particularly the federal agencies) with responsibilities in the field. Moreover, an understanding of the procedures followed by these agencies, together with knowledge of their historical underpinnings, assists in comprehension, allowing the clinician to serve both (1) as interpreter of government agencies' actions for his or her patients and (2) as effective advocate on behalf of patients to the government agencies involved.

U.S. environmental public health at the federal level is divided into various functional components and falls under the jurisdictions of a number of departments and agencies. These include the Departments of Health and Human Services (DHHS), Labor (DOL), and Agriculture (USDA), as well as several independent agencies, including the EPA and the Consumer Product Safety Commission (CPSC).*

Environmental Protection Agency

On July 9, 1970, President Richard Nixon submitted to Congress plans to establish the EPA.¹⁷ As the principal “watchdog” of the nation's environment, the EPA is responsible for both shaping and enforcing the environmental laws enacted by Congress. The EPA oversees compliance with a lengthy list of laws and regulations written to fulfill them. Among the most important environmental laws protecting human health and overseen by the EPA are:

- National Environmental Policy Act of 1969
- Clean Air Act (CAA, 1970)
- Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA, 1972)
- Safe Drinking Water Act (1974)
- Toxic Substances Control Act (1976)
- Resource Conservation and Recovery Act (RCRA, 1976)
- Clean Water Act (1977)
- Comprehensive Environmental Response, Compensation and Liability Act (CERCLA, 1980)
- Superfund Amendments and Reauthorization Act (SARA, 1986; amendment to CERCLA)
- Emergency Planning and Community Right-to-Know Act (EPCRA, 1986)

A substantial proportion of the EPA's resources have been divided among 10 regional offices for the purposes of administering these laws. The regions correspond to the 10 regions under which the DHHS administers some of its programs, providing a context by which federal agencies can integrate activities in the field. Under the

*Independent agencies report to the president but are not directly affiliated with an executive department headed by a cabinet secretary. Agency heads may or may not sit with the cabinet.

EPA's stewardship, the air, water, and soil are notably cleaner, particularly with respect to toxicants with an impact on human health.

The EPA protects people from water-borne toxicants by formulating and enforcing the National Primary Drinking Water Regulations. These standards regulate the content of microbiologic, radiologic, and toxicologic contamination of water destined for human consumption. In addition, the required frequency of monitoring and the definitions of compliance are set by the EPA.

Two laws constitute the EPA's principal authorization for activities related to the safe management of environmental hazardous wastes. CERCLA (also known as Superfund), enacted in 1980, was designed to manage the clean-up of closed or abandoned hazardous waste sites.¹⁸ Although the RCRA of 1976 had authorized the EPA to hold industrial polluters responsible for the clean-up of hazardous waste sites,¹⁹ CERCLA strengthened the procedures for holding polluters accountable and outlined provisions for clean-ups at sites where directly responsible parties cannot be identified.¹⁸

Under the CAA, the EPA formulated a series of regulations. Among them are regulations identifying and setting National Ambient Air Quality Standards (NAAQS). The six pollutants for which the NAAQS currently exist are:

1. Ozone
2. Particulate matter
3. Carbon monoxide
4. Sulfur dioxide
5. Nitrogen oxides
6. Lead

These six air contaminants are termed priority pollutants and are monitored widely throughout the United States. The measurements made in local areas are judged against the NAAQS, and the areas are determined to be attainment or nonattainment areas accordingly. Based on these determinations, corrective action is taken. The 1990 amendments also identified 188 chemicals as hazardous air pollutants (also known as air toxics) because these chemicals are reasonably common pollutants and are particularly toxic.

The tragic deaths of thousands of people from a massive unintentional release of toxic methyl isocyanate (MIC) gas in Bhopal, India, aroused concern about the possibility of a similar event occurring in the United States.²⁰ This concern was reinforced less than a year later by a release of toxic chemicals into the air by a plant in West Virginia that also handled MIC.²¹ Thus, in 1986, Congress passed the SARA.²² The EPCRA, part of the SARA, required all businesses storing hazardous chemicals to provide their area's local emergency planning committee (LEPC) with information concerning the location and quantity of these chemicals. LEPCs may develop response plans for potential environmental and public health emergencies in anticipation of inadvertent releases. Moreover, the EPCRA mandates annual data collection concerning actual releases of hazardous

chemicals. This information, designed to make companies accountable for their handling of toxic chemicals, is known as the toxic release inventory (TRI).^{23,24} The TRI covers toxic releases from various industrial sectors, including manufacturing, metal and coal mining, electrical utilities, and commercial hazardous waste treatment.

Consumer Product Safety Commission

The CPSC was created in 1972 as an independent, free-standing federal regulatory agency responsible for protecting the public "against unreasonable risks of injuries associated with consumer products."²⁵ Currently, the CPSC ensures the public's safety from over 15,000 consumer products. Among the laws enforced by the CPSC are the Federal Hazardous Substances Act (FHSA) and the Poison Prevention Packaging Act (PPPA). Passed in 1970, the PPPA requires the use of child-resistant packaging as a means of preventing accidental childhood poisoning.

The term *special packaging* means packaging that is designed or constructed to be significantly difficult for children younger than 5 years of age to open or for them to obtain a toxic or harmful amount of the substance contained therein within a reasonable time [12 U.S.C. § 1471 (4)].

Over-the-counter medications, prescription drugs, household cleaners, beauty aids and cosmetics, prepackaged fuels, and FHSA-designated hazardous substances are subject to the packaging legislation. Even solder with a lead content in excess of 0.2% is considered hazardous. Currently, 28 classes of products are included on the list of agents requiring child-resistant packaging.²⁶⁻²⁸ The CPSC also regulates the use of certain radioactive substances, as well as products involving electrical, mechanical, or thermal hazards. Although considered hazardous under the CPSC's legislation, pesticides are subject to regulation by the EPA under the FIFRA and are not regulated by the CPSC.

Knowledge of specific words on product labels, required under the FHSA, may be of use to clinicians: extremely flammable, corrosive, or highly toxic substances must be labeled with the signal word *DANGER*; all other hazardous substances must carry one of two signal words, *WARNING* or *CAUTION*. In addition, descriptions of the principal hazard and any precautionary measures to be employed when handling the substance must be included on the label. Substances may also be banned under the FHSA; these include toys or other articles intended for children that are determined to be hazardous substances and any products found to be too hazardous for household use, regardless of labeling.

In addition to its regulatory function, the CPSC runs the National Electronic Injury Surveillance System.^{29,30} This surveillance system relies on data collected from a sample of 100 hospital emergency departments to provide a national estimate of injuries (including poisonings) caused by consumer products. Available for query, this database includes information about the drug or drugs implicated in poisoning incidents.

Food and Drug Administration and U.S. Department of Agriculture

By the latter half of the 19th century, concerns about the purity of medications resulted in attempts by the government to enforce standards of safety. In 1848, for example, to combat the influx of “counterfeit, contaminated, diluted, and decomposed” drugs entering the country, Congress passed the Import Drugs Act.³¹ Congress became acutely aware of the impact of tainted drugs when, during the course of the U.S.-Mexican war (1847 to 1848), an estimated 11,000 U.S. soldiers died of disease and illness (out of 13,000 who lost their lives).³² Many of the men who died of malaria had been dispensed ineffective or sham medicines. Under the 1848 law, laboratories set up by the U.S. Customs Service were given the responsibility for ensuring the purity and potency of drugs imported into the country.³¹ By the early 1900s, however, popular and financial support for this initiative had waned and the program ended.

During the same period, so-called “patent medicines” also drew Congress’s attention. Despite containing such now-illicit substances as opium, heroin, and cocaine, these products were sold without restriction, and labels failed to fully disclose the active ingredients.³¹ The labels typically made fabulous (and usually fictitious) claims about the medicine’s efficacy, advertising cures for ailments as diverse as fatigue, toothache, gout, and diabetes.

Congress responded to the commonplace use of “patent” medicines and food adulterants by passing the Pure Food and Drug Act in 1906. This law was the first of its kind and required all food and drug labels to reflect package contents accurately.³³ Any food, drink, or drug being shipped across state lines and found to be improperly labeled (i.e., lacking a complete accounting of its contents) was subject to seizure; persons found responsible for the products could be prosecuted. Drugs had to be manufactured according to the standard set forth in the U.S. Pharmacopoeia.³³ Ingredients like alcohol, heroin, and cocaine had to be identified clearly on the label.

By 1862, the wholesomeness of foods came into question. Chemists within the USDA began to analyze food products for the presence of adulterants. Within a decade, USDA chemists were debating possible adverse effects of the arsenic- and copper-based pesticide residues then found in foods.³¹ Other food additives of the time included boric acid, potassium nitrate, saccharin, salicylic acid, sulfuric acid, benzoic acid, and formaldehyde.^{31,34}

The USDA Bureau of Chemistry had the responsibility of enforcing the Pure Food and Drug Act. To reflect its role more accurately, the Bureau was renamed the Food, Drug, and Insecticide Administration. In 1930, it became the Food and Drug Administration.³¹ During the rest of the 20th century, Congress continued to broaden the powers of the FDA by enacting other laws, many in response to public health disasters.

Today, according to its mission statement, the FDA is “responsible for protecting the public health by assuring the safety, efficacy, and security of human and veterinary

drugs, biological products, medical devices, our nation’s food supply, cosmetics, and products that emit radiation.”^{35,36}

Within the FDA, there are five regulatory centers. The Center for Veterinary Medicine evaluates the safety and efficacy of drugs used to treat livestock and companion animals such as dogs, cats, and horses.³⁷ Livestock drugs are also tested to make sure that residues, where they exist, do not pose a risk to the people who consume them. The Center for Food Safety and Applied Nutrition is responsible for ensuring the safety of the nation’s entire food supply, with the exception of fresh meat, poultry, and some egg products.³⁸ (Responsibility for the latter rests with the USDA. Protecting food in the United States from adulteration by terrorists is a role shared by the USDA and FDA.)

The Center for Drug Evaluation and Research conducts premarketing evaluation of all prescription and over-the-counter drugs and provides the lay public and health care providers with drug use information.³⁹ Oversight of the manufacture, marketing, and use of biologic products for health care (e.g., blood and blood products, vaccines, and protein-based drugs such as monoclonal antibodies) is provided by the Center for Biologics Evaluation and Research (CBER).⁴⁰ The FDA’s Center for Devices and Radiological Health (CDRH) regulates the safety of all medical devices marketed and used in the United States, including everything from tongue depressors and thermometers to contact lenses, pacemakers, orthopedic implants, heart valves, dialysis machines, and the computerized robotic arms used in surgery.⁴¹ The CDRH is also responsible for ensuring public safety from excessive and unnecessary radiation exposure from both medical and nonmedical devices. Thus, not only must radiology equipment and lasers meet safety standards, but household items such as microwave ovens, television sets, and cell phones are also subject to FDA regulation.

National Institute for Occupational Safety and Health

In 1970, Congress passed the Occupational Safety and Health Act (OSH Act, Williams-Steiger Act), creating both OSHA and NIOSH.⁴² The stated goal of the OSH Act was to ensure that workers are provided a “place of employment free from recognized hazards to safety and health.” In order to achieve this goal, Congress created the two agencies to serve dual functions: regulatory and research. OSHA, situated within the DOL, has the regulatory function. This agency is responsible for the creation and enforcement of workplace safety and health regulations. NIOSH, by contrast, conducts research to propose science-based standards designed to minimize work-related injuries and illnesses. NIOSH, part of the Centers for Disease Control and Prevention (CDC), is under the DHHS.

In addition to research aimed at preventing workplace injuries, NIOSH conducts injury surveillance and develops worker training and communication programs.⁴³

At the request of employers, employees (or their representatives), or government agencies, NIOSH investigators in the Health Hazard Evaluation Program conduct on-site workplace evaluations to identify potential or actual hazards, whether physical, chemical, or biological. The National Personal Protective Technology Laboratory conducts research that establishes standards of safety and protection for personal protective equipment such as respirators, gloves, and hard hats. The Sentinel Event Notification System for Occupational Risks (SENSOR) program, a collaborative effort with state health departments, has established ongoing surveillance programs to rapidly identify cases of exposures and injuries, including occupational asthma, pesticide poisoning, silicosis, amputations, burns, occupational dermatitis, and noise-induced hearing loss. Surveillance for occupational lead poisoning is conducted under a separate program, the Adult Blood Lead Epidemiology and Surveillance Program.

Agency for Toxic Substances and Disease Registry

In August 1978, the New York State Department of Health, the governor of New York, and President Jimmy Carter declared a state of emergency at the community of Love Canal, New York,⁴⁴ located near Niagara Falls. The houses and local public school of Love Canal were built on a former chemical waste dump site. Ultimately, families were evacuated, the school was closed, and state and federal funding was applied to the clean-up. Two years later (December 1980), Congress passed the Superfund law and in doing so, both expanded the powers of the EPA (as described above) and created a new agency, the ATSDR. The ATSDR was directed to assist the EPA in determining the exposure levels at which hazardous chemicals may result in adverse health effects.⁴⁵

The ATSDR conducts public health assessments at all sites proposed for or listed on the EPA's National Priorities List of sites for investigation and possible remediation.⁴⁶ The results of these public health assessments are made available to city, state, and federal agencies, and to the affected communities. In those situations where the ATSDR identifies exposure to hazardous substances at levels at or above those known to cause adverse health effects, they provide the EPA with recommendations to guide potential appropriate actions or interventions. In the event that a survey identifies an urgent public health threat, the ATSDR may warn the community by issuing a public health advisory.⁴⁶

The ATSDR is also legally required to develop and compile health information on hazardous substances. The ATSDR's Toxicological Profiles are a mandated health consultation activity and serve a broad purpose as key reference documents on specific substances. Each Toxicological Profile is based on comprehensive reviews of the toxicologic and epidemiologic literature available for a given chemical.⁴⁷

The ATSDR also conducts surveillance and registers exposed individuals for possible later follow-up. The

Hazardous Substances Emergency Events Surveillance System was created to gather information about both acute and threatened releases of hazardous substances that require some form of environmental or public health intervention.⁴⁸ Information concerning approximately 9000 events is captured annually. Of interest, only 25% to 30% of acute or threatened releases of hazardous substances are transportation related; the vast majority are "fixed facility" events that involve the release or threatened release of only a single hazardous substance. The National Exposure Registry is a database kept by the ATSDR of people who have been exposed to trichloroethylene, trichloroethane, benzene, or dioxin. The health of these individuals is then tracked.⁴⁹ The database thus serves as a tool to help facilitate epidemiologic studies of chemical exposures, generally at low levels and over long periods.

As part of its "Managing Hazardous Material Incidents" series, the ATSDR has developed medical management guidelines (MMGs), reference materials designed to assist emergency physicians and other emergency health care personnel to manage acute chemical and hazardous material exposures.⁵⁰ In addition to including basic chemical and exposure information and a summary of potential health effects that may result from exposure, MMGs provide prehospital management information, emergency department management information, and information concerning proper decontamination and use of personal protective equipment.⁵¹ Information for patients is also included in these documents. As part of its educational mission, the ATSDR publishes *Case Studies in Environmental Medicine*, a series of monographs written to provide health care providers with guidance concerning the management of exposed (and potentially exposed) individuals who present in an office setting.⁵²

National Center for Environmental Health

The National Center for Environmental Health (NCEH) of the CDC hosts a wide variety of scientific and programmatic activities in preventive toxicology. The NCEH has one of the foremost analytical toxicology laboratories in the world. The chemists and toxicologists of the NCEH laboratory have pioneered analyses for chemicals found at extremely low levels but which are nevertheless so potent that harm may result. Some analytical techniques are so sensitive that they yield measurements expressed in units of parts per quadrillion, that is, femtograms of analyte per gram of the matrix. To provide reliable analyses at this level of sensitivity, a program of intensive quality control with statistical checking on essentially every run has been put in place. The laboratory has become a center of reference for quality control techniques for measurement of specific chemicals in biologic matrices. The laboratory runs national programs of standardization for measurement of such analytes as cholesterol and lead. In the current era of concerns about terrorism, the laboratory has developed the capacity to measure rapidly and definitively some 200 analytes of concern for both

chemical warfare agents and toxic industrial chemicals that might be used by terrorists.

Another laboratory project, the periodically updated and expanded *National Report on Human Exposure to Environmental Chemicals*,⁵³ is of particular importance for clinical toxicologists. The project involves blood and urine samples collected as part of the National Health and Nutrition Examination Survey. The CDC's National Center for Health Statistics designed the survey such that appropriate statistical analysis yields estimates of the mean or median values (with confidence limits) of U.S. residents' levels of the chemicals measured in the specimens. The exposure of the U.S. population to an increasing number of substances is described in successive iterations of the report. The concept of "normal levels" is problematic when applied to xenobiotics. Nevertheless, the report provides a basis for comparison for the same analytes measured in individual cases. Although no xenobiotic level is "normal," a particularly high level may reflect "unusual" exposure.

Other programs of the NCEH include a program of targeted surveillance for high blood lead levels in children. This program also supports interventions designed to protect children from undue lead exposure. The asthma and respiratory diseases group investigates the factors involved in the gradually increasing levels seen in the United States in recent years of disease involving hyper-reactive airways.

A particularly strong asset of the NCEH is the capability to investigate new or unusual syndromes of chemical (or other environmental) origin. Although such investigations are typically supported by the very capable NCEH laboratory, a key part of the success of such investigations involves "old fashioned shoe leather epidemiology," requiring investigators to go to the field, ascertain key facts, organize data, and come to conclusions, supported (where possible) by laboratory analyses. The CDC's Epidemic Intelligence Service plays a key role in this activity.

National Institute of Environmental Health Sciences

The NIEHS, a component institute of the National Institutes of Health (NIH), supports and conducts research into the underlying mechanisms of disease caused by chemical and biologic agents found in the air, ground, food, and water, and develops appropriate interventions based on an understanding of those mechanisms.⁵⁴ The NIEHS is the lead agency in the National Toxicology Program (NTP), which conducts toxicologic testing programs within the DHHS. NTP also involves NIOSH and the FDA's National Center for Toxicologic Research.⁵⁵ In addition, the NTP provides administrative oversight to two centers: the Center for the Evaluation of Risks to Human Reproduction (CERHR) and the Center for Phototoxicology, a function it shares with the FDA (described above). Established in 1998, the CERHR assesses chemicals for their potential to affect human reproduction and development adversely.⁵⁶ The CERHR convenes independent panels to review all available scientific literature concerning chem-

icals that are nominated for review by industry, federal, state, and local governments, academia, environmental groups, and private citizens. The NIEHS/Environmental Genome Project conducts research designed to improve current knowledge of human genetic susceptibility to environmental exposures.⁵⁷ The research goals of the NIEHS/National Center for Toxicogenomics include improved understanding of the relationship between environmental exposures and human susceptibility to disease, identification of bio-markers of exposure to and disease caused by toxic substances, and creation of a public database of the effects of toxic substances in biologic systems.⁵⁸

NONGOVERNMENTAL ORGANIZATIONS

American Conference of Governmental Industrial Hygienists

The ACGIH was born out of the need to provide standards and guidance for managing occupational exposures to protect workers from health effects of harmful substances encountered in the workplace. Although the original members were largely government employees and its guidance is highly influential, the ACGIH is a private, not-for-profit, nongovernmental organization.⁵⁹ Members work as volunteers on committees to review the existing published, peer-reviewed literature. Experts in various scientific disciplines arrive at their judgments and guidance regarding the likely health impacts of exposures to chemicals and physical agents at specific levels. The members work to develop the guidance ultimately issued by the parent organization.

The bulk of this guidance ultimately developed by the ACGIH is issued as TLVs and biological exposure indices (BEIs). The TLV is meant to be the maximum permissible concentration of a material, generally expressed in parts per million in air, for some defined period of time (often 8 hours, but sometimes for 40 hours per week over an assumed working lifetime). TLVs and BEIs are guidelines, not standards. The ACGIH states that they are only two of multiple factors to be considered in evaluating specific workplace situations and conditions.

BEIs are intended for use in the practice of industrial hygiene as guidelines or recommendations to assist in the control of potential workplace health hazards and for no other use. Biologic monitoring entails measurement of the concentration of a chemical determinant in the biologic media of the exposed person and is an indicator of the uptake of the substance. The determinant (analyte) used to establish the BEI may be the chemical itself, one or more metabolites, or a characteristic reversible biochemical change induced by the chemical. The BEI is meant to correspond to the level of the determinant in a worker exposed at the level of the TLV.

Agencies of the United Nations

Established on April 7, 1948, the World Health Organization (WHO) is the United Nations' specialized

agency for health. The goal of WHO is to attain the highest possible level of health in all of the peoples of the world. Of interest, "health" is defined by WHO as state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity. A number of special units and subcomponents of WHO's program are dedicated to environmental health. Two deserve specific mention.

The International Programme on Chemical Safety (IPCS) is sponsored jointly by the United Nations Environment Programme, the International Labour Organisation, and WHO. The main objective of the IPCS is to carry out and disseminate evaluations of the effects of chemicals on human health and on the quality of the environment. Its activities include the development of epidemiologic, experimental laboratory, and risk assessment methods. The IPCS develops its methods with the specific aim of producing internationally comparable results. A further goal of the IPCS is the development of more person power in the field of toxicology. Other activities include developing the know-how to cope with chemical accidents, coordinating laboratory testing, conducting or supporting epidemiologic studies, and promoting research on the mechanisms of the biologic action of chemicals.

The IARC is also part of WHO. The IARC's mission is to coordinate and conduct research on the causes of human cancer and the mechanisms of carcinogenesis, and to develop scientific strategies for cancer control. The IARC is involved in both epidemiologic and laboratory research and disseminates scientific information through publications, meetings, courses, and fellowships.

ROBERT J. GELLER, MD

At a Glance...

- Pediatric environmental health is a relatively new discipline that examines the effects of environmental agents on the health of children.
- Children have greater risk of exposure to environmental agents, as well as greater susceptibility to toxic effects, than adults.
- A number of environmental pollutants are more likely to produce clinical toxicity in children than in adults. These include lead, mercury, and polychlorinated biphenyls.
- There is a growing list of environmental agents that act as endocrine disruptors with the potential to affect critical aspects of organogenesis in young children.
- Environmental regulations have recently begun to consider the unique susceptibilities of children in risk assessments and the establishment of exposure tolerances.

The field of pediatric environmental health may be unfamiliar to many. It is a relatively new discipline, one that attempts to combine the principles of environmental medicine with observations about metabolic pathways and toxicant-induced insults during the fetal, infant, and childhood periods of growth and development.

Many substances have the potential to affect children adversely. They range from organophosphate and carbamate pesticides to industrial chemicals such as polychlorinated biphenyls (PCBs) and by-products such as dioxins, from heavy metals such as mercury and lead to arsenic (Box 84-1). Even seemingly benign materials such as iodinated antiseptics and vaccine preservatives have become agents of concern.

This chapter provides an introduction to the principles of pediatric environmental health and discusses them in the context of several compounds. The chapter does not cover any of these issues exhaustively; the reader is

referred to the chapter covering the specific compound and to published monographs on pediatric environmental health for more information.¹⁻³ The reader also should recognize that our knowledge about many issues in pediatric environmental health remains fragmentary; consequently, different clinicians, scientists, and policy makers may reach differing conclusions even while using the same data.

ASSESSING RISK

For some compounds, injury occurs after a certain threshold concentration of the compound is exceeded in the target organ. For others, toxicity results from accumulation of one or more metabolites of the parent compound. When the concentration of the compound and its metabolites remain below the threshold level, toxic injury does not occur. This is often referred to as a *threshold*, or *deterministic* effect.

Other substances appear to pose a risk for toxic effect at any concentration. The risk at low concentrations is usually below the risk posed by other causes, but is not zero. As the intensity of exposure increases, the risk for adverse effect also increases. In some circumstances, intensity of exposure may reflect both dose and length of exposure. Effects displaying this pattern often are mediated by injury to DNA of a single cell or a few cells. This pattern can be called a *no-threshold*, or *stochastic*, effect.

Toxicologic effects usually follow deterministic patterns, whereas mutagenic and carcinogenic effects usually fit a stochastic model. Both deterministic and stochastic effects may display linear or curvilinear relationships between the risk for toxicity and the concentration of the substance. The slope of the line and the shape of the curve display the relative susceptibility of the individual to the compound. These concepts are illustrated in Figure 84-1.

In the science of risk assessment, the level below which toxicity cannot be demonstrated is often referred to as the *no observable adverse effect level* (NOAEL). This level is determined using available data, which are ideally human; in the absence of robust human data, data from various animal species at varying ages are used. It is always uncertain to what extent animal-derived NOAEL concentrations can be applied to humans across the age spectrum—humans may ultimately prove to be more susceptible (such as to thalidomide embryopathy), equally susceptible, or less susceptible than experimental animals. To account for these uncertainties, different expert and regulatory bodies take different approaches in establishing risk thresholds. One of the most widely used approaches is that of the U.S. Environmental

BOX 84-1**ENVIRONMENTAL TOXINS RELEVANT TO CHILDREN'S HEALTH**

Air particulates	Mercury
Arsenic	Ozone
Asbestos	Perchlorates
Carbon monoxide	Pesticides
Environmental tobacco smoke (ETS)	Polybrominated diphenyl ethers (PDBE)
Indoor air pollutants	Polychlorinated biphenyls (PCBs)
Lead	Radon
M-tert-butyl ether (MTBE)	Trichloroethylene

FIGURE 84-1. The dose–response curve of potential toxins, including drugs, chemicals, and physical agents, can have threshold deterministic and stochastic effects. Whether the curve is linear or curvilinear for stochastic phenomena can be debated, but it traverses 0. Toxicologic phenomena often follow an S-shaped curve, with a threshold below which no increased risks are expected. (From Brent RL, Tanski S, Weitzman M: A pediatric perspective on the unique vulnerability and resilience of the embryo and the child to environmental toxicants: the importance of rigorous research concerning age and agent. *Pediatrics* 2004;113[Suppl 4]:935–944.)

Protection Agency (EPA), which establishes a *reference dose* (RfD) or *reference concentration* (RfC) by starting with the NOAEL, adding a safety factor of 10 to account for interspecies difference, and adding another safety factor of 10 to account for interindividual differences. Since 1996, an additional safety factor of 10 is added to

account for differences between humans of various ages, having the primary goal of establishing safe tolerances for children.⁴ Existing data do not provide enough information to be certain that a factor of 10 is the best number to account for each of these differences.^{1,5} It is therefore important to remember that this strategy produces reasonable approximations for safe use in the absence of actual substance-specific data. It is desirable to obtain actual data, which can then be used to provide more accurate guidance. However, there is considerable controversy about the research ethics of intentionally exposing humans to toxic agents (e.g., pesticides) in an effort to firmly establish a NOAEL.

Some of the differences among infants, children, and adults in their response to substances can be attributed to the differences in pharmacodynamics and pharmacokinetics at different ages, which are addressed by the field of study called *developmental pharmacology*. Other differences in response between children and adults are related to physiologic differences between them. Table 84-1 summarizes these concepts.

DEVELOPMENTAL PHARMACOLOGY

Different enzyme systems mature at different rates during fetal development and childhood. Although drug dose estimations derived from adult doses per kilogram of body weight have been used for many years, we have learned that such dosing strategies sometimes do not produce the expected results. Toxic outcomes, such as the “gray-baby syndrome” following chloramphenicol use in neonates and increased neonatal sensitivity to opioids and benzodiazepines,^{6,7} have been observed when neonatal pharmacologic differences are not taken into account. Alternatively, dosing interpolated from adult doses to children may lead to decreased drug efficacy.

TABLE 84-1 Overview of Children’s Developmental Features that Can Affect Toxicokinetics

DEVELOPMENTAL FEATURE	RELEVANT AGE PERIOD	TOXICOKINETICS IMPLICATIONS
Body composition: lower lipid content, greater water content Larger liver weight/body weight	Birth through 3 mo Birth through 6 yr but largest ratios in first 2 yr	Less partitioning and retention of lipid-soluble chemicals; larger Vd for water-soluble chemicals Greater opportunity for hepatic extraction and metabolic clearance; however, also greater potential for activation to toxic metabolites
Immature enzyme function: phase I reactions, phase II reactions	Birth through 1 yr but largest differences in first 2 mo	Slower metabolic clearance of many drugs and environmental chemicals; less metabolic activation but also less removal of activated metabolites
Larger brain weight/body weight; greater blood flow to CNS; higher BBB permeability Immature renal function	Birth through 6 yr but largest differences in first 2 yr Birth through 2 mo	Greater CNS exposure, particularly for water-soluble chemicals that are normally impeded by BBB Slower elimination of renally cleared chemicals and their metabolites
Limited serum protein-binding capacity	Birth through 3 mo	Potential for greater amount of free toxicant and more extensive distribution for chemicals that are normally highly bound

BBB, blood-brain barrier; CNS, central nervous system; Vd, volume of distribution.
Adapted from Ginsberg G, Hattis D, Miller R, Sonawane B: Pediatric pharmacokinetic data: implications for environmental risk assessment for children. *Pediatrics* 2004;113 (Suppl 4):973–983.

Compounds dependent for their metabolism on cytochrome isoforms such as CYP1A2 and CYP2A4 may undergo minimal biotransformation in utero because of the immaturity of cytochrome isoenzyme function in the fetus. CYP3A7 is present in large quantities during late fetal development and growth, fading rapidly after birth. To the extent that CYP3A7 metabolizes substrates similar to CYP3A4, the behavior of compounds principally metabolized in adulthood by CYP3A4 can be predicted. However, even this remains an approximation because the metabolic patterns of CYP3A4 and CYP3A7 are not identical.⁸⁻¹² Developmental differences in cytochrome function also have implications in how children are affected by environmental toxicants. For example, polyaromatic hydrocarbons are metabolized to carcinogenic metabolites by CYP2A1. The relative immaturity of this enzyme in infants potentially confers protection from the carcinogenicity of these compounds. These concepts of developmental pharmacology are illustrated in Figure 84-2.

Other pharmacokinetic parameters also change as the child develops and matures. Total-body water decreases from about 0.8L/kg (80% of body weight) to about 0.6 L/kg (60% of body weight) by 5 months of age.⁸ Albumin binding sites may be present in lesser quantities, owing either to lower albumin levels or to these sites being occupied by bilirubin, which is normally

present in higher concentrations in neonates and young infants than in adults. Lipid content may be lower in the young infant, resulting in increased deposition of lipophilic compounds in lipophilic organs such as the central nervous system (CNS).

PHYSIOLOGIC SUSCEPTIBILITIES

Infants and young children differ from adults in other ways that make them more susceptible to exposure and are more likely to develop exaggerated responses when exposed to environmental toxicants.

Infants display rapid growth. Their weight typically doubles by 3 months of age and triples by the end of their first year of life. Their length increases by 50% in the first year. To fuel this rapid growth, infants consume large amounts of food relative to their body weight. Initially, this comes from breast milk or infant formula. Environmental toxicants may have an impact on both. For example, breast milk can contain contaminants such as dichlorodiphenyltrichloroethane (DDT), PCBs, and polybrominated diphenyl ethers (PDBE). Infant formula is typically used in a powder or concentrated form, both of which require the addition of water. A formula-fed infant may ingest more than 100 mL/kg/day of water. Consequently, even the smallest degree of water contamination can lead to significant exposures in infants. As newborns become infants, a small number of foods make up a disproportionate amount of their solid intake. For example, compared with adults, young children eat significantly more fruits, particularly apples and grapes; they also consume disproportionately greater amounts of potatoes and beef (Figure 84-3).

Infant skin is less keratinized and more permeable than adult skin, which may lead to higher absorption of substances across the skin. As an example, premature infants exposed to topical povidone-iodine antiseptic agents have had elevations of plasma iodine levels, with resultant impact on thyroid function.¹³ Melanocytes, the pigmented cells of the skin, are postulated to be more sensitive to the carcinogenic effects of exposure to ultraviolet light.¹³

FIGURE 84-2. Changes in the activity of cytochrome systems at various ages. (Adapted from Kearns GL, Abdel-Rahman SM, Alander SW, et al: Developmental pharmacology: drug disposition, action, and therapy in infants and children. *N Engl J Med* 2003;349:1157-1167, and Lacroix D, Sonnier M, Moncion A, et al: Expression of CYP3A in the human liver: evidence that the shift between CYP3A7 and CYP3A4 occurs immediately after birth. *Eur J Biochem* 1997;247:625-634.)

FIGURE 84-3. Differences in intake of selected food choices at various ages. (From Etzel RA, Balk SJ (eds): *Pediatric Environmental Health*, 2nd ed. Elk Grove Village, IL, American Academy of Pediatrics Committee on Environmental Health, 2003, p 14.)

The infant immune system is still maturing and is not fully functional for at least the first few months of life. Various compounds may affect the immature immune system's development differently than they affect a mature immune system. In terms of infant lymphocyte maturation, infant exposure to environmental agents in the current era is postulated to be biased toward developing immune systems with a predominance of Th2-type CD4 T cells; these favor the development of an atopic state, away from Th1-type cellular immune responses (the so-called hygiene hypothesis).¹⁴

During their first year of life, infants and young children have a relatively higher minute ventilation (500 mL/kg/min versus 140 mL/kg/min in adults). Moreover, they breathe air that is closer to the ground because they crawl rather than walk upright (the "personal breathing zone"). This combination of factors predisposes them to toxicity from inhaled substances, particularly those present in higher concentration in air close to the ground. Settling of heavier-than-air compounds can particularly occur when air is stagnant or has uneven circulation.

The immaturity of the child's gastrointestinal and renal systems also has potential impact on the effects of exposure to environmental agents. The gastrointestinal tract of the child has greater permeability than that of the adult. For example, the gastrointestinal tract of the child absorbs up to 50% of ingested lead, whereas the gut of an adult absorbs about 10%. The glomerular filtration rate of children does not achieve adult capacity before 6 months of postnatal age, thereby reducing the ability of children to excrete toxicants.

Several aspects of brain development place the child at significantly increased risk for adverse neurodevelopmental effects after exposure to CNS neurotoxins. First, dendritic arborization, the process by which neuronal dendrites proliferate extensively, occurs primarily in the first 3 years of life. Second, the critical process of neuronal pruning, which eliminates useless and redundant neuronal connections, occurs during the same period. Third, myelination of neurons in the CNS occurs progressively during the first few years of life. Finally, the blood-brain barrier, which is designed to protect the CNS by preventing the intrusion of xenobiotics, is not completely formed until the second or third year of life. As a consequence of these critical aspects of development, children have a much greater risk for CNS injury, which could be permanent, when they are exposed during early childhood to environmental toxicants known to have any of these effects. The greater toxicity of lead, mercury, and other CNS neurotoxins to children is presumed to be the result of these CNS vulnerabilities.¹⁵ Lead toxicity may be the result of both early and ongoing toxic effects of lead.¹⁶ Lead poisoning is discussed in more detail in the chapter on lead toxicity, and has also been the subject of several excellent recent reviews.¹⁵⁻¹⁷ The fetus and young infant are more susceptible to adverse neurodevelopmental outcomes after exposure to both organic mercury and inorganic mercury vapor. Severe methylmercury poisoning afflicted more than 3000 humans, many of them infants, in Minamata and Niigata, Japan, in the 1950s, as a result of

industrial discharges into coastal waters that were the source of fish eaten by local residents. Although their mothers remained asymptomatic, 22 infants exposed in utero to the methylmercury displayed severe developmental disabilities.¹⁸ A similar poisoning event occurred after the consumption of bread made from grain treated with a methylmercury fungicide.¹⁸ The brain of the fetus has been estimated to be 10 to 15 times more sensitive to mercury effects than the brain of infants and children.

The endocrine system of children may also be more susceptible to harm from environmental agents. So-called *environmental endocrine disruptors* (EED) are chemical that in vitro possess an ability to act on the endocrinologic system. The list of putative EEDs is long and includes herbicides, fungicides, and plasticizers. Agents of great concern are bisphenol-A (a weak estrogen found in many plastics), phthalates (an agent commonly used in plastics with suspected spermatotoxic effects), PCB (which can affect the duration of lactation in women and the age of menarche in young girls), arsenic (which appears to have toxicity on the adrenal cortex), and perchlorates, dioxin, and PDBE (all of which have suspected effects on the thyroid). The clinical significance of these compounds remains controversial.^{19,20}

GOVERNMENTAL AND NONGOVERNMENTAL APPROACHES

Our current knowledge does not always permit firm conclusions. Nonetheless, governmental and nongovernmental agencies, having a need to act prudently in order to mitigate risks to humans at all ages, must often perform risk assessments and provide recommendations in the absence of complete data. Many government agencies, at federal, state, and local levels, have enacted legislation aimed at protecting the public. Many other organizations also are involved in research, advocacy, and education regarding environmental issues and their impact on children.

The growing concern about environmental threats and the need to reduce exposure often comes in conflict with policy and recommendation, where an evidence-based approach is desired before restrictions are placed on the release of pollutants (known and suspected) into the environment. This issue has led to the development of what is known as the Precautionary Principle. The Precautionary Principle holds the belief that when agents are thought to be harmful, it is more prudent to restrict their use rather than to use them until evidence of harm is found. This Principle has become a key tenet in advocacy on environmental health, particularly children's environmental health. However, although the Precautionary Principle has been adopted by many nations and organizations (e.g., the European Union), it has met considerable resistance elsewhere. The basis of this resistance is that the Principle would produce undue restraint on the development of new products that help to advance society. Consequently, the Precautionary Principle remains controversial among both scientists and policy makers.

Many organizations, governmental and nongovernmental, have taken a lead role in protecting children from environmental threats. The American Academy of Pediatrics, for example, created its Committee on Environmental Health (COEH) in 1947 as a response to concerns about the impact of radioactive fallout from nuclear testing. The COEH has produced educational material and policy statements on issues in pediatric environmental health since its inception. Recently, the Committee produced a manual, *The Handbook on Pediatric Environmental Health*, designed to be a current, thorough resource on environmental health issues; a second edition of the handbook was released in 2003.¹ The EPA and the U.S. Agency for Toxic Substances and Disease Registry (ATSDR) jointly created the Pediatric Environmental Health Specialty Units (PEHSUs) in 1998, having the goal of creating a national network of environmental health clinical programs where parents and pediatricians could refer children for evaluation. A PEHSU is now located in each of the 10 U.S. EPA regions as well as in Mexico and Canada. The PEHSUs respond to inquiries from parents and professionals. They also educate the local population through education and outreach efforts. Additionally, EPA and the National Institute for Environmental Health Sciences (NIEHS) have created pediatric environmental health research units that are actively involved in performing and sponsoring research that improves understanding of pediatric environmental issues. Finally, in 1997, EPA created an Office of Child Health Protection whose goal is to ensure that EPA, as the nation's primary regulatory agency around environmental pollutants, consistently includes pediatric issues in all of its rulemaking.

CONCLUSIONS

The vulnerability and sensitivity of children to environmental agents is significantly different from that in adults. Because of the unique susceptibility of children to environmental toxicants, risk assessments and the subsequent policies they create now commonly include these pediatric issues.

A large group of environmental pollutants affects children much more than adults. Pollutants in this category include lead, mercury, endocrine disruptors, and pesticides. Because of marked differences in the effects of these toxicants between children and adults, clinical management is significantly different.

These principles of children's environmental health are rapidly evolving into a new and unique clinical discipline.

At a Glance...

- Patients with a number of psychiatric diagnoses may present with signs and symptoms they attribute to being poisoned.
- The determination of whether a chemical substance can cause a particular condition requires the application of appropriate methodology.
- The conduction of an epidemiologic study that applies the criteria promulgated by Hill can be used to clarify whether there is a statistically significant relationship between an exposure and outcome in question.
- Common perceived toxicologic syndromes for which application of appropriate methodology has failed to confirm a causal relationship are allegations of mercury toxicity from dental amalgam, systemic and cognitive symptoms from mold, childhood developmental disorders caused by the organomercurial preservative thimerosal in vaccines, and idiopathic environmental intolerance from low level exposures.

INTRODUCTION AND RELEVANT HISTORY

Matter, the tangible stuff of which biologic organisms and the world in which they live are made, is by definition composed of chemical substances. In the absence of a true vacuum, the entire world around us, both perceived and nonperceived (e.g., air), is a complex mixture of chemical substances. However this scientific depiction of our chemical world differs from the public perception that chemical substances, by their intrinsic nature, are harmful. Thus, for example, patients with the condition referred to as *idiopathic environmental intolerance* (IEI), formerly *multiple chemical sensitivity* (MCS), frequently complain that they develop symptoms when exposed to “chemicals.”

The fundamental misconception regarding our exposure to chemical substances in the minds of the lay public, and too often in that of some health care practitioners, is easily fueled by nonscientific, non-peer-reviewed information disseminated by the popular press and Internet. These misconceptions and popularizations of nonsupportable scientific myths can create the perception of being poisoned by chemical substances, particularly in those individuals whose psychological constitution renders them vulnerable to these beliefs. This chapter critically examines a number of these so-called toxic syndromes and assesses whether or not there is scientific support for concluding that they have a true toxicologic etiology.

PSYCHOPATHOLOGY AND THE PERCEPTION OF TOXIC INJURY

The understanding of the etiologic nature of these syndromes is of fundamental importance in patient care because the misattribution of a toxicologic etiology to a patient’s complaints may divert clinical attention from their psychiatric issues or medical diagnoses by reinforcing the belief that they are suffering a toxin-induced condition. Appreciation of the emotional features that may render an individual vulnerable to the development of these disorders is important for their appropriate treatment. Patients who attribute symptoms to a physical illness, when the true etiology is predominantly psychological in nature, are most commonly diagnosed with somatoform disorders, personality disorders, and mood disorders (i.e., depression and bipolar disorder). Alternatively, in cases in which secondary gain issues are present, such as in litigation, patients may engage in feigning of symptoms due to toxic exposure. This is diagnosed as malingering. When the sole purpose of the conscious, false presentation is to assume the so-called “sick role,” the diagnosis is factitious disorder. Somatoform disorders are a cluster of psychiatric conditions in which bodily perceptions or functions are influenced by a mental disorder. According to the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR), somatoform disorders exist when “physical symptoms that suggest a general medical condition are not fully explained by a general medical condition, the direct effects of a substance or by another mental disorder.”¹ The symptoms must cause significant distress or impairment in important areas of functioning and are not intentionally feigned. The key feature of the somatoform disorders is that psychological factors and conflicts are deemed important in initiating, exacerbating, or maintaining the disturbance. These patients characteristically are highly suggestible and are vulnerable to becoming convinced that they are experiencing serious physical problems. As such, they are frequently characterized as “reliable historians.” This may result in the institution of medical treatment that may further reinforce their belief system or lead to iatrogenic conditions. Frequently, this leads to a vicious cycle of overinterpreting symptoms, development of increased anxiety, and creation of additional physical symptoms.² Addition of medication to treat anxiety may lead to adverse effects, including those affecting cognition, a frequent complaint in toxic exposures.

If patient symptoms are limited to the neurologic realm (i.e., motor and sensory function deficits) the diagnosis of conversion disorder is made. This is the most common type of somatoform disorder. Historically, the term *conversion* was first used by Sigmund Freud to describe the substitution of a somatic symptom for a repressed thought. Today, the *DSM-IV-TR* definition is more limited, yet the historical basis still continues to have importance in arriving at treatment recommendations. Treatment is aimed at focusing on the patient's psychological issues and, when possible, gaining insight into the meaning of the patient's symptoms. Direct confrontation of the patient's physical symptoms is discouraged, and this approach most commonly results in increased somatic complaints.

ASSESSMENT OF TOXICOLOGIC CAUSATION

To assess whether a specific medical condition is potentially caused by a toxic exposure, it is necessary to formally assess the likelihood of the existence of a true causal nexus between the chemical exposure and the condition in question. Doing so requires a formal scientific analysis of the relevant data using appropriate methodology.

The determination of whether a causal nexus exists between a toxic exposure and a subsequent medical illness is necessary to assess the likelihood of causation. Often, the possibility of such an association is raised by animal studies or anecdotal observations, such as those originating from case reports or uncontrolled case series. In many circumstances, these kinds of observations cannot truly assess the risk, if any, of developing a specific medical condition after an exposure. Thus, these observations are primarily useful for generating hypotheses about a potential causal relationship. In most instances, a controlled study, such as an epidemiologic investigation or a prospective trial, constitutes the primary source of evidence supporting causal hypotheses. If an association between a chemical exposure is demonstrated to exist in an epidemiologic study, the likelihood that this association represents a true causal nexus can be assessed by using the criteria promulgated by Hill.³ This methodology is graphically illustrated in Figure 85-1.

A poignant example of anecdote versus epidemiology unfolded throughout the 1990s in the scientific investigation concerning the possible association between silicone breast implants and systemic rheumatologic conditions. Based on anecdotal observations of women with silicone breast implants who developed various rheumatologic conditions, it was hypothesized that there was a relationship between these devices and autoimmune or connective tissue diseases in these women. This was sensationalized in 1990 by a television broadcast by a major U.S. network suggesting that women were being harmed from these implants. The ensuing years were characterized by a flurry of litigation based on this hypothesized relationship, resulting in the bankruptcy of a major U.S. corporation. However, starting in 1993, and continuing throughout the next decade, at least 30 epidemiologic studies were published that evaluated the relationship between breast implants and systemic medical diseases or symptoms potentially referable thereto. This subsequent large number of studies has conclusively demonstrated that these implants do not confer any risk for having either these diseases or associated symptoms. Finally, in 1999, the U.S. National Academy of Sciences, Institute of Medicine (IOM) published a report concluding that there was no demonstrable association between silicone breast implants and the conditions that they were alleged to have caused.⁴ Since the publication of the IOM report, further epidemiologic studies have been published, adding yet additional data supporting the lack of relationship between silicone breast implants and systemic disease.^{5,6}

The scientific landscape is replete with other examples of overreaction to preliminary observations, which were subsequently proven wrong. It is interesting to note that there is a predictable evolutionary course for unfounded toxicologic notions. First, observations that lack scientific surety, such as anecdotes or rodent studies, generate a hypothesis that, before subject to the proper scrutiny described previously, becomes a widely held notion, often associated with considerable litigation. This attention leads to epidemiologic studies, which, if negative, generates an in-depth examination by the IOM, which finally puts the matter to rest. The tragedy of this repeating theme is that it consumes large amounts of societal resources, simply because of the sensationalism of preliminary observations.

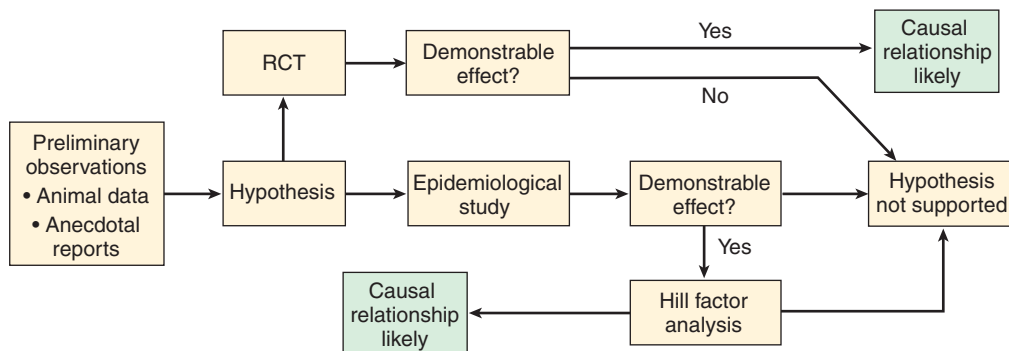

FIGURE 85-1 Steps in the formal methodology for assessing whether a causal nexus exists between a chemical exposure and a medical condition. This methodology employs Hill factor analysis.³ RCT, randomized clinical trial.

This chapter critically evaluates allegations of disease related to chemical exposures by focusing on four prototypical examples of alleged harm supported more by nonconventional sources than rigorous scientific studies. Yet these are perceived by a significant proportion of the population as representing true chemical hazards. Specifically, this chapter focuses on claims of systemic mercury poisoning from dental amalgam, autism from mercurial preservatives in vaccines, mold as a cause of systemic disease, and IEL.

DENTAL AMALGAMS AND MERCURY TOXICITY

Dental caries are a major form of oral morbidity, and their repair is essential to the maintenance of the masticatory function, which is important for ensuring normal human nutrition. The treatment of simple caries involves restoration with nonbiologic materials. Reports of the use of mercury for dental restoration can be found in 7th century Chinese literature. However, starting about 150 years ago, Western literature began to promote mercury-containing amalgams for this purpose. These are still used widely, although they are being replaced by other composites. The reason for the phasing out of mercury amalgams is primarily to reduce exposure to dental personnel and concern for environmental mercury contamination. However, there is an additional concern raised by advocacy groups who believe that systemic toxicity from mercury may occur as a result of having amalgams. Remarkably similar to the situation with breast implants, the discourse on this topic was further stimulated by a 1990 segment on the popular yet sensationalistic television program *60 Minutes* called “Is there Poison in Your Mouth?”

The controversy about potential adverse effects of amalgam stems from findings of concentrations of mercury in the oral cavity of amalgam-containing patients that might exceed occupational air level guidelines. These data generally derive from experiments using either vapor collectors, such as those that absorb mercury on gold or silver, or spectrophotometers. However, these instruments are designed to detect mercury leaks in large spaces. For example, accurate spectrophotometric analysis requires a constant flow rate, a condition that cannot be satisfied during intraoral measurements. In 1985, there were two reports of measurements of mercury intraoral mercury vapor, which incorrectly treated the concentration in their collection vessel as if it were representative of intraoral levels.^{7,8} Such an assumption introduced a large overestimation of oral mercury concentration.⁹⁻¹¹ In order to avoid this kind of error, it is important to avoid equating concentration measurements with dose. Dose is best determined by the release rate of mercury from the amalgams. As discussed subsequently, this has been done and found not to be toxicologically consequential.

Standard dental amalgams contain about 50% mercury in its elemental form (Hg^0), combined with

other metals such as copper or silver. Mercury has a small but measurable ability to volatilize (vapor pressure, 0.0013 mm at 20° C) (see Chapter 71). During normal wear and tear, small amounts of elemental mercury are vaporized into the oral cavity, where it can be inhaled or solubilized in saliva and swallowed. Microparticles may also be generated during the chewing process. It is this small amount of mercury that constitutes a systemic dose and has led to the concerns about alleged mercury poisonings from amalgams.

About 80% of mercury vapor that is inhaled is subsequently absorbed.¹² The amount of mercury released in patients with amalgam is less than 10 $\mu\text{g}/\text{day}$.¹³ For patients with few restorations, the ultimate pulmonary absorption may be as low as 1 $\mu\text{g}/\text{day}$; the absorption is greater in those with a larger number of amalgam surfaces.¹¹ In contrast, only 0.01% to 0.04% of evaporated mercury vapor that is swallowed will be absorbed.¹² This also amounts to about 1 $\mu\text{g}/\text{day}$, but it is in the form of mercuric ion, which does not appreciably cross the blood-brain barrier. The amount of mercury absorbed is, thus, significantly less than the World Health Organization (WHO) acceptable daily limit of mercury ingestion of 40 μg . Once absorbed into the circulation, mercury has a blood half-life of about 2 days¹⁴ but a total-body half-life of about 60 days.¹⁵ There is some pulmonary clearance of circulating mercury; up to 15% of the absorbed dose is exhaled by 1-week after exposure^{16,17} (Fig. 85-2). To put these doses in context, the total mercury exposure from all sources in nonoccupationally exposed individuals is estimated to be between 2.3 to 5.8 $\mu\text{g}/\text{day}$.¹⁸ Thus, in non-fish-eating populations, dental amalgam is potentially the largest source of mercury exposure. Heavy fish or seafood eaters may ingest larger amounts of mercury, but in the form of the organomercurial methyl mercury.

Being lipid soluble, Hg^0 may bidirectionally diffuse across the blood-brain barrier (see Fig. 85-2) and has the potential to be neurotoxic in sufficient doses. Once in the brain, elemental mercury that does not diffuse out may be oxidized to Hg^{2+} (mercuric ion). The mercuric ion has a very high affinity for sulfhydryl groups, such as those found on glutathione (GSH), cysteine, metallothioneins, polypeptides, and proteins.¹⁹ Mercury can also bind to selenium. It is likely that binding to GSH, metallothioneins, and selenium represents protective pathways, whereas binding to sulfhydryl groups of structural proteins and enzymes may be either protective or result in functional alterations. Although the kidney is the major storage organ for Hg^0 , about 7% of an absorbed dose is stored in the brain.^{16,20} Studies on human cadavers indicate that occipital lobe mercury concentrations in the absence of amalgams are about 7 ng/g.²¹ Each amalgam surface adds only about 0.24 ng/g to this value.^{10,22} Occipital lobe is chosen for these studies because it is a primary target of mercury toxicity, explaining the characteristic constriction of visual fields seen in mercurialism. Most of the elemental mercury absorbed is systemically oxidized by catalase to Hg^{2+} , which can be excreted. Although there is some biliary mercury clearance, most (60%) is renally

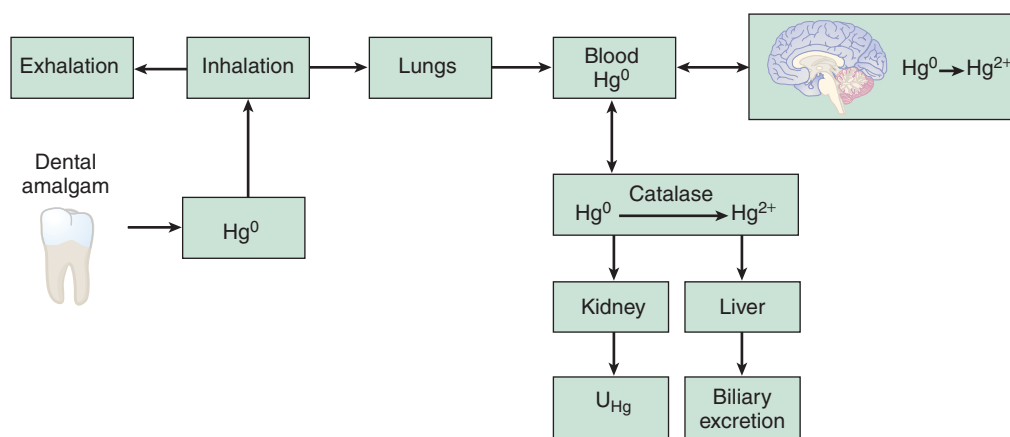

FIGURE 85-2 Body handling of mercury released from dental amalgam.

eliminated.²³ Thus, urine mercury concentrations are an excellent quantitative biomarker for Hg^0 exposure.²⁴

Because mercury vapor is released from amalgams, there is a relationship between the number of amalgam surfaces and the blood and urine mercury concentration (U_{Hg}).²⁴ However, the U_{Hg} of amalgam-bearing patients is in the 2- to 4- $\mu\text{g}/\text{L}$ range, which is 12- to 25-fold lower than the acceptable U_{Hg} for occupationally exposed workers.¹⁵ The combined urinary and biliary excretion of mercury is sufficient to clear an absorbed daily amalgam-derived dose.¹³

Elemental mercury has been implicated as causing immune dysfunction, antibiotic resistance, autoimmune diseases such as systemic lupus erythematosus and multiple sclerosis, and vague symptoms of neurotoxicity. Like most chemical substances, elemental mercury can cause hypersensitivity reactions in predisposed individuals. These are very rare; about 50 cases have been reported. The literature contains descriptions of a few cases of type I (anaphylactic) reactions.²⁵ More commonly, when hypersensitivity reactions occur from dental amalgam, they represent a type IV reaction and are manifested by oral lichenoid manifestations.²⁶⁻²⁹ However, there is little to support allegations of alterations in normal flora, systemic immunologic abnormalities, or autoimmune disease resulting from amalgams. Among the most studied of the effects of amalgam have been those relating to mood and to neurocognitive and neuropsychological function. The most comprehensive study to date broadly assessed health effects related to any body system, evaluated neurologic effects in great detail, and assessed for renal disease because the kidney is a major end organ for mercury poisoning.³⁰ No amalgam-related adverse effects were found. However, a high frequency of psychiatric diagnoses has been reported in patients who attribute their symptoms to amalgams.^{31,32} In a dedicated multidisciplinary clinic for patients with concern about amalgam, it was found that among 379 patients evaluated, the presence of symptoms, as measured by the Standard Symptom Checklist-90 (SCL-90) questionnaire, was very high, with 20 or

more symptoms commonly reported.³³ The most common symptoms were myalgias, arthralgias, weakness, fatigue, dizziness, difficulty in concentrating, headache, anxiety, and depression. More than 70% of the patients had serious psychological trauma in the past year, and nearly 10% of patients were found to have previously undiagnosed significant medical problems. The results of the SCL-90 showed a tendency to somatization in almost 70% of the patients. Elevated parameters for anxiety, depression, and obsessive tendencies were common. No patient had mercury toxicity.³³ A number of other recent studies have similarly suggested psychological etiologies for amalgam-related symptoms.³⁴⁻³⁶ A recent in-depth review commissioned by the U.S. government found that the existing data of this body of literature fail to support amalgam-related health effects.³⁷

Poisoning from elemental mercury is well described and is characterized by tremor, constriction of visual fields, alterations in renal function, ataxia, psychological syndrome known as erethism, and gingivitis-stomatitis (see Chapter 71). This characteristic spectrum of mercurialism is markedly different than the aforementioned complaints of individuals with symptoms they attribute to dental amalgam.^{38,39}

Further support for the notional, rather than physiologic, basis for complaints related to mercury from dental amalgams comes from the study of the effects of chelation therapy on symptoms in patients who have attributed their illnesses to their amalgams. In a double-blinded randomized trial on patients ascribing their symptoms to dental amalgam, there was improvement reported after chelation therapy. Improvement was similar, however, in the group that received placebo.⁴⁰ The significant placebo effect demonstrable in these patients might indicate that they have heightened suggestibility.

Subsequent to concern raised by advocacy groups, governmental agencies in Europe,⁴¹ Canada,^{42,43} Australia,⁴⁴ and the United States,^{37,45,46} as well as nongovernmental organizations such as WHO,⁴⁷ the

American¹⁸ and Canadian Dental Associations,¹⁸ and the National Multiple Sclerosis Society⁴⁸ studied the strength of the association between dental amalgams and human mercury poisoning. These groups have all concluded that, in the absence of demonstrable hypersensitivity reactions, there are insufficient scientific data to conclude that there is a relationship between mercury exposure from dental amalgams and their various alleged effects.

AUTISM FROM THIMEROSAL IN VACCINES

The organomercurial preservative thimerosal has been used in a number of biologic preparations since the 1930s. At that time, various mercurials were used for a number of purposes, including the treatment of infectious diseases and as diuretics. Nonorganomercurials are no longer used for these purposes because of their relatively low margin of safety and the introduction of more efficacious agents. However, organomercurials were found to have minimal toxicity and a favorable safety profile. Based on this, ethyl mercury salicylate (thimerosal) was developed and ultimately became widely used as a pharmaceutical under the brand name of Merthiolate. A number of early papers indicated that relatively large doses of Merthiolate did not cause toxicity to humans or animals.⁴⁹ The first major clinical use of Merthiolate use was reported in 1930, which involved intravenous administration of large doses of thimerosal as an “antiseptic solution” for the treatment of meningococcal meningitis.⁵⁰ Thimerosal was also administered intranasally to people with positive nasopharyngeal cultures for meningococcus. No significant toxicity from thimerosal administration to either the patient or the carriers was reported.

Widespread use of Merthiolate blossomed during World War II when large amounts of serum and plasma were used for resuscitation and volume support. Despite its widespread use, no significant toxicity was associated with Merthiolate except for possible allergic reactions. Throughout this time period, and for the balance of the 20th century, thimerosal was widely used.

Because of the tremendous public health benefit of vaccines, the number and types of vaccinations steadily rose throughout the 1990s. Coincident with the increased intensity of childhood vaccination, there has been a rise in the incidence of autism spectrum disorder (ASD), largely due to changes in diagnostic practices. This temporal relationship has led to speculation that there may be a relationship between the administration of vaccines and childhood ASD. A number of advocacy groups that have embraced the concept that vaccines are causally related to the increase in ASD have focused on the thimerosal in these vaccines and have suggested that this compound may cause autism. These claims have been widely distributed on a number of Internet sites. As a result, many families have opted to attempt to forgo vaccination or even subject their children to chelation therapy. Speculation about the role of thimerosal in the

etiology of ASD was fueled by a widely quoted analysis that inappropriately applied the U.S. Environmental Protection Agency (EPA) reference dose (RfD) for *methyl mercury* to thimerosal.⁵¹ Restriction of the analysis to the first 6 months of life and a full vaccination schedule leads to the potential for exceeding this dose based on vaccine administration. However, this is an illogical comparison for a number of important reasons. The EPA RfD, as noted previously, is for methyl mercury. Thimerosal is known to quickly dissociate to ethyl mercury. Ethyl mercury and methyl mercury are markedly different in their toxicologic and pharmacokinetic properties. Thus, the methyl mercury RfD should not be considered applicable to thimerosal or ethyl mercury.⁵² Further, the RfD for methyl mercury is based on a study of a fish-eating population in the Faroe Islands, where subtle decrements on neurocognitive testing in children have reported an inverse correlation between blood and hair mercury concentrations and testing results.⁵³ A very similar study, done on another predominantly fish-eating population in the Seychelles Islands, however, has failed to find a similar effect based on hair mercury concentrations.⁵⁴ Thus, the Faroe data, on which the EPA RfD is based, are questionable. It should also be noted that the effects reported in the Faroese cohort are very subtle and based strictly on sensitive neurocognitive testing. There were no clinically discernible mercury-related effects based on physical examinations or maternal reports. Thus, the EPA RfD is based on very subtle and questionable effects that have nothing at all to do with ASD. The concentration of mercury from vaccines, which before the removal of thimerosal in 1999 was generally 12.5 or 25 μg per vaccination, is extremely small and therefore would not be expected to cause toxicity of any kind.

Because of the allegations of ASD being caused by thimerosal from childhood vaccination, a number of epidemiologic studies have evaluated whether an association exists between mercury administration from thimerosal and ASD. These studies have failed to find a relationship between the administration of mercury-containing vaccines and ASD.⁵⁵ Based on these epidemiologic studies, the considerations described previously, and other factors, the IOM published a report in 2003 formally rejecting the hypothesis of an association between thimerosal administration and the subsequent development of ASD.⁵⁵

MOLD AS A SOURCE OF SYSTEMIC DISEASE

The term *mold*, as used in this chapter, refers to a ubiquitous subgroup of fungi that grow as multicellular visible colonies containing large numbers of intertwined hyphae. Fungi are a group of spore-forming eukaryotic organisms that some put in their own unique kingdom. Other nonmold fungi of toxicologic interest are mushrooms, which are discussed in detail in Chapter 23. An additional group of nonmold fungi is responsible for human morbidity, including opportunistic organisms

(e.g., coccidioides, histoplasma) and superficial integumental infections such as tinea pedis and onychomycosis.

Mold tends to grow in damp environments, a condition satisfied by virtually all buildings some, or most, of the time. Concern for environmental mold as a source of major human disease to the nonimmunocompromised host was fueled in the early 1990s when investigators initially implicated the mold *Stachybotrys chartarum* in several cases of infantile pulmonary hemorrhage in Cleveland.⁵⁶ Although these cases focused attention on potential systemic disease caused by environmental mold exposure, particularly *Stachybotrys* species, subsequent reanalysis of these cases by both the IOM and the U.S. Centers for Disease Control and Prevention have failed to verify the link between mold exposure and these cases.^{57,58} In the interim, however, there has been an explosion of allegations on the Internet, fueled by advocacy groups and other interested parties, linking environmental mold exposure and multiple systemic symptoms or diseases, a phenomenon that one editorialist deemed “mold madness.”⁵⁹

There are a number of health problems that are potentially attributable to molds; therefore, any complaint of mold-related illness must consider these diagnoses. Most prominent are allergic reactions, which may be either immunoglobulin E (IgE)- or IgG-mediated. The former causes atopic effects, such as rhinosinusitis, atopic asthma, or dermatitis. IgE is generally reactive with fungal proteins of either hyphal or spore origin. The most prominent indoor molds that cause immediate hypersensitivity are *Aspergillus* and *Penicillium* species.⁶⁰ Typical outdoor molds of interest are *Alternaria* and *Cladosporium* species.⁶⁰ Individuals who have IgE-mediated immediate hypersensitivity to molds tend to be more generally atopic and thus respond to other common environmental allergens. Much less common is IgG-mediated hypersensitivity in the form of extrinsic allergic alveolitis (EAA), formally referred to as hypersensitivity pneumonitis. Individuals with mold-related EAA have generally been exposed to large amounts of mold-derived protein and develop an exaggerated IgG response. Because this is due to inhalation, the antibody-antigen interaction occurs in the lung. A more detailed discussion of mold-related EAA can be found in other references.⁵⁷ Ingestion of the plant fungus *Claviceps purpurea* caused the vasospastic syndrome known as *St. Anthony's fire* from ergot alkaloids produced by the fungus.⁶¹

Molds may also produce mycotoxins, which are large molecules elaborated from fungi. Because of their size, they have a low vapor pressure and are thus not a significant airborne threat. However, when ingested, mycotoxins may cause aflatoxicosis and manifest as liver or renal disease. Mold is also found as a commensal organism colonizing the human vagina and gastrointestinal tract.

A number of adverse health outcomes have been associated with exposure to indoor mold. These have primarily been related to the respiratory system but have also involved allegations of dermatologic, gastrointestinal, connective tissue, immune, and neuropsychiatric syn-

dromes, including fatigue. Patients who complain of mold-related systemic symptoms do not generally test positive for allergic responses to these fungi, nor can a relationship between symptoms and dose be demonstrated.⁶² Because of the profound public concern for adverse effects from moldy environments, the IOM undertook a detailed evaluation of the potential adverse effects of damp indoor spaces.⁶³ Their methodology involved four levels of scientific certainty, the highest being sufficient evidence of a causal relationship and the lowest being inadequate or insufficient evidence to determine whether an association exists between damp indoor environment or mold and adverse health outcomes. There was no health effect that was considered to be documented well enough to meet the sufficient evidence of a causal relationship standard. Some upper respiratory effects were thought to be characterized by sufficient evidence of an association, and others were characterized by limited or suggestive evidence of an association. All the other effects were found to characterize the lowest level of surety, indicating that there was not evidence to determine an association. Although the IOM report is the most comprehensive to date, other professional societies, including the American College of Occupational and Environmental Medicine and the Texas Medical Association, have taken similar positions.^{57,64}

Thus, based on currently available information, other than the allergic and opportunistic effects described previously, there are few data to support the widespread notion of more diffuse toxic effects of exposure to mold.

IDIOPATHIC ENVIRONMENTAL INTOLERANCE

Originally referred to as multiple chemical sensitivity (MCS), this syndrome is now more properly referred to as idiopathic environmental intolerance (IEI). The former designation, invoking the concept of sensitization, has an etiologic implication. Sensitization is properly viewed as an immunologic phenomenon. In fact, early proponents of a physiologic basis for this syndrome evoked such an immunologic ideology. However, with the subsequent evolution of a significant body of data refuting an immunologic basis for MCS, this designation became obsolete. As the designation for this syndrome has morphed, so has the nomenclature of its proponents. Formally called “clinical ecologists,” the group of physicians advocating a physiologic basis for IEI now designate themselves “environmental medicine” physicians. However, environmental medicine is not an accepted medical specialty in the United States. It is important to distinguish this group from the recognized specialty of Occupational and Environmental Medicine. The ethos of the latter group is directly contrary to that of “environmental physicians.” The American College of Occupational and Environmental Medicine has formally rejected a physiologic basis for IEI.⁶⁵

In 1996, a WHO/German Government Conference suggested that idiopathic environmental intolerance was a more appropriate designation.⁶⁶ The 1996 Conference

determined that IEI was a symptom complex experienced by people after exposure to nonspecific environmental chemicals at concentrations and doses that do not affect most people with a repetitive pattern of symptom occurrence, not explainable by any well-accepted medical condition.

There have been two major categories of theories proposed to explain the occurrence of these symptoms in the absence of a medical explanation. Toxicogenic theories posit that low-level “chemical” exposures in a hypothesized physiologic vulnerable population trigger these repetitive symptoms in an as yet scientifically unexplainable fashion. In contrast, psychogenic theories are based on the concept of an overvalued belief of toxic harm based on psychological factors. A recent in-depth critical analysis of these two disparate theories strongly concluded that the psychogenic explanation is most consistent with the current state of scientific knowledge.^{67,68}

The optimum methodologic approach to the study of IEI uses exposure chambers, where the subject is exposed to either filtered room air or substances they have previously identified as “provocants.” The odor properties are masked by innocuous substances such as peppermint, which is also added to the air in placebo trials. Pioneering work in this field by Staudenmayer and colleagues has shown with this methodology that patients complaining of IEI cannot identify their provocants in anything more than chance fashion.⁶⁹ The WHO has assessed IEI and recommended that the existence of this condition could best be verified by exposure chamber experiments.⁶⁶ The results of exposure chamber studies, therefore, provide strong support for the psychogenic theory of IEI symptoms. The diagnoses that apply would most commonly be in the realm of somatoform disorders, although individual psychiatric evaluation is mandatory before such a diagnosis can be established. Many patients with IEI symptoms have overlap syndromes with other conditions that are often explainable by a somatoform disorder, such as the mold or dental amalgam syndromes discussed earlier in this chapter. Examples of other conditions commonly explainable by the presence of a somatoform disorder are some cases of fibromyalgia, sick-building syndrome, and chronic fatigue syndrome.

CHRISTOPHER H. LINDEN, MD

At a Glance...

- Smoke inhalation accounts for more than 80% of fire-related fatalities, most of which result from residential fires.
- The pathophysiology of smoke inhalation is multifactorial and involves additive or synergistic toxicity from hypoxia, thermal injury, and numerous chemical toxins (e.g., carbon monoxide, hydrogen cyanide, irritant gases).
- The ultimate cause of death in patients with smoke inhalation is asphyxia (i.e., tissue hypoxia and consequent acidosis).
- The carboxyhemoglobin fraction is elevated in virtually all patients exhibiting signs and symptoms of asphyxia.
- Unexplained coma, severe metabolic (lactic) acidosis, and refractory hypotension victims suggests cyanide poisoning.
- Urgent endotracheal intubation is indicated in patients with cyanosis or hypoxemia despite oxygen therapy, respiratory depression or acute hypercarbia, pulmonary edema, altered mental states, full-thickness burns of the face or neck, and respiratory distress due to upper airway obstruction.
- Intubation should also be considered for patients with upper airway pathology on laryngoscopy or a respiratory rate of more than 30 breaths/min who do not improve with oxygen or other pharmacologic therapy.
- Hyperbaric oxygen can be effective in treating carbon monoxide or cyanide poisoning, cerebral edema, and thermal burns; it should also be considered for patients with refractory hypoxemia.
- When cyanide poisoning is suspected in smoke inhalation victims, sodium thiosulfate may be administered without nitrates.

Smoke is a complex mixture of liquid and solid aerosols, fumes, gases, and vapors resulting from thermal decomposition or pyrolysis.^{1,2} Although commonly defined as the visible cloud emitted from a material that has been ignited, smoke is not always visible. In fires, pyrolysis usually begins as flaming combustion (oxidative pyrolysis or thermo-oxidation) resulting from the application of an igniting source (e.g., spark or flame) to a flammable material. As heat is generated and oxygen is consumed, smoldering combustion (oxidative pyrolysis without flame) and nonoxidative or anaerobic pyrolysis become the dominant processes. Pyrolysis can also result from the application of intense heat without fire or flame. Metal fume fever and polymer fume fever, which result from the inhalation of products generated when metals and synthetic polymers (e.g., fluorocarbons and other plastics) are heated above their melting points, are classic examples.^{3,4} Hence, the adage, “where there’s smoke, there’s fire,” is not always true.

Although not often appreciated, the scene of smoldering combustion is more far more hazardous than that of flaming combustion.² Not only is less oxygen

available, more toxic gases are present, and the potential for flare-up is greater. Because combustion is less complete, more carbon monoxide (CO), a product of incomplete combustion, is evolved during smoldering combustion than during flaming combustion, where carbon dioxide (CO₂) is the predominant product of combustion. In addition, combustible gases generated under conditions of oxygen depletion can suddenly ignite, particularly when enclosed spaces are subsequently opened (i.e., supplied with oxygen). Examples include “flashover” (the simultaneous ignition of all surfaces of a room or structure without the progressive spread of flame) and explosive “flare-up,” as exemplified in the 1991 movie *Backdraft*. Preventing such events explains the “C” in the fire response acronym RACE (rescue, alarm, close all doors and windows, extinguish) and the recommendation that a person attempting to escape a fire scene not open a door if it is hot.

Thousands of potentially toxic organic and inorganic chemicals are generated when materials undergo pyrolysis.^{1,2,5-11} Their identity, amount, and rate of production depend on the source material and the temperature, rate, and mode of pyrolysis. However, technical limitations and lack of knowledge of the materials and conditions involved, which vary with time and space, make it impossible to determine precisely what chemicals (and physical factors) are present at the scene of naturally occurring events such as fires. Those most widely studied and thought to be most responsible for morbidity and mortality in human smoke inhalation are listed in Table 86-1.

Although smoke invariably contains CO, the pathophysiology and management of smoke inhalation are far more complex than of pure CO poisoning (see Chapter 87). In contrast to CO poisoning, morbidity and mortality from smoke inhalation are due to multiple chemical and physical factors (see Table 86-1). CO poisoning is often involved, but other causes of asphyxia, particularly inhalation (respiratory tract) injury, must also be evaluated and treated.

EPIDEMIOLOGY AND HISTORY

In the United States, more than 4000 people die from fire-related injuries each year (about 2.3 deaths per 100,000 population).¹² Smoke inhalation is the primary cause of death in more than 80% of cases, with surface burns and other trauma accounting for the remainder.^{1,2,13} Of note, in some commercial aircraft crashes, more people die from smoke inhalation secondary to postcrash fire than from injuries sustained on impact.¹⁴

Eighty percent of smoke inhalation deaths occur within 6 hours of exposure and 93% within 24 hours.^{12,15}

TABLE 86-1 Factors Involved in the Pathophysiology of Smoke Inhalation

MECHANISM OF ASPHYXIA	CAUSE	SOURCE
Oxygen deficiency (simple asphyxia)	Ambient hypoxia Carbon dioxide Multiple other gases	All combustible materials
Functional anemia (abnormal hemoglobin)	Carbon monoxide Methemoglobin inducers	All combustible materials Unknown
Cytochrome oxidase inhibition (cellular asphyxia)	Carbon monoxide Hydrogen cyanide	All combustible materials Animal products, acrylics, acrylonitrile-butadiene-styrene plastics, melamine resins, nylons, urea-formaldehyde foam insulation, wool
Airway or lung injury (corrosive effects)	Acrolein, other aldehydes and hydrocarbons, organic acids, nitrogen oxides	Most combustible materials
	Ammonia, isocyanates	Same as for hydrogen cyanide
	Carbonyl fluoride	Fluorocarbons (e.g., Teflon)
	Halogen acids, phosgene	Fire extinguishers, flame retardants, acrylics, films, polyvinylchloride plastic, resins
Mechanical airway obstruction Central nervous system depression	Heat, flame, steam Sulfur oxides	Most combustible materials Animal and petroleum products, rubber, wool
	Soot Alcohol Drugs Cellular asphyxiants Hypoxemia Trauma	All combustible materials

In victims who are dead when discovered, death has historically been attributed to asphyxia due to CO poisoning or severe upper- and lower-airway obstruction and pneumonitis. Environmental oxygen depletion, heat, and cyanide poisoning are now considered contributing factors.¹⁶ In those who are found alive but moribund, early death results from respiratory failure due to progressive airway and lung injury. Delayed deaths primarily result from anoxic brain damage, pulmonary edema, bacterial pneumonia, sepsis, and pulmonary embolism.

About 75% of fire-related fatalities in the United States result from residential fires.¹² Carelessness with cigarettes, matches, flammable liquids (e.g., fuels and cooking oils), wood stoves, and other heating devices and malfunctioning appliances and heating systems are the underlying causes in most instances. In multiperson-dwelling fires, children younger than 5 years of age, the elderly, those with physical or cognitive disabilities, and those impaired by alcohol or other drugs are at higher risk for death than able-bodied, unimpaired adults.¹² More than half of home fire deaths result from fires in the 5% of homes with no smoke alarms. Despite stricter building codes, increased use of smoke detectors, and improvements in medical care, the annual number of fire-related fatalities has changed little in the past 60 years.

Before World War II, most fire-related fatalities were due to surface burns rather than smoke inhalation.^{1,2} During the next two decades, the incidence of death due to smoke inhalation tripled.¹⁷ In 1951, Zapp, considered the father of combustion toxicology, first reported that

more fatalities were caused by smoke inhalation than by surface burns.¹⁸ It was not initially recognized that pyrolysis products of plastics or synthetic polymers, which were introduced during the previous two decades and increasingly used in the construction and furnishing of buildings, were responsible for these observations. When first introduced, plastics were promoted by manufacturers as nonburning and self-extinguishing.¹

In 1962, Zapp was again the first to report that pyrolysis products of synthetic polymers (e.g., polyamine, polyethylene, polypropylene, polystyrene, polyurethane, polyvinyl chloride) were different from and more toxic than those from natural materials (e.g., cotton, wood, and wool).¹⁹ Subsequent research confirmed these findings. Plastics manufacturers, however, continued to deny responsibility. In 1972, the Federal Trade Commission initiated a complaint charging the plastics industry with failing to disclose, misrepresenting, and falsifying evidence.¹

It is now known that, compared with natural materials, plastics (and other synthetics) spread flame faster, make flare-ups and flashover more likely, and generate more heat more quickly, more and denser visible smoke, and greater amounts of more toxic invisible products of pyrolysis.¹ Paradoxically, although newer structures are less likely to catch fire, building construction materials and contents have become more dangerous when subjected to thermal decomposition. This, along with population increases, most likely explains why the annual number of fire-related fatalities has remained relatively constant.

In most countries, every fire death is subject to investigation by a coroner or medical examiner and nonmedicolegal authorities. Forensic investigations have attempted to define the role or contribution of individual chemical and physical factors in causing death by analyzing autopsy data and by fire dynamics modeling. Infamous single events that have been studied include fires at the Cleveland Clinic in 1929,²⁰ the Coconut Grove (Boston) night club in 1942,^{21,22} the Maura County (Tennessee) jail in 1977,²³ the Las Vegas MGM Grand hotel in 1980,²⁴ the Westchase (Houston) Hilton hotel in 1982,²⁵ the aircraft crash in Manchester (England) in 1985,¹⁴ the Dupont Plaza Hotel (San Juan, Puerto Rico) in 1986,²⁶ and the Happy Land Social Club (New York City) in 1990.¹⁶ Data from multiple fire locations have been reported from Wayne County (Detroit area),²⁷ Cuayhoga County (Case Western Reserve University, Cleveland),^{28,29} the Foundation for Fire Safety (16 jurisdictions in the United States and Canada),³⁰ Maryland,³¹ Mississippi (University of Southern Mississippi),³² Glasgow (Scotland),³³⁻³⁵ Munich (Germany),³⁶ New York City,^{5,37,38} Oslo (Norway),³⁹ and Paris (France).⁴⁰ In many instances, victims were found dead in areas remote from the fire, sometimes without evidence of heat, smoke, or soot, emphasizing the fact that in enclosed spaces, fatal smoke inhalation can occur without palpable or visible warning.

Despite such investigations, the specific toxicants responsible for morbidity and mortality in human smoke inhalation remain uncertain and unpredictable.¹⁶ For example, in many fires, victims have lethal carboxyhemoglobin (COHb) fractions,^{5,27,37,38} lethal blood cyanide (CN) levels,³⁰ or both,^{16,40} but a correlation between the two is not necessarily present.^{14,29,30} In other fires, nonlethal COHb fractions and CN levels are found, and death is attributed to respiratory tract injury from irritant gases^{24,28} or to heat shock and oxygen depletion.²⁵ Even in a single fire, factors responsible for death vary from individual to individual.¹⁶

One objective of forensic investigations is to determine whether death resulted from smoke inhalation or whether fire was used to conceal a prior death (e.g., a homicide or suicide). Historically, COHb has been used as a biomarker of smoke inhalation. Multiple studies have shown that COHb fractions in victims of fatal smoke inhalation are lower than in nonfire CO fatalities (e.g., from exposure to pyrolysis products of fossil fuels).^{27,31,38} In fire exposures, a COHb fraction of 50% or greater is considered evidence that CO was the principal cause of death and that the victim died from smoke inhalation.¹⁶ In contrast, in nonfire exposures, a COHb fraction of 60% or greater is generally used when assessing whether, "more likely than not," death was due to CO poisoning. Again, the reason for this difference is that multiple other factors are involved in the pathogenesis of smoke inhalation. It is now clear that fire victims can have COHb fractions well below 50%, yet their death can clearly be attributed to smoke inhalation. Analysis of fire fatality data shows that COHb fractions have declined over time. It follows that other chemical or physical factors have become relatively more important.

One such factor is hydrogen cyanide gas (HCN). In contrast to CO, the definition of a lethal blood CN

level is controversial, with 1 to 3 $\mu\text{g}/\text{mL}$ considered potentially lethal after the inhalation of HCN.¹⁶ Interestingly, in the first study to measure CN levels in fire victims, none had potentially lethal levels.²⁶ Also in contrast to CO, analysis of fire fatality data shows that blood CN levels in fire fatalities and the fraction of victims with potentially lethal CN levels have been increasing with time.¹⁶ Irritant gases are also considered to have an increasing role in morbidity and mortality from smoke inhalation. Increased use of synthetic materials in the construction and furnishing of buildings is again the likely explanation for these trends.

Nitrogen oxides produced by burning nitrocellulose x-ray film were implicated as the cause of inhalation injury in victims of the 1929 Cleveland Clinic fire.¹⁹ It is now known that ammonia, HCN, isocyanates, methemoglobin inducers, and other respiratory tract irritants are also generated when nitrogen-containing compounds undergo pyrolysis. Inhalation injuries in victims of the 1942 Coconut Grove night club fire were described as similar to those caused by "certain war gases," presumably referring to chlorine and phosgene, the gases used in World War I.²⁰ It is now appreciated that these gases, along with many other irritants (see Table 86-1), are indeed found in smoke.

The toxicity of the individual chemical and physical factors that contribute to morbidity and mortality is well known. Recent research has focused on the effect of combinations of factors. Most significantly, these studies show additive or synergistic toxicity when oxygen depletion and irritant gas exposure is combined with CO and HCN (see later), again emphasizing the fact that the pathophysiology of smoke inhalation is multifactorial.

Attempts to find practical, nontoxic fire retardants have met with limited success.^{1,2} When applied or added to materials, a variety of chemicals (e.g., antimony oxide; aluminum, boron, bromine, chlorine, molybdenum, and organophosphorus compounds; halogenated polymers) make them more difficult to ignite and less likely to propagate flame. None is completely effective or safe. Fire retardants themselves can produce toxic products when thermally degraded.

Smoke alarms decrease the risk for death from fire by up to 60%.^{12,41} Both ionization smoke alarms, which contain material that ionizes the air and creates an electrical path when products of combustion enter the device, and photoelectric alarms, which contain a light source that activates a photocell when light is reflected off smoke particles, provide a warning well before life-threatening conditions develop. Sprinkler systems are also advocated for the prevention of fire-related morbidity and mortality, but data regarding their efficacy are limited, particularly in residential settings.^{12,41} Sprinkler systems typically require an air temperature of 150° C at the ceiling level for activation. Although such temperatures are reached before immediately lethal conditions develop, they do not occur until many minutes after conditions become sufficient to activate smoke alarms or cause inhalation injury.¹⁶ Hence, it is unlikely that sprinkler systems will be shown to be as effective as smoke alarms in preventing morbidity and mortality from smoke inhalation.

PATHOPHYSIOLOGY

Chemical and physical agents most commonly implicated in the pathophysiology of smoke inhalation are listed in Table 86-1. The severity of injury varies with both time and space. Those victims with longer exposure time and shorter distance to the source (i.e., greater toxicant concentrations) will have more severe effects. There is a hyperbolic relationship between the time of onset and severity of effects and exposure conditions: the greater the exposure, the more rapid and pronounced the effects, and vice versa.

In a closed space, potential lethal conditions can develop within minutes of fire ignition.⁴² Smoke initially accumulates in a hot layer at the ceiling level and subsequently descends toward the floor.¹⁶ This explains why those attempting escape a fire scene are advised to crawl or stay close to the floor (i.e., “fall and crawl”). Indeed, there are anecdotal reports of survivors collapsing or fainting, falling to the floor (where they breathe cooler and less contaminated air), regaining consciousness, and subsequently crawling to safety.

Victims succumb because of incapacitation (cognitive and physical dysfunction) and escape impairment that results from smoke inhalation, other fire scene factors, and preexisting or concurrent illness or infirmity.^{8,16} Factors that contribute to incapacitation and escape impairment include asphyxia; coughing, choking, and dyspnea; impaired vision due to smoke, darkness, and ocular irritation; surface burns and traumatic injuries; physical obstacles such as debris, fire, heat, and slippery surfaces; and alcohol or drug intoxication, extremes of age, cardiovascular or pulmonary disease, and physical handicaps. Incapacitation and escape impairment increase smoke exposure and result in further cognitive and physical dysfunction. A progressive downward spiral ensues, ending with physical collapse, loss of consciousness, apnea, and cardiac arrest. Natural reactions to a fire, such as attempting to extinguish it and attempting to warn and rescue others, also prolong exposure. Indeed, many victims appear to have been attempting to escape before their death, and significant numbers die upon reentering the fire scene.¹²

Regardless of contributing factors, the ultimate cause of death in patients with smoke inhalation is asphyxia (i.e., tissue hypoxia, hypercarbia, and acidosis). Asphyxia may be due to oxygen deficiency (i.e., breathing air rarified by combustion or containing gases that lower the partial pressure of oxygen), impaired oxygen transport and delivery (e.g., by COHb and methemoglobin), inhibition of cellular respiration (e.g., by CO and CN), central respiratory depression (e.g., by CO, CN, and carbon dioxide), and direct or indirect obstruction of air passages and alveoli (e.g., by heat, humidity, irritant gases, and soot).

CO, heat, and oxygen deficiency are produced by all fires and are the primary causes of death due to enclosed-space fuel fires under experimental conditions.¹⁸ Historically, CO poisoning (see Chapter 87) has been considered the primary cause of death in human

smoke inhalation.³⁴ However, when a COHb fraction of 50% or greater is used as the criterion for death from CO due to smoke inhalation, this conclusion is no longer true. Since about 1970, fewer than half of the fatalities in multiple fire databases (primarily residential fires) have COHb fractions of 50% or greater. For example, in the Maryland study, 40% of victims dead at the scene had COHb fractions less than 50%, 24% had COHb fractions less than 30% (the fraction associated with incapacitation and escape impairment but not death), and 9% had COHb fractions less than 10%.³¹ Similar findings have been reported by others.^{27-30,34,39} The data from single mass casualty incidents is even more impressive. Most victims in the MGM Grand Hotel, the Dupont Plaza Hotel, and the Manchester aircraft fires had COHb fractions less than 50% (88%, 95%, and 92%, respectively), and a greater percentage had COHb fractions less than 30% (41%, 40%, and 28%, respectively).^{14,24,26}

For a variety of reasons, assessing the contribution of CO to morbidity and mortality from smoke inhalation is difficult. Although COHb fractions generally correlate with the severity of inhalation injury, victims of smoke inhalation can have high COHb fractions without significant pulmonary toxicity, and vice versa.^{15,31,38,43-48} Because manifestations of CO poisoning are virtually identical to other causes of asphyxia, the relative contribution of CO cannot be determined by clinical assessment. In addition, COHb fractions correlate with clinical toxicity only after relatively brief exposures. The longer the duration of exposure, the greater the effect at a given COHb fraction.³⁰ This suggests that it takes time for blood and tissues levels of CO to equilibrate and that the area under the time–concentration curve (AUC) must be considered when interpreting COHb fractions. The effect of CO also depends on the extent of its binding to and inhibition of cytochrome oxidase, the mechanism of CO-induced cellular asphyxia. Binding of CO to cytochrome oxidase depends on the oxidation state of this enzyme, with binding to the reduced (deoxygenated) form being greater than it is to the oxidized form. The same is true for CN. This is the rationale for oxygen therapy in CO and CN poisoning. It also explains why the lethality of CO is enhanced when combined with oxygen depletion or HCN exposure. In experimental animals, these three agents act synergistically, with time to death and lethal levels of CO and CN decreasing as much as 10-fold in combined exposures.^{16,49} In contrast, the effect of combining irritant gases with oxygen depletion, CO, or HCN appears to be simply additive.⁵⁰⁻⁵⁴ These findings probably explain why sublethal levels of both COHb and CN and insignificant inhalation injury are observed in some fire fatalities.

The higher the ambient air temperature and humidity, the greater the morbidity and mortality from smoke inhalation in experimental animals.⁵⁵ Exposure of animals to dry air heated to 200° C for 5 minutes or to 125° C for 15 minutes is potentially lethal.⁵ Shorter exposures to dry air at temperatures of 350° C to 500° C result in tracheitis.⁵⁶ Exposure to steam, which has much greater heat capacity, results in bronchitis and pul-

monary parenchymal damage in addition to tracheitis at such temperatures. High skin surface temperature and hyperthermia undoubtedly contribute to incapacitation and escape impairment. Surprisingly, however, respiratory tract injury secondary to heat and humidity is relatively uncommon in human exposures and occurs primarily in those with concomitant surface burns.^{25,57}

Decreased ambient oxygen fractions, which occur as oxygen is progressively consumed during combustion, result in hypoxic asphyxia. At sea level, the normal oxygen fraction is about 21%. An acute reduction in the inspired oxygen reduction to 15% to 18% results in dyspnea on exertion, and a reduction to 10% to 14% results in confusion and dyspnea at rest.¹ At fractions of 6% to 8%, loss of consciousness followed by death occurs within 5 to 8 minutes. Experimentally, lethal oxygen fractions do not occur until the temperature is quite high (about 315° C).¹⁶ This combination, however, is rapidly lethal. In addition, as noted earlier, oxygen depletion enhances the toxicity of both CO and CN. Although the effects of ambient hypoxia are indistinguishable from those of other causes of asphyxia and cannot be assessed clinically, circumstantial and experimental evidence suggest that it plays a significant role in causing fire scene deaths. Because this condition is readily reversible and ceases to exist after removal from the fire scene, its only subsequent effects are those related to anoxic organ damage.

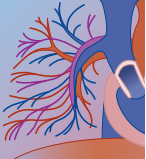

HCN is produced when materials containing nitrogen (e.g., acrylonitrile plastics, melamine resins, nylon, wool, urea-formaldehyde foam insulation) are burned. The pathophysiology of cyanide poisoning is discussed in Chapter 88. HCN is more potent and produces more rapid incapacitation and death than CO in experimental animals.¹⁶ Potentially toxic CN blood levels have been noted in as many as 30% of survivors and 100% of fatalities, and potentially lethal levels have been reported in up to 10% of survivors and 70% of fatalities.^{11,29,30,35,40,46,58,59} Data are difficult to interpret, however, because the technique and time of blood sampling, storage, and analysis and definitions of potentially toxic and potentially fatal blood CN concentrations vary from study to study. Using cutoffs of 1 µg/mL or greater and 3 µg/mL or greater, potentially toxic and potentially lethal blood CN levels were found in 7% to 74% and 0% to 46% of multiple fire fatalities, respectively.¹⁶ In single-casualty incidents, potentially toxic and potentially lethal levels were noted in 48% to 87% and 5% to 33%, respectively. As noted earlier, the highest blood CN levels are noted in victims of recent fires.

For a number of other reasons, the contribution of CN to death from smoke inhalation is difficult to quantify.¹⁶ The kinetics of CN are much more complex than for CO, and few data exist regarding its kinetics after HCN inhalation. Such exposure results in a rapid rise in the blood CN level, which may not be in equilibrium with those in mitochondria, and thus not reflect tissue toxicity. As with CO, CN binding to cytochrome oxidase and its toxicity are enhanced by oxygen depletion, and CN, CO, and oxygen depletion

have synergistic effects in experimental animals. Although blood CN levels usually correlate with the both the COHb fraction^{16,35,40} and the severity of inhalation injury,^{46,58,59} this is not always true. In some fires, high CN levels with low COHb fraction are seen,¹⁴ and vice versa.¹⁶ Such apparently “antagonistic” findings could result if high concentrations of either HCN or CO (but not both) were present, with respiratory depression caused by one agent preventing the uptake of the other agent. In those found dead at the fire scene, levels of CN and CO tend to be lower when both are present, consistent with an additive or synergistic effect in humans. The interpretation of such data depends on the level of CN assumed to be lethal.¹⁶ As with other factors, manifestations of CN poisoning are indistinguishable from other causes of asphyxia, preventing clinical assessment of its role in human morbidity. Furthermore, blood CN levels are not routinely available and cannot be rapidly measured. Finally, the short half-life of CN, about 1 hour,⁴⁰ suggests that its role in nonfatal smoke inhalation is minor.

Smoke contains a variety of chemicals that are directly toxic to the mucosal surfaces of the eyes and respiratory tract (see Table 86-1). Differences in pyrolysis products explain why smoke from natural materials is more irritating or corrosive than that from synthetic ones. Smoke from materials of animal (e.g., fur, hide, silk, wool) or plant (e.g., cotton, paper, wood) origin contains mostly aldehydes (e.g., acetaldehyde, formaldehyde, acrolein) and lesser amounts of organic acids (e.g., formic and acetic acid), alcohols, and aliphatic and aromatic hydrocarbons.^{2,5-10} Smoke from animal products also contains appreciable amounts of ammonia (NH₃), nitrogen oxides (primarily NO₂), and sulfur oxides (primarily SO₂). With the exception of NH₃, these chemicals are considered mildly to moderately corrosive to tissues. Because they also have low water solubility, they tend to travel to the distal respiratory tract and cause bronchial, bronchiolar, and alveolar injury.

Smoke from synthetic materials contains a greater amount and variety of mildly to moderately corrosive organic compounds (e.g., acids, alcohols, aldehydes, aliphatic and aromatic hydrocarbons, amines and nitriles, halogenated hydrocarbons, ketones, and polymer monomers such as acrylates, esters, carbonates, phenols, and styrene) along with ammonia, and nitrogen and sulfur oxides.^{2,5-11,60} Most important, smoke from halogenated materials (e.g., acrylics, fire extinguishers and retardants, solvents, and polyvinylchloride) contains hydrogen bromide (HBr), hydrogen chloride (HCl), hydrogen fluoride (HF), phosgene (CCl₂O), and carbonyl fluoride (CF₂O or fluophosgene). CCl₂O and CF₂O are instantly hydrolyzed to their respective acids and CO₂ on contact with water.³ All these compounds are inorganic acids, which, in contrast to organic ones, are considered highly corrosive to mucosal tissues. Remarkably, the inhalation of HCl causes incapacitation faster than CO (but slower than HCN) in experimental animals.¹⁶ Acids and bases (e.g., NH₃) have high water solubility and tend to dissolve in the moist tissues of the

upper airway, causing nasopharyngeal, laryngeal, and tracheal injury. They can also cause immediate or delayed pulmonary toxicity. Persistent or permanent respiratory dysfunction can occur after acute inhalation injury (see later) or with chronic exposure to smoke (e.g., in tobacco smokers or firefighters).⁶¹

Delayed pulmonary effects are characteristic of polymer fume fever.⁴ This syndrome is a flulike illness that occurs several hours after the inhalation of products generated when fluorocarbon polymers such as polytetrafluoroethylene (PTFE, Teflon) are heated to about 400° C. This can occur during manufacturing processes (when ventilation fails or is insufficient), when workers smoke contaminated cigarettes (e.g., without first washing their hands), when lubricants are heated by friction, and when coated cookware is overheated in the home. Fine particulates are thought to cause the pyrogenic reaction, and vapors (e.g., carbonyl fluoride) are thought to be responsible for respiratory effects. The inhalation of smoke from the combustion of PTFE or its pyrolysis at higher temperatures results in more fulminant and typical inhalation injury. Metal fume fever is discussed in Chapter 75.

The tissue toxicity of smoke, like other inflammatory reactions, appears to be mediated by arachidonic acid metabolites (e.g., leukotrienes, prostacyclins, and thromboxanes), cytokines (e.g., platelet-activating factor), free radicals (e.g., superoxide, peroxide, hydroxyl), and activated polymorphonuclear leukocytes.⁶² In experimental animals, smoke inhalation causes mucosal edema, necrosis and pseudomembrane formation, and obstruction in the trachea and bronchi, followed by pulmonary vascular congestion, alveolar edema, atelectasis, and bronchopneumonia.⁶³ Respiratory tract inflammation also results in bronchospasm, loss of ciliary function, destruction of surfactant, and increased microvascular permeability.^{47,64,65} Increased shunting (secondary to pulmonary vasoconstriction), loss of lung compliance, and ventilation-perfusion mismatching may ensue. Although concentrations of irritants (in air and tissues) are difficult to measure, their contribution to morbidity and mortality in human smoke inhalation can be assessed both clinically and pathologically.

CO₂, along with CO, constitutes most of the gaseous fraction of smoke.² An increased CO₂ fraction in inspired air causes simple asphyxia by physically displacing oxygen. Increasing blood levels of CO₂ initially stimulate and subsequently depress brainstem respiratory centers. High levels also cause generalized central nervous depression. These actions could increase exposure to smoke by increasing ventilation and causing incapacitation, and potentially contribute to fire scene deaths. As with oxygen depletion, except for postanoxic organ dysfunction, the effects of CO₂ are readily reversible when exposure ends, and thus probably contribute little to subsequent morbidity and mortality.

Methemoglobinemia is an infrequently reported complication of smoke inhalation.⁶⁶ It is not clear whether this is due to infrequent occurrence or infrequent recognition. The identity of the offending toxicants is also unknown. Aromatic amino (-NH₂), nitro (-NO₂) and nitroso (-NO) compounds and oxides of nitrogen have been suggested as etiologies. The

pathophysiology of methemoglobinemia is discussed in Chapter 14. Effects are similar to those of anemia and difficult to distinguish from other causes of asphyxia. Although COHb fractions are usually elevated when methemoglobinemia is present, there does not appear to be a direct correlation between the two. Given that the oxygen binding and delivery by hemoglobin are decreased by both COHb and methemoglobin (MetHb), their combined effects are likely to be additive.

Soot, the particulate fraction of smoke, is similar to activated charcoal and relatively inert.^{2,5-11} Large amounts can cause mechanical airway obstruction. Although this usually occurs at the bronchiolar level (resulting in atelectasis and subsequent pneumonia), in extreme situations (e.g., volcanic eruptions), it can result in upper airway obstruction. More significantly, however, soot can adsorb toxic gases and liquids and act as vehicle for delivering them to various locations along the respiratory tract. Where a particle settles depends on its size.² Those smaller than 1 μm reach the alveoli (primarily by diffusion), those 1 to 5 μm in size settle on tracheal, bronchial, and bronchiolar surfaces (as a result of sedimentation), and those measuring 5 to 30 μm are trapped in the nasopharynx (by inertial impaction). The same is true for aerosolized liquid particles of similar size.

Smoke also contains carcinogens, which are primarily of concern in those with chronic exposure.^{2,7,61} All fires generate benzopyrene, the classic chemical initiator of carcinogenesis, as well as hundreds of other polyaromatic hydrocarbons (PAHs), some of which are known to be promoting agents. Such chemicals appear to be responsible for the increased incidence of lung cancer in tobacco smokers and have been linked with an increased risk for lung cancer in foundry workers.⁶⁷ Interestingly, PAHs present in soot were probably also responsible for the high incidence of scrotal cancer in chimney sweeps, described more than 200 years ago by the English surgeon Percivall Pott and considered to be the first recognized occupational cancer. Whether or not others with occupational exposure to smoke (e.g., blacksmiths, firefighters) are at increased risk for cancer is unknown.

Fires involving plastics, especially polyvinyl chloride, can emit acrylonitrile, arsenic, benzene, chromium, and vinyl chloride. Those involving transformers may result in exposure to polychlorinated biphenyls, polychlorinated dibenzofuran contaminants, and pyrolysis products such as polychlorinated dibenzofurans, chlorinated biphenylenes, and dioxin. Finally, smoke from both natural and synthetic materials may contain formaldehyde. All these chemicals are known or suspected human carcinogens.

TOXICOLOGY

Clinical Manifestations

The clinical course of smoke inhalation can be divided into early, intermediate, and late stages.^{47,68} During the first 36 hours, the systemic effects of asphyxia and the local (i.e., respiratory tract) effects of irritant gases, heat,

humidity, and soot predominate. Six hours to 5 days after exposure, pulmonary edema, cerebral edema, and the multiple-organ dysfunction syndrome develop in patients with prolonged or severe hypoxia. Complications that occur or become apparent days to weeks after exposure include permanent central nervous system (CNS) damage (e.g., coma, encephalopathy) due to anoxia, bronchiectasis and subglottic stenosis due to airway injury or its treatment (e.g., endotracheal intubation), pneumonia and sepsis due to impaired defense mechanisms, and malnutrition, pressure sores, and thromboembolism in those with prolonged critical illness. Chronic sequelae such as asthma (reactive airways dysfunction syndrome), bronchiolitis obliterans, chronic bronchitis and obstructive pulmonary disease, and pulmonary fibrosis can develop days to years after the original insult.

Victims of smoke inhalation may present with signs and symptoms of asphyxia or inhalation injury.^{15,44,47,48,62,64,65,68-75} Both are typically present in those with significant exposures, but isolated inhalation injury is common in those with mild exposures. Surface burns, other trauma, and alcohol or drug intoxication may also be present. The larger the surface burn, the more likely there will be concomitant inhalation injury.^{62,68-70,74} Respiratory failure and mortality from smoke inhalation is higher in those with concomitant surface burns than in those without them. Traumatic injuries may result from falling objects, jumping to escape, and structural collapse. Intoxicating levels of ethanol have been reported in 30% to 53% of fatalities due to residential fires.^{12,46}

Asphyxia is manifested primarily by CNS and cardiovascular dysfunction.^{44,48,64,69,72,74,75} Nausea, vomiting, and diarrhea may also be noted. Manifestations of asphyxia are present at the time of exposure and again later, if inhalation injury worsens with time. CNS effects range from agitation, anxiety, confusion, dizziness, and transient loss of consciousness to coma with seizures or abnormal posturing. Headache is a prominent, sensitive, and relatively specific manifestation of CO poisoning. It can also be seen in CN poisoning and with methemoglobinemia. Cardiovascular manifestations may include dysrhythmias, heart failure, hypotension, and myocardial ischemia or infarction. Underlying cardiovascular disease increases the risk for cardiac complications and may be a contributing factor in as many as 20% of smoke inhalation fatalities.⁴⁶

The COHb fraction is elevated in virtually all patients exhibiting signs and symptoms of asphyxia. It may also be elevated in patients with isolated or predominantly respiratory complaints and findings. Blood CN levels may also be elevated, particularly in those with CNS and cardiovascular dysfunction, but methemoglobinemia appears to be rare. Findings that are relatively uncommon yet specific to CO poisoning include retinal hemorrhages and cherry-red skin color. Lack of a color difference between retinal arterioles and venules (i.e., an equally red appearance) has been described in CN poisoning. An elevated plasma lactate concentration (>10 mEq/L) correlates with the presence of high blood

CN levels.⁴⁰ However, lactic acidosis invariably accompanies severe or prolonged tissue hypoxia or shock regardless of the underlying cause. Hypoxemia and respiratory acidosis (hypercapnia, $PCO_2 > 40$ mm Hg) may be seen in patients with CNS depression or severe inhalation injury. Cyanosis from methemoglobinemia usually appears more gray or brown than that due to hypoxemia, which is purplish. Blood containing a high MetHb fraction has a milk-chocolate color.

Inhalation injury may involve the upper (laryngotracheal) or lower (bronchopulmonary) respiratory tract.^{15,44,47,62,64,65,68-72,74,75} The lower respiratory tract is affected more often than the upper. Cutaneous burns of more than 15% body surface area, a history of exposure in an enclosed space, an altered level of consciousness, and carbonaceous sputum production are associated with a high incidence of bronchopulmonary injury. Facial and neck burns are associated with a high incidence of both upper and lower respiratory tract injury. Those with preexisting pulmonary disease are more susceptible to the respiratory effects of smoke.

Nonspecific manifestations of inhalation injury include cough, dyspnea, tachycardia, tachypnea, retractions, and hypoxemia. Hypoxemia is usually defined as an oxygen saturation less than 95% by pulse oximetry or arterial blood gas (ABG) analysis (SpO_2 and SaO_2 , respectively), a partial pressure of oxygen (PO_2) less than 85% in an arterial sample, or an arterial oxygen tension-to-inspired oxygen fraction ratio (PaO_2/FiO_2) of less than 400 in an otherwise healthy person breathing room air. Cyanosis, which corresponds to 5 g/dL of reduced or deoxyhemoglobin or an oxygen saturation of about 60% in a healthy adult with a normal hemoglobin level, and respiratory acidosis may be seen in severe cases.

In most patients with smoke exposure, some degree of conjunctivitis, lacrimation, pharyngitis, and rhinitis is also present. Corneal abrasions caused by soot are also relatively common. Exposure to fire or extreme heat may result in corneal burns or desiccation with superficial sloughing. Examination of the nose, mouth, and throat may reveal erythema, edema, or soot. In severe cases, singed nasal hair and mucosal ulcerations and hemorrhage may be seen.

Signs and symptoms of laryngotracheal involvement include drooling, dysphasia, hoarseness, neck pain, and stridor.^{15,44,47,64,68-78} Complete obstruction of the upper airway can occur in severe cases. Mucosal edema, erythema, blistering, ulceration, and sloughing; laryngospasm; increased secretions; and soot may be seen on laryngoscopy.⁶⁸⁻⁷⁰ Laryngeal, epiglottic, and periglottic edema may be visible on soft tissue neck radiographs. A chest radiograph may reveal tracheal narrowing. A sawtoothed or plateau pattern of the inspiratory curve and an expiratory-to-inspiratory ratio greater than 1 may be seen on flow-volume loop spirometry.⁷⁷

Complaints and physical findings indicative of bronchopulmonary injury include chest burning or tightness, carbonaceous sputum production, rhonchi, rales, and wheezing.^{15,44,47,64,68-75} In some symptomatic patients, no auscultatory abnormalities are noted. Rales or crackles may be localized (e.g., from atelectasis

or pneumonia) or diffuse (e.g., from pneumonitis or pulmonary edema). Fever and leukocytosis may accompany atelectasis, pneumonitis, or pneumonia. When they occur within 2 days of exposure, atelectasis or inflammation rather than infection is the likely cause. Fever is also a characteristic feature of polymer fume fever.⁴ A chest radiograph may reveal peribronchial cuffing (due to airway edema) and patchy or diffuse infiltrates (due to atelectasis, pneumonitis, pneumonia, or pulmonary edema).^{44,79-83} It may appear normal, however, when obtained soon after exposure.^{44,79} High-resolution thin-section chest computed tomography can detect late complications such as bronchiectasis, bronchiolitis obliterans, and interstitial lung disease.⁴⁷

Bronchial and bronchiolar obstructions cause decreased peak expiratory flow rate (PEFR), forced expiratory volume in the first second (FEV₁), and forced vital capacity (FVC) on bedside spirometry.^{70,78,79} An increased expiratory-to-inspiratory ratio on flow-volume loop spirometry is more sensitive in detecting increases in small airway resistance. Radionuclide (xenon or technetium) ventilation-perfusion imaging may show segmental delayed washout (retention of gas for more than 90 seconds) in areas of small airway obstruction before abnormalities appear on plain films.^{70,78,84,85} Formal spirometry may reveal a restrictive pattern in patients with decreased lung compliance due to pulmonary parenchymal damage. Unventilated areas on lung scanning and decreased CO₂ diffusing capacity usually indicate parenchymal injury but can also be seen with severe airway obstruction. Bronchoscopy may reveal crusts, casts, and plugs (mucus or soot) along with mucosal injury.^{37,69,86}

Pulmonary edema and bacterial pneumonia are common complications in patients with significant inhalation injury.^{15,44,47,68-73,75} Pulmonary edema occurs in 5% to 30% of hospitalized patients and is associated with a mortality rate as high as 70%. It can be acute or insidious in onset and progress to fulminant adult respiratory distress syndrome (ARDS). It can also occur in patients with extensive cutaneous burns in the absence of significant smoke inhalation. Bacterial pneumonia is even more common, occurring in 15% to 60% of hospitalized patients and associated with mortality rates of 50% or greater. Pneumonia that develops within 3 to 4 days of exposure is usually due to *Staphylococcus aureus*. When it occurs later, gram-negative organisms such as *Escherichia coli* and *Enterobacter*, *Klebsiella*, and *Pseudomonas* species are the likely etiology.

DIAGNOSIS AND EVALUATION

The history should include details of exposure; symptoms, condition, and treatment before arrival; and past medical history. If the patient is unable to provide details, rescuers or other witnesses should be questioned. The nature of the material that generated the smoke

(e.g., natural or synthetic); the presence or absence of flame, heat, steam, or explosion; a description of the smoke (e.g., density, color, odor); and the duration of exposure and the time elapsed since exposure should be noted. Of particular importance is whether the exposure occurred indoors or out in the open. The possibility of concomitant drug or alcohol use, trauma, and attempted arson, murder, or suicide should also be explored. How and where a comatose victim was found may provide valuable clues. Firefighters should be asked about mask use, its fit and functioning, and its method of oxygen delivery (e.g., by demand valve or by continuous positive pressure). Exposure to invisible gases may occur when they remove their masks after a fire has been extinguished (e.g., during the clean-up or cool-down period). Firefighters should also be asked about the duration and intensity of exertion, the type and amount of protective gear, and environmental conditions. Answers to these questions may suggest additional or alternative diagnoses such as dehydration and hypothermia or hyperthermia.

The nature of symptoms at the time of exposure or discovery, as well as at the time of arrival, is important in assessing the severity of an exposure. Altered mental status, collapse, or syncope at the scene suggests significant CO or CN poisoning or inhalation injury. These events may be overlooked if clinical improvement has occurred by the time of arrival (e.g., if oxygen was administered or presentation was delayed). Cyanosis unresponsive to oxygen suggests severe inhalation injury or methemoglobinemia. The presence of preexisting disease must be considered when interpreting clinical events and determining disposition and treatment.

Vital signs should be carefully evaluated. Particular attention should be given to the respiratory rate. Body temperature should be measured as soon as possible for all patients. This vital sign is often not measured until very late in the evaluation of critically ill patients (i.e., those at greatest risk for hyperthermia or hypothermia). Oxygen saturation measured by ear or finger pulse oximetry (SpO₂) should be considered a fifth vital sign and obtained in all patients.

The physical examination should first focus on assessing the patency of the airway and adequacy of respirations. Cardiovascular stability, CNS function (mental status as well as level of consciousness), and skin color and integrity should then be evaluated. A trauma survey should be included in the evaluation of those with a history of trauma or altered mental status. Patients with respiratory symptoms must be frequently reevaluated for signs of upper airway obstruction, hypoxia, and hypercapnia. Those with abnormal vital signs, altered mental status, hypoxemia, hypercapnia, chest pain, or respiratory distress should have continuous cardiac monitoring. Those who have eye signs or symptoms or are unresponsive should have an ophthalmologic evaluation that includes fluorescein examination to check for corneal injury. Those who are unresponsive should also have a funduscopic examination to assess for papilledema and to compare the color of retinal arterioles and venules.

The SpO_2 may be falsely elevated and near normal when COHb and MetHb are present (see Chapters 14 and 87). Hence, unless the history suggests trivial exposure and the patient is asymptomatic and has normal results on physical examination, COHb and MetHb fractions should be measured. In those who are awake and who have mild respiratory symptoms and normal cardiopulmonary findings, venous blood, placed in a heparinized ABG collection syringe, can be used instead of an arterial sample for measuring COHb and MetHb fractions.⁴¹ If COHb and MetHb fractions cannot readily be measured, a decreased oxygen saturation measured directly by co-oximetry in conjunction with a normal PO_2 (and hence normal calculated oxygen saturation) suggests the diagnosis of either CO poisoning or methemoglobinemia. The oxygen saturation gap, the difference between the calculated and measured oxygen saturation, can be used to estimate the fraction of COHb or MetHb, but it cannot differentiate the two.

The SpO_2 is also less sensitive than the PO_2 in detecting mild hypoxemia because the oxygen-hemoglobin dissociation curve, which relates oxygen saturation to the PO_2 , is S shaped and nearly flat above a PO_2 of 60 mm Hg (corresponding to an SpO_2 of 90%), and a relatively large decrease in the PO_2 occurs before the SpO_2 changes appreciably. Measuring the PO_2 in an arterial sample may therefore be helpful in confirming or excluding inhalation injury when the diagnosis is not clear (e.g., the patient with dyspnea, normal SpO_2 , and normal exam who may simply be anxious). Both the SpO_2 and PO_2 can be normal in patients with inhalation injury, however, and pulmonary function testing may also be necessary.

In patients treated with oxygen, assessing the degree of hypoxemia and severity of inhalation injury can be accomplished by calculating the PO_2/FiO_2 ratio, with FiO_2 expressed as a decimal fraction rather than as a percentage (e.g., room air has an FiO_2 of 0.21, not 21%). Although the FiO_2 is known with certainty only when the patient is intubated and on a ventilator, Venturi masks deliver oxygen at fairly reliable and known concentrations. In patients receiving oxygen by nasal cannula, the FiO_2 can be estimated by adding 0.04 to the room air FiO_2 for each liter per minute of oxygen administered (up to a maximum of 6 L/min, after which the FiO_2 will not increase, unless a mask is also used). For example, 4 L/min of nasal O_2 will provide an FiO_2 of about 0.37 (= 0.21 + 4 × 0.04). A mask with a reservoir bag will deliver an FiO_2 of about 0.6 at an oxygen flow rate of 10 L/min or greater. As noted earlier, the normal PO_2/FiO_2 ratio is about 400 in a healthy adult. In patients with smoke inhalation, a PO_2/FiO_2 ratio of less than 200 indicates severe bronchopulmonary injury and a potentially fatal outcome.

Patients with altered mental status, cardiovascular abnormalities, respiratory distress, or significant hypoxemia should be assessed for acid-base disturbances and hypercapnia by ABG analysis. If metabolic (lactic) acidosis is present, COHb and MetHb fractions are not elevated, and the PO_2 is normal, CN poisoning should be

suspected. Unexplained coma and refractory hypotension also suggest CN poisoning. Although CN levels are not widely available and results will not be known in time to alter therapy, obtaining a blood CN level may retrospectively confirm the diagnosis of cyanide poisoning.

Calculating the alveolar-arterial PO_2 (A-A) gradient may sometimes be helpful in patients with hypoxemia and hypercapnia. The A-A gradient ($150 - 1.25 \times P_{CO_2} - PO_2$, where 150 is the alveolar PO_2) is normally $2.5 + 0.21 \times \text{age}$ (in years). It is increased in patients with inhalation injury but not in those with extrapulmonary causes of hypoxemia and hypercapnia (e.g., hypoventilation secondary to muscular weakness or CNS depression). Patients with signs and symptoms of inhalation who are not in acute distress should have bedside pulmonary function testing. Those who have persistent symptoms and are otherwise normal should be referred for comprehensive pulmonary function testing.

Patients with altered mental status, cardiovascular abnormalities, respiratory distress, or significant hypoxemia should also have a chest radiograph and electrocardiogram. A chest x-ray is also suggested for patients with respiratory complaints or abnormal lung sounds. Those with chest pain, palpitations, or an abnormal cardiac rhythm, and those with other signs or symptoms and a history of cardiopulmonary disease should also have an electrocardiogram.

The evaluation of patients with upper respiratory tract signs and symptoms who do not have respiratory distress or other indications for immediate endotracheal intubation (see later) is best accomplished by fiberoptic laryngoscopy. Alternatively, soft tissue radiographs of the neck and flow-volume loop spirometry can be used to detect upper airway narrowing. Bronchoscopy can be performed to assess the lower airway. Although it is said to be the best test for confirming the diagnosis of inhalation injury,^{47,73,85} it will not detect small airway or pulmonary parenchymal injury, and the prognostic value of abnormal findings remains controversial.⁸⁷

The possibility of occult alcohol or drug intoxication and trauma should also be considered in patients with abnormal mental status or vital signs. Depending on the history and clinical presentation, toxicology testing and additional imaging studies (e.g., cervical spine films, computed tomography of the head) may be indicated. Women of childbearing age who have findings suggestive of significant smoke exposure, particularly those with elevated COHb fractions, should have a pregnancy test.

MANAGEMENT

Prehospital care should begin with the prompt but safe removal of the patient from the smoky environment. Rescue attempts should left to fire department personnel. Rescuers should never enter a fire scene without respiratory, eye, and skin protection. All patients exposed to smoke should receive supplemental oxygen. Decontamination measures such as irrigation of the eyes

and skin may also be indicated. Blankets should be provided if the patient is wet or cold, or if clothing removal is necessary.

Basic and advanced cardiac and trauma life support measures should be instituted as necessary. Urgent endotracheal intubation is indicated for patients with respiratory distress due to upper airway obstruction, cyanosis or hypoxemia ($\text{SpO}_2 < 90\%$, $\text{PO}_2 < 60$ mm Hg, or PO_2/FIO_2 ratio < 100) despite oxygen therapy by reservoir mask, respiratory depression (respiratory rate < 12 breaths/min), acute hypercarbia (PCO_2 45–50 mm Hg or greater), pulmonary edema, altered or depressed mental status, and full-thickness burns of the face or neck.^{68-70,72,76,78} Intubation should also be considered for patients with upper airway pathology on laryngoscopy or a respiratory rate of more than 30 breaths/min who do not improve with oxygen or other pharmacologic therapy. Assisted ventilation using continuous positive airway pressure by mask (CPAP or BiPAP) is a reasonable alternative to endotracheal intubation for the treatment of hypoxemia and hypercapnia due to bronchopulmonary injury.^{88,89}

When performing endotracheal intubation, the largest possible endotracheal tube should be used so that bronchoscopy can subsequently be accomplished. Nasotracheal intubation, alternative airways (e.g., laryngeal mask or Combitube, surgical procedures), or use of a fiberoptic laryngoscope or bronchoscope may be necessary in those with constricting perioral or neck burns or if airway edema prevents visualization of the larynx. If the history or physical examination suggests the possibility of head or neck trauma, cervical spine injury precautions should be taken until radiographs preclude this possibility.

After intubation, the airway should be suctioned aggressively to remove secretions and inhaled debris. Oxygen should be humidified to prevent drying of secretions. Positive end-expiratory pressure at 5 to 10 cm H_2O should be routinely administered to prevent or treat atelectasis.^{68,85} Higher pressures may be necessary for patients who remain hypoxic despite administration of 100% oxygen. Chest physiotherapy and postural drainage may also be helpful.

Bronchoscopy is indicated for therapeutic purposes in intubated patients with inhalation injury because it allows for more effective and directed removal of inhaled debris and bronchial secretions. It may be especially useful in patients with lobar atelectasis or focal infiltrates on chest radiographs. For those with inspissated mucous plugs or bronchial casts, repeated bronchoscopy may be necessary. Tracheostomy should be reserved for those who require prolonged intubation (3 weeks or more) because it is associated with significant complications and increased mortality.⁹⁰

Inhaled (aerosolized) racemic epinephrine or albuterol may be tried in patients who have upper airway signs and symptoms but who do not require immediate endotracheal intubation. Such patients must be carefully monitored for deterioration. Inhaled and parenteral bronchodilators (e.g., albuterol, isoproterenol, terbutaline) should be administered to patients with wheezing or other evidence of lower airway obstruction. Incentive

spirometry and encouragement of coughing may also be helpful.

Corticosteroids are of potential benefit for laryngeal edema and small airways dysfunction. They may also be useful in the treatment of cerebral edema, irritant-induced bronchiolitis obliterans, and postextubation stridor. However, corticosteroids may increase mortality from infection, particularly in patients with pulmonary parenchymal injury and surface burns.^{69,91} In patients with inhalation injury, a single large dose of corticosteroid administered at the time of presentation is reasonable. Reserving subsequent doses for those with severe upper airway obstruction and refractory wheezing is suggested.

Positive-pressure ventilation with positive end-expiratory pressure (PEEP) is the treatment of choice for pulmonary edema secondary to smoke inhalation.⁹² Complications include decreased cardiac output and pulmonary barotrauma. High-frequency ventilation may reduce the incidence of pneumonia and decrease mortality.^{93,94} Inhaled nitric oxide and arteriovenous or venovenous extracorporeal membrane oxygenation (ECMO) should be considered for patients with hypoxemia refractory to other measures.^{95,96} Experimental evidence suggests that nonsteroidal anti-inflammatory drugs (e.g., ibuprofen), antioxidants and free radical scavengers (e.g., superoxide dismutase, catalase, deferoxamine, butylated hydroxytoluene/piperonyl butoxide, mannitol), endotracheal fluorocarbons and exogenous surfactant, heparin, and hyperbaric oxygen may be beneficial in the treatment of pneumonitis and pulmonary edema.⁹⁷⁻¹⁰² Hyperbaric oxygen (HBO) can also be effective in treating CO poisoning, CN poisoning, cerebral edema, and thermal burns.¹⁰³ It should also be considered for patients with refractory hypoxemia.

Patients with concomitant surface burns and inhalation injury may require more fluids for circulatory support than those with either alone.^{94,104} The assertion that excessive fluid resuscitation may worsen airway and pulmonary edema and should be avoided^{69,70,78} has recently been challenged.¹⁰⁵ Worsening edema may simply be the natural course of inhalation injury. The use of fluid restriction and diuretics for the treatment of edema due to inhalation injury is also controversial.^{94,104,105} They are potentially dangerous, particularly in those with surface burns or shock. The goal of fluid therapy should be to maintain normal cardiac output. In critically ill patients, Swan-Ganz catheterization with hemodynamic monitoring may help optimize such therapy.

Antibiotic therapy should be reserved for patients with documented pulmonary infection. Prophylactic use of antibiotics is of no benefit and may foster the development of infection by drug-resistant organisms. The choice of agent should be guided by the results of sputum Gram stain, culture, and sensitivity. In patients with fever and leukocytosis persisting or developing more than 2 days after exposure, empirical therapy with an agent effective against *S. aureus* (e.g., cefazolin or nafcillin), as well as gram-negative bacteria including *Pseudomonas* species (e.g., gentamicin, cefotaxime, or ticarcillin), can be initiated if laboratory results are not immediately available.

CO poisoning and methemoglobinemia should generally be treated according to usual guidelines (see Chapters 14 and 87). HBO will not be effective in CO (or CN) poisoning unless a high PO_2 level can be achieved. Hence, patients with severe inhalation injury (i.e., hypoxemia despite the administration of 100% oxygen by endotracheal tube) may not benefit from HBO. In addition, the indications for its use in these conditions remain controversial.

The treatment of CN poisoning (see Chapter 88) in victims of smoke inhalation is also controversial. Although sodium thiosulfate and hydroxycobalamin can be given safely, an effective formulation of hydroxycobalamin is not yet available in the United States, and nitrites, which induce methemoglobinemia, could cause additional asphyxia in patients with hypoxemia or elevated COHb fractions. Hence, it is suggested that nitrites be reserved for those in extremis or those who remain critically ill with persistent coma, seizures, cardiac dysrhythmias, shock, and lactic acidosis despite intubation and 100% oxygen.¹⁰⁵ Sodium thiosulfate alone may be administered when CN poisoning is suspected because it will enhance the metabolism of CN (enhances conversion of CN to thiocyanate) and is safe (see Chapter 88 for recommended dosing). Because HBO therapy provides enough dissolved oxygen to sustain life in the absence of hemoglobin and obviates concerns over the induction of methemoglobin, it has also been suggested that nitrites be withheld until after HBO therapy has been begun. However, the short half-life of CN and the length of time usually required to arrange for HBO therapy makes it unlikely that nitrites will be necessary or effective in those who survive long enough to receive HBO therapy.

Disposition

The disposition of patients with smoke inhalation depends on its severity. Patients who are asymptomatic on arrival or who become asymptomatic with oxygen therapy alone can be discharged if they have normal findings on physical examination and ancillary testing. Those with mild symptoms and minor abnormalities on clinical evaluation or ancillary testing can also be discharged if they are otherwise healthy and their condition remains stable after a period of observation. Depending on clinical findings, observation for 1 to 6 hours is recommended before discharge. All discharged patients should be instructed to call or return immediately if symptoms develop, recur, or worsen. Patients who do not meet discharge criteria should be admitted. Depending on the nature and severity of injury and the presence or absence of preexisting disease, an observation area, regular floor, or telemetry, intermediate, or critical care unit may be appropriate. Critically ill patients are best managed at a tertiary care facility or burn center and should be transferred if necessary. Although patients with severe CO or CN poisoning may benefit from HBO therapy, HBO treatment centers do not necessarily provide adult or pediatric intensive care or burn services. Hence, the level of care available at such facilities, as well as patient

stability and the nature of other injuries, should be considered when deciding if transfer for HBO therapy is appropriate.

Carbon Monoxide Poisoning

ERIC J. LAVONAS, MD

At a Glance...

- Carboxyhemoglobin levels confirm the diagnosis of carbon monoxide poisoning, but severity of illness, rather than levels, determines the type and intensity of treatment.
- Treatment consists of patient removal from exposure environment and administration of high-flow, high-concentration oxygen at normobaric or hyperbaric pressure.
- Hyperbaric oxygen therapy is most likely to benefit patients with severe carbon monoxide poisoning, such as those with loss of consciousness, persistent altered mental status, seizures, ataxia, hypotension, myocardial injury, and significant symptoms that do not resolve with surface pressure oxygen.
- Pregnant patients with acute carbon monoxide poisoning should be treated with hyperbaric oxygen therapy if they meet criteria defined for nonpregnant patients or if there are signs of fetal distress; treatment with normobaric oxygen should be prolonged because of the slower elimination of carbon monoxide from the fetus.

INTRODUCTION AND RELEVANT HISTORY

Carbon monoxide (CO), a colorless, odorless, nonirritating gas created by incomplete burning of carbonaceous fossil fuels, is a ubiquitous toxin. Mild CO poisoning often masquerades as nonspecific headache or is misdiagnosed as viral illness, whereas moderate to severe CO poisoning produces significant morbidity (e.g., delayed neurologic dysfunction) and mortality and provokes treatment controversy. With more than 2000 annual deaths and at least 15,000 to 40,000 diagnosed cases of nonfatal acute CO poisoning occurring annually in the United States, this poison affects the practice of all physicians.

EPIDEMIOLOGY

Carbon monoxide poisoning is the third leading cause of accidental poisoning death in the United States.¹ Although CO death rates have declined by 80% since the introduction of the catalytic converter in 1975, CO was still responsible for 2379 deaths in the United States in 1998.² Most of these deaths were due to suicide, but a large number of accidental poisonings also occurred (Tables 87-1 and 87-2). In addition to those listed, common sources of accidental CO poisoning include small engines (i.e., electrical generators and power washers), propane-powered fork lifts, boats, ice skating rink resurfacers (Zambonis), paint strippers (methylene chloride), and fires (i.e., victims of smoke inhalation).^{3,4} About 40,000 people are diagnosed with CO poisoning

in emergency departments in the United States annually.³ Among emergency department patients with headache or “flulike symptoms,” the incidence of occult CO poisoning (defined as venous carboxyhemoglobin [COHb] level of 10%) may range from 0.2% to 23.6%.⁵⁻¹¹ Outbreaks of CO poisoning occur after storm-related power outages, in both warm and cold weather.¹² During these outages, charcoal and electrical generators predominate as sources of CO. Poor and immigrant populations are at highest risk.

STRUCTURE AND STRUCTURE–ACTIVITY RELATIONSHIPS

Carbon monoxide is colorless, odorless, and tasteless. Because it has almost the same density as air, CO dis-

TABLE 87-1 Sources of Carbon Monoxide in Fatal Poisoning, 1998

CARBON MONOXIDE	NO. OF FATALITIES
All carbon monoxide–related deaths	2379

tributes equally throughout an enclosed area. Because CO is a small, nonpolar molecule, it penetrates through standard drywall and can disperse throughout separate units of a multifamily dwelling.

PHARMACOLOGY

Pathophysiology

Carbon monoxide enters the body through the lungs, where it binds to hemoglobin with an affinity 200 to 240 times that of oxygen.¹³ The binding of CO to one of the four binding sites on the hemoglobin tetramer shifts hemoglobin to its high-affinity conformation. This shifts the oxyhemoglobin dissociation curve to the left, greatly impairing the ability of hemoglobin to deliver oxygen to tissues. This enhanced affinity and impaired unloading of oxygen is referred to as the *Haldane effect*.

COHb plays only a partial role in the pathogenesis of CO poisoning. This is suggested by the clinical observation that COHb levels do not correlate with the severity of clinical effects and can be low in the face of coma from CO poisoning.¹⁴ Further evidence is provided by a canine study that revealed markedly differing mortality rates for dogs with similar blood COHb levels but differing tissue CO levels.¹⁵ In this study, death occurred uniformly in dogs that breathed air containing 13% CO for 15 minutes resulting in COHb blood levels of about 65%. In contrast, death did not occur in other groups of dogs that were transfused with enough COHb red blood cells to produce blood COHb levels of 60%. In addition, death did not occur in a third group of dogs that had their blood hemoglobin content reduced by 68% through phlebotomy. Thus, animals spontaneously breathing CO had a higher total-body content of CO from its tissue redistribution. Redistributed or "tissue" CO accounts for 10% to 15% of total-body CO stores but is critical to the pathophysiology of CO.¹⁶

CO produces tissue toxicity from its avid binding to other heme proteins (cytochromes), such as myoglobin, the cytochrome a_3 complex (cytochrome oxidase) of the mitochondrial respiratory chain, and guanylate cyclase. Myoglobin's affinity for CO is about 30 to 60 times greater than that for oxygen.¹⁷ CO binding to myoglobin impairs myocardial oxygen uptake from blood into the mitochondria of tissues. Binding of CO to cytochrome oxidase disrupts cellular respiration and oxygen utilization in all tissues, including the brain. Although cytochrome oxidase binds oxygen with greater affinity than CO, CO competes with oxygen for binding sites under conditions of cellular hypoxia and dissociates slowly from cytochrome oxidase once binding has occurred.¹⁸

In addition to direct cytochrome oxidase blockade, CO promotes the production of reactive nitrogen species that further inhibit cellular cytochrome oxidase and electron transport.^{19,20} Cellular hypoxia causes free radical release from vascular endothelial cells and platelets. Concurrently, CO displaces nitric oxide (NO) from heme-containing proteins in endothelial cells and

platelets.²¹ Once released from cells, NO reacts with free radicals to produce peroxyxynitrate (ONOO⁻), which further inhibits cytochrome oxidase, injures DNA and cell membranes, and triggers apoptosis in neuronal tissue.^{19,21}

In addition to cellular hypoxia, CO produces smooth muscle relaxation and vasodilation. CO binds to and stimulates the activity of the heme protein, guanylate cyclase.²² This results in an increased production of the smooth muscle relaxant, cyclic guanosine monophosphate (cGMP). The displacement of NO from platelets and endothelial cells by CO also results in vasodilation.^{21,23} NO, also known as *endothelial derived relaxation factor*, is a potent smooth muscle relaxant. Headache from CO poisoning is likely mediated by extracerebral and intracerebral vasodilation. Hypotension and syncope from CO poisoning may be mediated by some combination of peripheral vasodilation, with COHb-induced myocardial ischemia, direct myocardial depressant effects, and loss of central control of vasomotor tone. Clinically, hypotension and syncope (even if transient) signify serious CO exposure and are ominous predictors of serious neurologic sequelae.^{24,25} Brain areas that have high oxygen requirements or are watershed regions of perfusion (e.g., basal ganglia, hippocampus, and subcortical white matter) are particularly susceptible to CO-mediated injury. In monkeys, cerebral white matter lesions correlated better with decreases in blood pressure than with COHb levels, and it has been suggested that an episode of hypotension may be required for severe neurologic deficits to occur.²⁶ In essence, cellular hypoxia is often accompanied by tissue ischemia. These primary CO-induced pathophysiologic processes (hypoxia and ischemia) induce a cascade of secondary events (ischemia reperfusion effects) that are integral to short- and long-term central nervous system (CNS) toxicity associated with CO.

The histopathology of CO poisoning is similar to that of postanoxic encephalopathy, or so-called reperfusion injury. Brain reperfusion injury patterns are largely mediated by oxidative damage initiated by oxygen free radicals and sustained by second-generation lipid radicals. Current evidence suggests that xanthine oxidase activity is largely responsible for the generation of free radicals associated with CO-mediated lipid peroxidation and brain injury.²⁷ When CO exposure is associated with tissue hypoxia, adenosine dinucleotide triphosphate (ATP) stores are depleted in tissues. Simultaneously, the cells have a greatly increased demand for ATP to repair oxidative damage. In a series of steps, ATP is converted to uric acid and an oxygen free radical.

Investigations by Thom and colleagues indicate that significant CO exposure produces a cascade of biochemical events responsible for delayed neurologic sequelae.^{19,21,23,24,27} Significant CO exposure promotes release of NO from endothelial cells and platelets. Concurrently, impaired mitochondrial function and oxidative stress promotes production and release of oxygen free radicals from these cells. NO reacts with oxygen radicals to form peroxyxynitrite. Peroxyxynitrite binds to perivascular tissue proteins causing endothelial

injury. Endothelial injury provokes expression of adherence molecules (e.g., β -integrin) on cell surfaces, which promotes leukocyte binding to injured endothelial cells. Leukocytes release proteases that further augment the activity of xanthine oxidase and production of oxygen free radicals. Subsequently, brain lipid peroxidation and delayed CNS toxicity ensue. Brain injury is also mediated by additional mechanisms, such as activation of excitatory amino acids (e.g., glutamate) and apoptosis-related enzymes (e.g., caspase-1).^{23,28}

Pharmacokinetics

Carbon monoxide uptake and elimination occur through the lungs and are dependent on minute volume. Only a small amount of CO is metabolized by oxidation to carbon dioxide. Because CO diffusion through the alveoli is rapid and complete, the amount of CO dissolved in arterial blood is directly related to the concentration of CO in the air of the patient's environment. Depending on conditions, whole-body equilibrium may only be reached after 4 to 6 hours of exposure. Conversely, measurements of CO concentration in expired air correlate well with venous CO levels. Overall, the amount of CO absorbed by the body depends on ambient air CO and oxygen concentrations, minute ventilation, and duration of exposure. In human volunteer studies, the elimination of CO in room air (21% oxygen) ranges from 249 to 320 minutes.^{29,30} Administration of 100% oxygen shortens the elimination half-life to 47 to 80 minutes at normal atmospheric pressure and to about 20 minutes at 2.5 to 3 atmospheric pressure.^{31,32}

Methylene chloride (see Chapter 93), found in paint strippers, degreasers, and other solvents, is another potential source of CO poisoning. It is readily absorbed from the lungs and gastrointestinal tract; lesser amounts may also be absorbed from the skin. Once absorbed, methylene chloride is slowly metabolized in the liver to CO and carbon dioxide. Peak CO levels from methylene chloride depend on the route of exposure but may not occur for over 8 hours. Because of ongoing CO production through metabolism of methylene chloride, the half-life of CO may appear to be prolonged, up to 13 hours, in these cases.^{33,34}

Special Populations

Because of their rapid respiratory rate, children may be more susceptible to CO poisoning than adults. Advanced age may be a risk factor for adverse neurologic outcomes after CO poisoning.³⁵

Although fetal hemoglobin has a higher affinity for CO than hemoglobin A in similar pH and P_{O_2} conditions, this effect is largely counteracted by the acidemic, hypoxic milieu of the normal fetus. As a result, fetal COHb levels are expected to be within 10% of maternal levels.³⁶ Based on animal data and mathematical models, the elimination half-life of fetal COHb is significantly longer (up to 3.5 times greater) than that of adult COHb.^{37,38}

TOXICOLOGY

Clinical Manifestations

ACUTE EFFECTS

Signs and symptoms of mild CO poisoning include headache, nausea, vomiting, diarrhea, dizziness, weakness, dyspnea, and fatigue (Table 87-3). Misdiagnoses, such as viral illness and benign headache, are common. In one study, the diagnosis of CO poisoning was initially missed in up to 30% of cases; the most common incorrect diagnosis, "food poisoning" was made in 43% of these cases. The diagnosis of CO poisoning should be considered for patients presenting with one or more of the listed symptoms in the absence of fever.³⁹ A history of exposure to possible CO sources (e.g., fossil fuel heat, engines, propane and natural gas appliances, grills) or groups of patients with similar complaints should suggest occult CO poisoning and prompt blood or breath testing for CO.⁸ With more severe exposure, patients can present with signs of neurologic, cardiovascular, and pulmonary dysfunction. These effects include confusion, irritability, ataxia, coma, focal neurologic deficits, seizures, syncope, hypotension, arrhythmias, myocardial ischemia or infarction, tachycardia, tachypnea, noncardiogenic and cardiogenic pulmonary edema, and respiratory and cardiac arrest.

In general, any organ can be affected by CO. Table 87-4 lists the spectrum of complications that can be associated with CO poisoning. Unusual complications include retinal hemorrhages, compartment syndromes, rhabdomyolysis and renal failure, skin blisters, bowel ischemia, and peripheral neuropathy. Although patients with more severe signs of acute CO poisoning (e.g., syncope, hypotension, coma) are more likely to develop delayed and long-lasting morbidity, this is not uniformly true. Patients with mild toxicity may develop delayed neurologic sequelae, and those with severe toxicity may have complete recovery.

CHRONIC EFFECTS

Some CO-poisoned patients develop lasting signs of brain injury, most commonly cognitive and personality

TABLE 87-3 Acute Symptoms in 1144 Patients with Carbon Monoxide Poisoning

SYMPTOM	PERCENTAGE OF PATIENTS
Headache	85
Dizziness	69
Fatigue or generalized weakness	67
Nausea or vomiting	52
Trouble thinking or confusion	37
Loss of consciousness	35*
Dyspnea	7
Chest pain	2

*Patients with loss of consciousness (LOC) were excluded from Thom's series ($N = 65$ without LOC; number with LOC excluded not stated). Data from references 35, 41–43, 64, 68, and 90.

TABLE 87-4 Spectrum of Complications Due to Carbon Monoxide Poisoning

SYSTEM	COMPLICATIONS
Central nervous	Impaired cognition, memory dysfunction, vertigo, ataxia, parkinsonism, muscle rigidity, gait disturbance, disorientation, mutism, urinary incontinence, fecal incontinence, cortical blindness, hearing loss, tinnitus, nystagmus, seizures, coma, electroencephalographic abnormalities, cerebral edema, leukoencephalopathy, diabetes insipidus, globus pallidus necrosis
Psychiatric	Personality changes, depression, flattened affect, Tourette's syndrome, anxiety, agitation, poor impulse control
Cardiovascular	Tachycardia, easy fatigue, hypotension, ischemic electrocardiographic changes, arrhythmias, new-onset angina or exacerbation of existing angina, myocardial infarction
Pulmonary	Shortness of breath, pulmonary edema, hemoptysis
Gastrointestinal	Nausea, vomiting, abdominal cramps, diarrhea, gastrointestinal bleeding
Ophthalmologic	Decreased acuity, retrobulbar neuritis, paracentral scotomata, papilledema, flame-shaped retinal hemorrhages
Dermatologic	Erythematous patches, cherry-red skin, bullae, alopecia, sweat gland necrosis
Muscular	Rhabdomyolysis, compartment syndrome
Hematologic	Disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, leukocytosis
Metabolic	Lactic acidosis, hyperglycemia, hypocalcemia, hyperamylasemia (salivary origin)

changes and parkinsonism. These may develop at the time of CO poisoning and continue (persistent neurologic sequelae) or develop after an asymptomatic interval of 3 to 21 days (delayed neurologic sequelae, or DNS). Longer latent periods have been reported. DNS manifest with a variety of neurologic and psychiatric signs and symptoms. Commonly described findings include memory loss, confusion, ataxia, incontinence, emotional lability, hallucinations, personality changes, blindness, and parkinsonism. There are no established diagnostic criteria for this disorder, and the observed incidence varies widely, from 12% to 74% for CO poisoning victims in recently published clinical trials.^{35,40-45} One recent study, which paired 32 CO poisoning victims (8 of whom had loss of consciousness and 24 of whom received hyperbaric oxygen [HBO]) with gender, age, and educationally matched controls, found no evidence of the syndrome at all.⁴⁴ Many patients recover to normal over several weeks to months.^{45,46}

DIAGNOSIS

Laboratory Testing

The diagnosis of CO poisoning is based on suggestive history and physical findings coupled with confirmatory COHb testing (Table 87-5). CO levels can be tested in either whole blood or exhaled air. In hospitals, the most commonly used technique is to measure COHb as a percentage of total hemoglobin using a multiple wavelength spectrophotometer. Blood is collected in a closed, heparinized container (a blood gas syringe or "green-top" tube) and analyzed on a co-oximeter. Because there is no significant difference between venous and arterial COHb levels, either type of sample is appropriate.⁴⁷ Because of endogenous CO production, some COHb is present in the blood of healthy subjects. Normal COHb levels are 0.5% to 2% in nonsmokers and up to 10% to 12% in smokers. Levels are somewhat

higher in pregnant women, infants, and patients with hemolytic anemia. COHb is often misinterpreted as oxyhemoglobin by simple bedside pulse oximetry. Pulse oximetry overestimates oxyhemoglobin measurements by the approximate amount of COHb that is present.⁴⁸ Thus, co-oximetry is required to measure COHb levels accurately.

TABLE 87-5 Relationship of Carbon Monoxide Levels in Air and Carboxyhemoglobin Levels at Steady State

CARBON MONOXIDE CONCENTRATION IN AIR (PPM)	CARBOXYHEMOGLOBIN (%) ACHIEVED AT STEADY STATE	NOTES
10	1.5	Approximate upper limit of normal in nonsmokers
35	5	NIOSH-recommended exposure level for 8-hr workday
50	7	Current OSHA 8-hr permissible exposure level for 8-hr workday
70	10	Approximate upper limit of normal in smokers
350	35	NIOSH recommends supplied-air respirator use
1200	65	Immediately dangerous to life and health level (NIOSH)

NIOSH, National Institute of Occupational Safety and Health; OSHA, Occupational Safety and Health Administration. Calculated from formulas in reference 36, assuming adult patients with normal hemoglobin. Interindividual variability exists.

An alternative method, more commonly used in Europe, is to measure CO directly. A blood sample is diluted and mixed with a reagent to liberate CO from hemoglobin. The CO content of head-space gas is then measured with gas chromatography or infrared spectrophotometry.^{49,50} Although this method is more accurate for measuring low CO levels, there is no clear advantage in the assessment of acute poisoning.

COHb “spot tests,” performed by adding sodium hydroxide or ammonia to a tube of blood and observing for a persistent pink color, are neither sensitive nor specific.⁵¹

Breath analysis is a valid alternative to blood testing.^{52,53} However, because patient cooperation is necessary, breath analysis may be impractical in young children and patients with significantly altered mental status. Models vary greatly in their ease of use, and some give false-positive results in the presence of ethanol. Normal levels of CO in exhaled air are 0 to 6 ppm in nonsmokers and up to 70 ppm in smokers. Most analyzers automatically convert these levels to predicted COHb levels for medical use.

A promising new technology is noninvasive pulse co-oximetry. These devices, which are essentially a technological improvement on pulse oximetry, use multiple wavelengths of light to directly measure oxyhemoglobin, deoxyhemoglobin, and COHb (and, in some models, methemoglobin) through a probe applied to the finger or ear. Because this procedure is rapid and noninvasive and does not require patient cooperation, it has the potential to replace exhaled breath and blood co-oximetry analysis for the diagnosis of CO poisoning.

COHb levels do not correlate well with clinical severity, outcome, or response to therapy.^{41-43,46,54} The role of a COHb measurement is to confirm or exclude that a CO exposure has occurred. The diagnosis of CO poisoning is made when an elevated COHb level is documented concurrently with history, signs, and symptoms suggestive of poisoning. In order to interpret COHb measurements, it is important to know the time since cessation of exposure and whether the patient was on oxygen during this time. Although COHb elimination varies considerably between individuals, a reasonable estimate is to assume that COHb levels fall by half every 4 to 5 hours in patients breathing air and every 1 hour in patients breathing oxygen by mask. If calculations reveal a “predicted peak” COHb level of less than 10%, symptomatic CO poisoning is unlikely, and an alternative diagnosis should be sought. If the diagnosis of CO poisoning is confirmed, the history and physical examination guide the choice of therapy. Depending on the route of exposure, patients with methylene chloride poisoning may need serial measurements of blood COHb to rule out significant CO poisoning.

Arterial blood gas measurements are not useful to make the diagnosis of CO poisoning. They provide useful information with regard to the adequacy of ventilation and presence and degree of metabolic acidosis.⁵⁵

Although elevated blood lactate levels may occur in severe CO poisoning, most patients in published case series have normal lactate levels. It is not clear whether

elevated lactate is an independent risk factor in CO victims who otherwise appear well. CO poisoning rarely causes a lactate level greater than 4 mmol/L; an alternate explanation for lactic acidosis, such as cyanide poisoning or shock, should be sought. In particular, the measurement of blood lactate may be a useful surrogate for cyanide poisoning for smoke inhalation victims (see Chapters 86 and 88).

Carbon monoxide poisoning can cause myocardial infarction. In one case series, patients who demonstrated clinical evidence of myocardial injury (elevated CK-MB, elevated troponin I, and/or diagnostic ECG changes) were followed prospectively.⁵⁶ Survivors had a significant increase in cardiac and all-cause mortality over several years after the poisoning, compared with CO-poisoned patients who did not have myocardial injury.

Unfortunately, it is difficult to extrapolate from this study to a management strategy for patients with CO-induced myocardial infarction. All patients in this study were treated with HBO; HBO did not prevent the increased mortality, and it is speculative to say whether the rate would have been different had HBO not been employed. Patients with myocardial infarction were older and more severely poisoned than those without such injury, potentially confounding these results. Because CO can cause diffuse myocardial injury in the absence of coronary artery disease, it unclear whether evidence of myocardial infarction indicates a need for coronary angiography in the CO-poisoned patient or whether cardiac stress testing is safe or accurate in the immediate aftermath of CO poisoning.

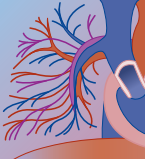

Any patient who suffers a prolonged period of unconsciousness or shock may develop complications such as rhabdomyolysis, compartment syndrome, renal failure, or disseminated intravascular coagulopathy. Testing for these conditions should be performed when clinical suspicion is high.

Other Diagnostic Testing

All women with childbearing potential who are suspected of having CO poisoning should have a pregnancy test. Although this topic is controversial, many experts recommend a prolonged period of oxygen therapy and a lower threshold for hyperbaric oxygen treatment if the CO poisoning victim is pregnant. An assessment of fetal status, such as a fetal heart rate, nonstress test, or ultrasound, should be performed when practical.

An ECG should be performed on individuals with a history of chest pain, dyspnea, or hypotension. Other testing, such as head computed tomography (CT) or lumbar puncture, may be needed to exclude other causes of altered mental status when the diagnosis of CO poisoning is inconclusive.

A special neuropsychological battery has been developed to detect subtle impairment in CO poisoning victims that might be missed by routine neurologic testing.⁵⁷ Performance on this battery is altered with CO poisoning and improves with therapy. However, the test is designed only to detect neuropsychological impairment and does not distinguish CO poisoning from other

causes of encephalopathy, including alcohol. The battery is somewhat cumbersome, requires 30 to 45 minutes to administer, must be administered in a quiet area, requires fluency and literacy in English, assumes normal intelligence, is not valid for children younger than 15 years, and does not predict patients at risk for developing delayed neurologic sequelae.^{43,57} A standard focused neurologic examination, including mini-mental status examination and testing for ataxia, is adequate for routine clinical use.

Chest radiography is recommended for all seriously poisoned patients and those with cardiopulmonary signs and symptoms. Noncardiogenic pulmonary edema may be evident on chest radiograph. Brain CT is recommended for seriously poisoned patients. Brain CT may show signs of cerebral infarction secondary to hypoxia or ischemia. Symmetric low-density lesions of the globus pallidus, putamen, and caudate may be detected as early as 12 hours after CO poisoning and are associated with a poorer prognosis.^{58,59} Brain magnetic resonance imaging (MRI) is able to detect basal ganglia lesions with greater sensitivity than head CT. In addition, other abnormal findings demonstrated on head MRI in CO-poisoned patients include diffuse, symmetric white matter lesions of the periventricular areas.⁶⁰

Differential Diagnosis

Just as CO poisoning can mimic other illnesses, many other conditions cause encephalopathy, headache, nausea, weakness, or hypotension. When the diagnosis of CO poisoning is excluded or uncertain, testing for occult trauma, stroke, infection, drug intoxication, or metabolic derangement may be necessary. Rapid bedside tests should be used to exclude hypoglycemia and hypoxemia in almost all patients. Victims of smoke inhalation who have significant lactic acidosis should be suspected of having associated cyanide poisoning.

MANAGEMENT

Supportive Measures

All patients should receive aggressive supportive care while the diagnosis of CO poisoning is established. Patients with significant CNS or respiratory depression should have their airway protected, breathing assisted, and cardiovascular support provided as necessary. The administration of high-concentration, high-flow oxygen by tight-fitting face mask or endotracheal tube is fundamental. Severely poisoned patients should have continuous cardiac monitoring, an intravenous (IV) line established, and an ECG performed. Continuous pulse oximetry and parenteral thiamine, dextrose (or rapid fingerstick glucose determination), and naloxone should be considered for patients with altered mental status or seizures because of the potential for concurrent illness. Hypotension may be treated with IV fluids and, if necessary, vasoactive infusions.

Decontamination

Immediate removal from the contaminated environment is critical. Except for methylene chloride exposures, CO absorption ceases as soon as the patient is removed from the poisoned environment. Although CO victims have elevated amounts of CO in exhaled air, the amount involved poses no danger to health care workers. Although placing the patient on oxygen speeds the elimination of CO from the body, no form of decontamination is required.

Laboratory Monitoring

Serial measurements of COHb or breath CO are not helpful in management unless the exposure was to methylene chloride. Once the diagnosis of CO poisoning is established, further lab monitoring is only indicated as required by other medical conditions (e.g., cyanide poisoning, shock, trauma, and metabolic acidosis).

Antidotes

The antidote for CO poisoning is oxygen, which should be administered at a concentration as close to fiO_2 1.0 as reasonably achievable and for a period of at least 4 hours. High-concentration oxygen is delivered by a tight-fitting, reservoir-containing (non-rebreather) face-mask or by endotracheal tube. Oxygen is delivered at ambient (atmospheric) pressure or elevated ambient pressure. Although the practice of administering oxygen has never been tested to see if it improves outcome, oxygen therapy is safe, inexpensive, and convenient and greatly improves the rate of CO elimination. The 4-hour duration of therapy is chosen for practicality and because it allows even the most severely poisoned patients (i.e., COHb > 40%) to eliminate CO to negligible levels.

Many experts recommend HBO or administration of oxygen at 2 to 3 atmospheres pressure absolute (ATA) in a hyperbaric chamber. Although HBO is reasonably safe, it is considerably more expensive and less convenient than administration of oxygen at ambient pressure ("normobaric" oxygen, or NBO), particularly if transfer to another facility is required.

In experimental animal models of severe CO poisoning, HBO therapy decreases brain injury by a variety of mechanisms, including improved mitochondrial oxidative metabolism, inhibition of leukocyte adherence to injured vasculature, and reduced lipid peroxidation. In this setting, HBO has a paradoxical, and beneficial, antioxidant effect.^{23,28,61-63} However, although treatment with HBO eliminated hippocampal cell death in a mouse model of CO poisoning, there was no difference in learning and memory testing.⁶⁴

At least seven case series and nonrandomized clinical trials of HBO for CO poisoning have been published.⁶⁵⁻⁷¹ Few of these studies assessed outcomes by objective measures, and none were blinded. All reported a benefit from HBO over standard NBO therapy. Five randomized clinical trials studying the effect of HBO on neuropsychological outcomes have been published and are listed in Table 87-6. Three of these trials reported a

benefit to HBO, and two showed NBO to be equally efficacious. These trials have differed greatly in entry criteria, blinding, time from poisoning to experimental therapy, and outcome measures studied. Only two were double-blinded, employed sham “hyperbaric” therapy in the NBO arm, and measured outcomes by objective neuropsychological testing.^{42,43} These studies produced conflicting results; one study found a strong advantage to HBO, whereas the other showed no benefit and a nonsignificant trend toward harm. A fifth randomized trial used a nonclinical end point, which makes interpretation of results and extrapolation to clinical practice virtually impossible.⁵⁴ Methodologic differences between studies and missing data make formal meta-analysis of these trials impossible. A crude summary of the results suggests that HBO provides an advantage over NBO that is nearly statistically significant ($P = 0.056$; Chi-squared, 1 degree of freedom), but clinically very modest; only 1 of every 21 patients receiving HBO appeared to benefit from the therapy.

If HBO does prevent neurologic injury, it must do so by a mechanism other than enhancing CO elimination from the blood. In all trials for which the data are reported, COHb had declined to negligible levels in almost all patients by the time HBO therapy could be initiated, and COHb levels did not correlate with neurologic outcome or response to therapy. From animal studies, HBO appears to displace CO from mitochondrial cytochromes, has antioxidant effects that minimize ischemic-reperfusion injury, and prevents cellular apoptosis.

Although expensive and inconvenient, HBO therapy is reasonably safe; chamber-related complications occur in 0 to 8% of patients.^{35,43,72} Complications include middle ear or sinus barotrauma (most common), seizures (1%), pneumothorax, gas embolism, and intolerable claustrophobia. HBO therapy is not available in most American hospitals. Transport to a center that can deliver HBO may contribute greatly to expense, inconvenience, and treatment delay.

Unfortunately, no single or combination of factors has been shown to reliably predict which CO poisoning patients will develop DNS. Most CO-poisoned patients recover completely with NBO alone, and therefore would not benefit from or need HBO therapy. In addition, no trial of HBO therapy has included children. Although outcomes are generally worse in elderly people, regardless of treatment, it is unclear whether the benefits of HBO are any greater in this group. Despite the lack of reliably identifying patients with CO poisoning at high risk for developing DNS, criteria have been proposed to use as indications for HBO in patients with CO poisoning^{73,74} (Box 87-1). These indications have not been prospectively evaluated and validated, but their presence should provoke strong consideration for HBO treatment.

Almost all experts recommend HBO therapy for pregnant women with significant CO poisoning, regardless of stage of pregnancy or severity of clinical signs and symptoms. A landmark study in pregnant ewes showed that COHb levels in the fetus rise more slowly than in the mother, ultimately reaching a level 98% higher than the

BOX 87-1**INDICATIONS AND CONSIDERATIONS FOR HYPERBARIC OXYGEN TREATMENT IN CARBON MONOXIDE POISONING****Accepted Indications**

Altered mental status
History of loss of consciousness or syncope
Coma
Seizures
Focal neurologic deficits
Pregnancy with evidence of fetal distress

Considerations

Metabolic acidosis
Cardiac end-organ effects (severe arrhythmia, ischemia, or infarction)
Extremes of age
COHb level > 25%–40%
Abnormal neuropsychometric testing
Persistent neurologic symptoms after 4–6 hr of high-flow normobaric oxygen
Pregnancy with COHb level > 15%–20%

COHb, carboxyhemoglobin.

Adapted from references 73, 74, and 85.

maternal level.⁷⁵ When CO exposure was discontinued, CO was eliminated from the fetus at about half the maternal rate. However, these results cannot be extrapolated directly to humans. Sheep hemoglobin A has a lower affinity for CO than human hemoglobin A, whereas sheep fetal hemoglobin has a much higher affinity for CO than human fetal hemoglobin.⁷⁶ During human poisoning, the peak fetal COHb percentage should be within 1% to 4% of maternal peak levels.^{36,76} CO poisoning interferes with oxygen delivery to the fetus, but because the normal fetus is profoundly hypoxic and acidotic by postnatal standards, it unclear at what threshold this would lead to injury. Although unclear, pregnant patients likely need longer treatment with oxygen because of the slower elimination of CO across the placenta, particularly when the CO exposure occurred over several hours or more.⁷⁵

It is known that severe maternal CO poisoning can cause intrauterine fetal demise, limb and vertebral anomalies, cranial deformities, brain injury, transient hepatomegaly, and congestive heart failure in the newborn.⁷⁷⁻⁷⁹ It is unclear, however, whether mild to moderate maternal CO poisoning can produce adverse fetal outcomes. Three case series have examined pregnancy outcomes in CO-poisoned women.⁷⁷⁻⁷⁹ In all cases, women with minor CO poisoning (no loss of consciousness and normal mental status) delivered healthy babies, despite not receiving HBO. Animal studies suggest that a single CO exposure can lead to intrauterine hypoxia, fetal brain injury, and increased rates of fetal death.⁸⁰⁻⁸² It is unclear from these studies, however, whether exposures that lead to adverse fetal

outcome can occur in the absence of significant maternal poisoning. The efficacy of NBO or HBO for preventing adverse fetal outcomes for pregnant patients with CO poisoning has not been determined. To date, pregnant women have been excluded from all published trials of HBO in CO poisoning.

HBO is generally considered safe for the fetus and has been used safely in pregnant women with CO poisoning.⁸³ The results in these patients were similar to those of the pregnant women treated without HBO. When the mothers had normal mentation, the fetuses universally did well, whereas maternal coma or loss of consciousness carried a poor prognosis despite HBO.

Patients who develop cardiac arrest as a result of CO poisoning have very poor outcomes. In one series of such patients, none (0 of 18) survived to hospital discharge despite aggressive therapy, including HBO.⁸⁴

A reasonable algorithm for managing CO-poisoned patients is presented in Figure 87-1. This management strategy is in keeping with a recent position statement of the Undersea and Hyperbaric Medical Society and the consensus report of a panel of CO-poisoning experts.^{73,85} Unresolved issues include which subgroups of CO poisoned patients are most likely to benefit from HBO, the optimum HBO treatment pressure and number of sessions, the necessary intensity of NBO therapy in patients not receiving HBO, and the “window of opportunity” after which brain injury is irreversible even with therapy.⁷³

In addition to oxygen therapy, several novel neuroprotective strategies have been evaluated in a mouse model of CO poisoning. Glutamate antagonists (riluzole), caspase-inhibitors (disulfiram), nitric oxide synthase inhibitors (*N*-nitro-L-arginine methyl ester, or L-NAME), adenosine agonists (2-chloro-*N*⁶-cyclopentyl-adenosine, or CCPA), and adenosine deaminase inhibitors (erythro-9-2-hydroxy-3-nonyl-adenine, or EHNA), have all been shown to prevent hippocampal damage and learning and memory defects in mice.⁸⁶⁻⁸⁸ HBO did not prevent neurologic injury in the same model.⁶⁴ Although riluzole and disulfiram have been found to be safe and effective treatment for other human diseases, neither has been tested in human victims of CO poisoning.

Elimination

DISPOSITION

Victims of CO poisoning can be released from the hospital after 4 to 6 hours of oxygen therapy (whether NBO or a combination of HBO) if they are neurologically normal, have no more than mild symptoms, and have no unmet medical or psychiatric needs. NBO may be discontinued before 4 hours for patients with mild CO poisoning whose symptoms have resolved and who have COHb levels below 5%.⁸⁹ Patients who do not recover fully after initial therapy should receive further high-flow oxygen treatment and consideration for HBO referral and treatment. Patients with moderate to severe CO poisoning should be considered for HBO treatment upon arrival and subsequently admitted to the hospital, preferably to an intensive care unit.

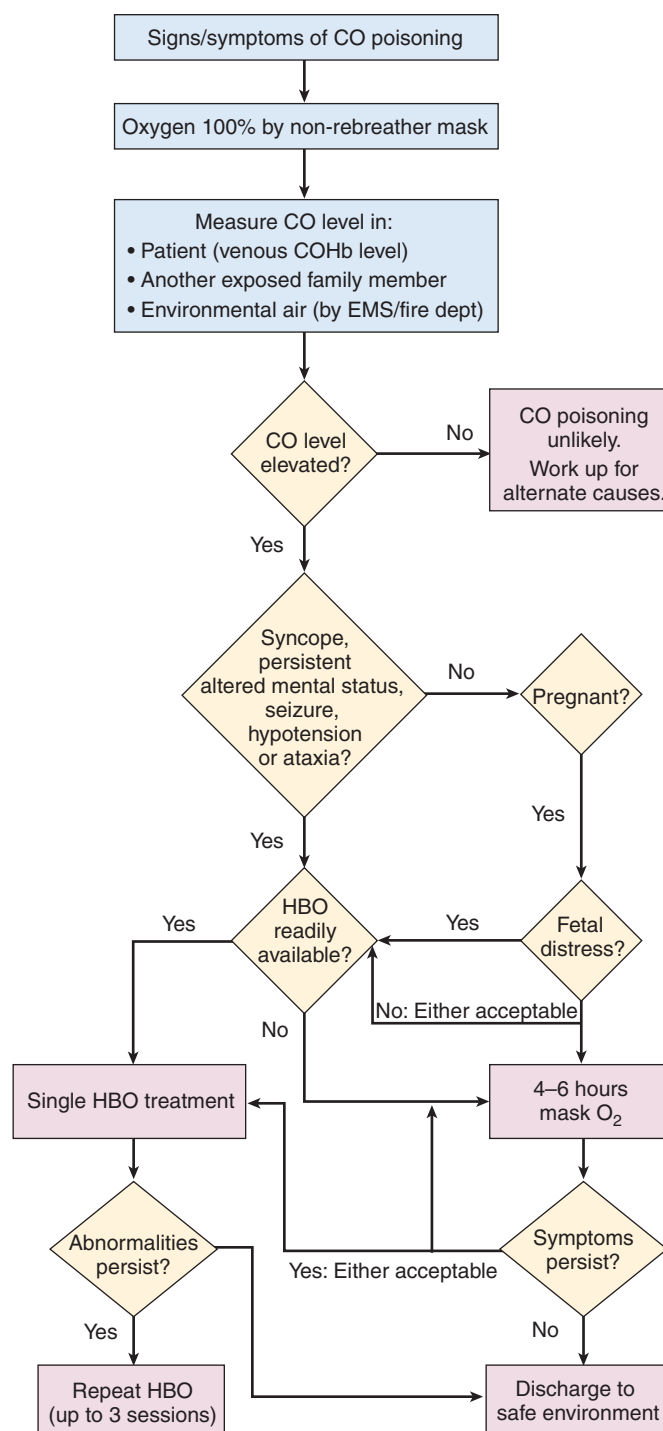

FIGURE 87-1 Suggested management algorithm for carbon monoxide poisoning.

Upon hospital discharge, patients should be warned of the possibility of delayed neuropsychological complications and provided with instructions about what to do if these occur. All patients diagnosed with CO poisoning who are discharged from the emergency department after NBO treatment should also have mandatory medical follow-up within 1 to 2 weeks so that repeat neurologic evaluation can be conducted. Most

patients return to normal within 3 to 12 months.^{13,21} Because of the increased risk of cardiovascular mortality, patients who suffer myocardial infarction due to CO poisoning should have long-term follow-up and cardiac risk assessment performed.⁵⁶

ALAN H. HALL, MD

At a Glance...

- Severe acute cyanide poisoning can be seen in a wide variety of settings, including enclosed-space fire smoke inhalation.
- Cyanide is a credible toxic terrorism threat agent.
- Whole-blood cyanide levels require several hours or longer to obtain.
- Emergent suspicion of the diagnosis and the decision to administer specific antidotes must be made on clinical and screening laboratory grounds.
- Elevated plasma lactate levels are a specific and sensitive indicator of the presence of significant cyanide poisoning in both smoke inhalation and pure cyanide poisoning cases.
- Several specific cyanide antidotes are available throughout the world.
- In the United States, only the cyanide antidote kit containing amyl nitrite for inhalation administration and sodium nitrite/sodium thiosulfate for intravenous administration is available as of June 2006.
- Amyl nitrite inhalation is an effective first-aid measure, especially in cases of hydrogen cyanide gas exposure.
- Growing evidence indicates that hydroxocobalamin may be the cyanide antidote of choice because of its efficacy and superior safety and adverse effects profile.
- The nitrite and thiosulfate antidote kit is not efficacious for sodium azide poisoning; hydroxocobalamin may be of theoretical benefit based on limited *in vitro* data.

INTRODUCTION AND RELEVANT HISTORY

Cyanide poisoning may be encountered in a wide variety of settings. Cyanide salts and hydrocyanic acid are used in common industrial processes such as electroplating, jewelry and metal cleaning, precious metal extraction, laboratory assays, and photographic processes.¹⁻⁴ Hydrogen cyanide is a chemical intermediate for the manufacture of synthetic fibers, plastics, and nitriles.⁵ Criminal tampering by replacement of the ingredients in over-the-counter capsules with cyanide salts has resulted in a number of deaths.^{6,7} Victims of enclosed-space fire-smoke inhalation may have both cyanide and carbon monoxide poisoning.^{8,9}

Cyanide and carbon monoxide are synergistic toxicants¹⁰ (see Chapters 86 and 87). Nontraumatic deaths in aircraft accidents may be due to inhalation of carbon monoxide and cyanide combustion products.¹¹ A number of compounds can liberate cyanide on spontaneous or thermal decomposition or by chemical reaction with acids (e.g., cyanogen, cyanogen bromide, cyanogen iodide, cyanogen chloride, calcium cyanide).¹ Cyanogen halides and hydrogen cyanide are potential

chemical warfare agents.¹² At low concentrations, however, cyanogen halides are primarily lacrimating and pulmonary irritant agents.³

Cyanogenic compounds (laetrile, amygdalin from plant sources, nitrile compounds such as acetonitrile or propionitrile) can release cyanide during metabolism, chemical reaction in the gut, or bacterial degradation after ingestion.^{3,13-17} Acute cyanide poisoning from apricot or peach kernels is unusual because the pits are usually swallowed whole and simply pass through the gastrointestinal tract; rare cases have been reported.¹⁸ Severe or fatal cyanide poisoning with symptom onset delay of several hours has followed accidental acetonitrile ingestion from glue-on artificial nail-removing compounds.^{19,20}

Acrylonitrile is a special case. After inhalation or dermal exposure, it both undergoes hepatic metabolism releasing cyanide and is itself hepatotoxic. Whole blood cyanide levels as high as 4.3 µg/mL have been found in patients with acrylonitrile poisoning.¹⁷ In addition to supportive care and cyanide antidotes, treatment with *N*-acetylcysteine in a manner similar to that for acetaminophen poisoning has been recommended to prevent hepatotoxicity¹⁷ (see Chapter 47).

Sodium nitroprusside releases cyanide during metabolism, which can result in elevated whole blood cyanide levels, and, occasionally, clinical cyanide poisoning.²¹⁻²⁴

Coadministration of sodium thiosulfate or hydroxocobalamin can prevent cyanide toxicity, especially in patients receiving sodium nitroprusside infusions at rates greater than 2 µg/kg/minute^{24,25} (see Chapter 61).

The frequent lack of correlation between blood cyanide levels and cyanide poisoning symptoms during nitroprusside administration suggests that the decision of whether to administer antidote therapy must be made on clinical grounds (e.g., presence of lactic acidosis or signs and symptoms consistent with cyanide poisoning). Clinical symptoms in this setting may, however, be due to thiocyanate accumulation.²⁶

Chronic exposure to low levels of cyanide has been postulated to cause retrobulbar optic atrophy (in heavy smokers) and ataxic peripheral neuropathy (tropical ataxic neuropathy), as well as konzo (spastic upper motor neuron paraparesis) in people who consume large amounts of improperly prepared cassava, which contains the cyanogenic glycosides linamarin and lotaustralin in both roots and leaves.^{27,28} Development of these neuropathies seems to require both chronic low-level cyanide exposure and either a deficiency of the endogenous cyanide-detoxifying enzyme rhodanese or protein-calorie malnutrition with dietary sulfur deficiency. A condition resembling acute cyanide poisoning treatable with hydroxocobalamin has resulted from acute ingestion of improperly prepared cassava.²⁹

Mild disorders of vitamin B₁₂ and folate levels and some subclinical thyroid function abnormalities were noted in one group of workers with chronic cyanide salt exposure.²

Thyroid enlargement (goiter) and altered iodine-131 uptake have also been described in workers chronically exposed to cyanide³ and in populations eating an iodine-deficient monotonous cassava diet.³⁰

EPIDEMIOLOGY

Despite widespread cyanide and cyanogenic compound use, serious acute cyanide poisoning is rare. Of a total of 2,267,979 human poison exposures reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System (TESS) during 2001, only 303 involved cyanide poisoning; of these, 17 were in children younger than 6 years of age, 17 were in patients 6 to 19 years of age, and 263 were in patients older than 19 years of age (the remainder were in patients of unknown age).³¹

Of the 295 cases in which the reason for exposure was known, 237 were unintentional exposures, 37 were intentional exposures, and 21 were classified as other.

A total of 199 (65%) of these patients were treated in a health care facility.³¹ Of cyanide antidotes available in the United States, amyl nitrite was not listed in the 2001 TESS database, sodium nitrite administration was recorded in 27 instances, and sodium thiosulfate administration was recorded in 57 instances.

Of the 303 cyanide exposures, clinical outcome was known in only 194 (64%).³¹ In 64 cases (21%), no signs or symptoms of cyanide poisoning developed; 116 patients (38%) became symptomatic, and 7 (2.3%) developed major symptoms (life-threatening signs or symptoms; significant residual disability or disfigurement).³¹ Fourteen TESS-reported patients (4.6%) died of cyanide poisoning during 2001.³¹

Some details of these 14 fatal cyanide poisonings were available.³¹ One involved combined carbon monoxide and cyanide poisoning from smoke inhalation (carboxyhemoglobin level, 35%; whole blood cyanide level, 40 µg/mL).

Of the 13 “pure” fatal cyanide poisoning cases, all were adults.³¹ Ingestion of the involved cyanide compound was intentional in 12, and 1 case was classified as unintentional misuse. In three of these cases, whole blood cyanide levels were more than 20 µg/mL, 66 µg/mL, and 26.7 µg/mL; times after ingestion were not specified.

An adult man who worked in a jewelry shop drank from an already-open bottle of soda and rapidly developed fatal cardiac arrest. The soda was subsequently found to have a pH of 7 and a cyanide concentration of 100 mg/L.³¹

An elderly retired chemist accidentally ingested a swallow of sodium cyanide-copper cyanide etching solution. He was apparently successfully resuscitated from the initial severe cyanide poisoning, but subsequently developed fatal liver, renal, and pancreatic

damage, suggesting that copper poisoning contributed to the fatal outcome.³¹

PHARMACOLOGY

Pathophysiology

Cyanide produces histotoxic hypoxia by binding with the ferric iron (Fe³⁺) of mitochondrial cytochrome oxidase, thus disrupting the normal functioning of the electron transport chain and the ability of cells to utilize O₂ in oxidative phosphorylation.¹ The result is a shift to anaerobic metabolism, a substantial decrease in adenosine triphosphate synthesis, depletion of cellular energy stores, and greatly increased lactic acid production, which causes an elevated anion-gap metabolic acidosis. Numerous iron- or copper-containing enzymes are inhibited by cyanide, but cytochrome oxidase inhibition is the major intracellular toxic mechanism in cyanide poisoning.³

The tissue hypoxia of cyanide poisoning has several causes. Those tissues most dependent on oxidative phosphorylation—heart and brain—are the most severely and rapidly affected. Central inhibition of the respiratory centers leads to hypoventilation, which in turn produces hypoxic hypoxia.

Myocardial depression with decreased cardiac output produces stagnation hypoxia. Until the stage of respiratory depression or arrest, the blood is relatively normally oxygenated. However, the tissues are unable to extract and utilize this O₂, which leads to a greater than normal amount of O₂ in venous blood and an increased venous O₂ percent saturation.

Cyanide binding to cytochrome oxidase is a reversible process. The endogenous enzyme, rhodanese, is a natural defense against cyanide exposure. This enzyme complexes cyanide with sulfane sulfur, forming much less toxic thiocyanate. The body's sulfur pool is small, however, and the availability of sulfane sulfur constitutes the rate-limiting factor in natural cyanide detoxification. In the absence of an exogenous source of sulfur, rhodanese activity is too slow to prevent serious toxicity or death in significant cyanide poisoning.

The central nervous system is a primary target organ in cyanide poisoning.^{32,33} The mechanism by which cyanide exposure causes neurotoxicity is not completely understood. An increase in intraneuronal calcium levels and lipid peroxidation, perhaps initiated by cyanide-induced decreased adenosine triphosphate levels, which impairs sodium and calcium extrusion processes, might be a mechanism of nerve injury.³⁴ Cyanide-induced apoptosis is mediated by cytochrome-*c* release from mitochondria.³⁵ Generation of reactive oxygen species (ROS) also plays an important role in cyanide-induced apoptosis in cortical neurons.³³

Pharmacokinetics

TOXICOKINETICS

The toxicokinetics of cyanide are not well understood. Available data are either from animal experiments or

anecdotal human case reports. In dog plasma *in vitro*, cyanide is about 60% protein bound.³⁶ *In vivo*, whole blood cyanide levels may be four or more times greater than serum levels because of the concentration of cyanide in erythrocytes.¹

The volume of distribution (Vd) of cyanide in dogs is 0.498 L/kg.³⁷ A similar Vd of 0.41 L/kg was estimated in a single case of human potassium cyanide poisoning.³⁸ In this same case, estimates of other toxicokinetic parameters were area under the curve (AUC) 48 µg/mL/hr, clearance 163 mL/min, initial phase half-life ($t_{1/2\alpha}$) 20 to 30 minutes, and terminal-phase elimination half-life ($t_{1/2\beta}$) 19 hours.³⁸ The last value is consistent with findings in dogs showing only minimal excretion within the first 3 hours after oral administration, despite absorption of about 95%.³⁶ In victims of human cyanide poisoning from smoke inhalation, blood cyanide half-life was about 60 minutes.⁹

TOXICODYNAMICS

In a single patient not treated with specific antidotes, the average urinary cyanide excretion over nearly 40 hours was 0.64 mg/hr after a probable ingestion of between 117 and 511 mg of potassium cyanide.⁶ In this same patient, the mean whole blood cyanide level 1 hour after ingestion was 8.2 µg/mL. This level increased to a mean of 19.7 µg/mL at 3 hours and to 23.4 µg/mL at 9 hours after ingestion. Despite intensive supportive treatment, this patient died about 40 hours after ingestion.

In contrast, in a patient who survived ingestion of 1 g of potassium cyanide after treatment with sodium nitrite and sodium thiosulfate, the highest whole blood cyanide level was 15.68 µg/mL at 1.75 hours after ingestion; this level decreased to 0.82 µg/mL at 5 hours after ingestion.³⁸ In another patient who survived cyanide poisoning secondary to dermal and inhalation exposure to propionitrile, treatment with hydroxocobalamin–sodium thiosulfate was associated with a decrease in the whole blood cyanide level from 5.71 µg/mL at 2 hours after exposure to 0.93 µg/mL 30 minutes later.¹³ Specific cyanide antidote administration is associated with more rapid decreases in whole blood cyanide levels than is seen in patients not administered antidotes.¹

TOXICOLOGY

Clinical Manifestations

The natural history of severe acute cyanide poisoning is a rapid progression (faster with inhalation than ingestion) to coma, shock, respiratory failure, and death.¹ Less severely poisoned patients administered only intensive supportive care have survived,^{6,39} whereas patients also administered specific antidotes have survived with whole blood cyanide levels as high as 40 µg/mL.⁴⁰ Most patients who recover from acute cyanide poisoning do not have permanent sequelae, although rare cases of parkinsonian-like states with bilaterally symmetric lesions in the basal ganglia (putamen or globus pallidus) or memory deficits and personality changes have been reported.^{16,41–43}

The clinical presentation depends on the route, dose, and time elapsed since exposure. Patients with inhalation exposure to high concentrations may experience sudden loss of consciousness after only a few breaths.^{3,44} Combined inhalation and dermal or pure dermal exposure to a gas containing 19% hydrogen cyanide caused severe acute cyanide poisoning in two workers with whole blood cyanide levels of 5.3 and 6.75 µg/mL, respectively.⁴⁵ Patients who ingest potentially fatal amounts of cyanide salts may not develop life-threatening symptoms for up to 0.5 to 1 hour after exposure.³⁸ Delayed onset of symptoms (after 1 to 12 or more hours) may follow exposure to cyanogens such as laetrile, amygdalin, and nitrile compounds.^{6,15,19,20}

In patients who do not experience sudden collapse, the initial signs and symptoms can resemble those of anxiety or hyperventilation.¹ Early signs include central nervous system stimulation (giddiness, headache, anxiety), tachycardia, hyperpnea, mild hypertension, and palpitations.⁶

Late signs are nausea, vomiting, tachycardia or bradycardia, hypotension, seizures (rare), coma, apnea, dilated pupils, and a variety of cardiac effects, including erratic supraventricular or ventricular arrhythmias, atrioventricular blocks, ischemic changes on electrocardiography, and asystole.¹ Noncardiogenic pulmonary edema may rarely occur, even after ingestion of cyanide salts.³⁹

Of 21 acute cyanide poisoning victims, the following effects were noted: loss of consciousness ($N = 15$), metabolic acidosis ($N = 14$), cardiopulmonary failure ($N = 9$), anoxic encephalopathy ($N = 6$), and diabetes insipidus or conditions mimicking this condition ($N = 1–3$), which may be an ominous sign.¹⁶

The smell of “bitter almonds” (often described as “musty”) may be appreciated in some cases, but the ability to detect this odor is genetically determined, and many people cannot do so.¹ Cyanosis is a late sign usually only noted at the stage of apnea and circulatory collapse.¹

Dermal exposure to cyanide can result in systemic cyanide poisoning due to serious burns from molten cyanide salts, immersion in vats of cyanide salt solutions (with the potential for ingestion and vapor inhalation as well as dermal exposure), or total-body contamination with cyanide salts in confined spaces. Severe acute cyanide poisoning can rarely result from dermal exposure to hydrogen cyanide gas.⁴⁵

Diagnosis

The initial physical examination focuses on the vital signs and the respiratory, cardiovascular, and central nervous systems. Continuous vital signs and electrocardiographic monitoring should be done. Whole blood cyanide levels are available, but generally take hours to obtain and cannot be used to guide emergent diagnosis or therapy.¹ They can, however, document the diagnosis and response to treatment.

LABORATORY TESTING

Plasma lactate, serum electrolytes, and arterial blood gases should be monitored as frequently as necessary to

guide fluid, electrolyte, sodium bicarbonate, and respiratory therapy. Pulse oximetry may be unreliable in cases of smoke inhalation with combined carbon monoxide and cyanide poisoning and after administration of methemoglobin-inducing cyanide antidotes.

Based on anecdotal case reports and animal experiments, certain screening laboratory values may help suggest the diagnosis when no history is available.¹ Cyanide produces lactic acidosis, which can be confirmed by plasma lactate measurements.^{15,46} Normal plasma lactate levels are 1.0 mEq/L (mmol/L) or less. Lactic acidosis is present when serum lactate levels are more than 2.0 mEq/L (mmol/L). In combined poisoning with carbon monoxide and cyanide from smoke inhalation, plasma lactate levels may be the best marker of the presence and severity of a cyanide poisoning component.⁹ Plasma lactate levels of 10 mEq/L (mmol/L) or greater in smoke inhalation victims without severe burns or levels of 8 mEq/L (mmol/L) or greater in patients with “pure” cyanide exposure are sensitive and specific indicators of cyanide poisoning.^{47,48}

If the patient is still breathing or is receiving assisted ventilation, the arterial partial pressure of O₂ may be relatively normal. Cyanide inhibits the extraction of O₂ from the blood at the tissue level. Thus, more O₂ than normal is present in the venous blood; this may be reflected by an increased (>40 mm Hg) peripheral venous partial pressure of O₂, an increased measured peripheral venous O₂ percent saturation (>70%), or a narrowing of the normal difference between the measured arterial O₂ percent saturation and the measured central venous or pulmonary artery O₂ percent saturation (the normal central venous O₂ percent saturation is about 70%).^{1,16} However, a mixed venous O₂ percent saturation less than 90% does not, in itself, exclude acute cyanide poisoning.¹⁵

OTHER DIAGNOSTIC TESTING

If pulmonary edema develops, a chest radiograph should be obtained periodically.

A smoke inhalation clinical scoring system (scale from 1 to 10) based on the following clinical findings has been proposed: hoarseness (1 point); stridor (1 point); carbonaceous sputum (1 point); soot in the airways (1 point); singed nasal hairs (1 point); facial burns (1 point); abnormal chest auscultation findings (1 point); mental status change (1 point); and abnormal findings on chest radiography (2 points). In one case series, this clinical scoring system was predictive of a fatal outcome after smoke inhalation exposure from enclosed-space fires; it was also the strongest predictor of measured carboxyhemoglobin and whole blood cyanide levels.⁴⁹

DIFFERENTIAL DIAGNOSIS

Other cytochrome oxidase inhibitors such as hydrogen sulfide and sodium azide may produce clinical and laboratory findings similar to those seen in cyanide poisoning (see Chapter 91 and later discussion in this chapter on Sodium Azide). Although sodium nitrite might

have some efficacy in the treatment of hydrogen sulfide poisoning, it is ineffective for treating sodium azide poisoning.⁵⁰

MANAGEMENT

Supportive Measures

Cyanide-exposed patients with only restlessness, anxiety, or hyperventilation do not require antidote therapy. Such patients should be administered supplemental O₂ and undergo a few hours of clinical monitoring. Antidotes should be administered only if more serious symptoms develop.

Rescuers must not enter areas with high airborne concentrations of cyanide without a self-contained breathing apparatus or air-supplied respirators. Mouth-to-mouth breathing should be avoided if at all possible, and care must be taken by rescuers not to inhale the victim's exhaled breath. Appropriate prehospital care consists of airway management, including endotracheal intubation if required, administration of 100% supplemental O₂ by tight-fitting mask or endotracheal tube, placement of at least one large-bore intravenous line, administration of sodium bicarbonate if shock (with presumed metabolic acidosis) is present, decontamination of exposed skin or eyes, administration of standard antiarrhythmic or anticonvulsant medications if necessary, and administration of amyl nitrite by inhalation.

Amyl nitrite pearls may be broken in gauze and held close to the nose and mouth of patients who are spontaneously breathing. Alternatively, they may be placed into the lip of the facemask or inside the resuscitation bag in patients with apnea or hypoventilation. Amyl nitrite should be inhaled for 30 seconds of each minute, and a used pearl should be replaced with a fresh one every 3 to 4 minutes. Amyl nitrite and supplemental O₂ administration alone have been efficacious in treating hydrogen cyanide-poisoned patients in one occupational exposure setting.⁵¹ Supportive measures alone may sometimes prove to be satisfactory,^{39,44} although patients administered specific antidotes together with supportive therapy have survived with higher whole blood cyanide levels, awakened sooner from coma, and had more rapid resolution of acidosis.^{6,38,39}

Standard antiarrhythmic and anticonvulsant medications are appropriate for the treatment of cyanide-induced arrhythmias and seizures. Atropine or vasopressors may be required if symptomatic bradycardia or hypotension unresponsive to less aggressive measures are present.

Normobaric O₂ is synergistic with cyanide antidotes. Although not proved, hyperbaric oxygen (HBO) may be efficacious in patients not responsive to supportive and antidotal therapy, and some severely cyanide-poisoned patients treated with HBO have survived.^{14,46} Smoke inhalation victims with serious known carbon monoxide poisoning and suspected cyanide toxicity may be treated with HBO when available.⁸

Decontamination

Exposed skin and eyes should be copiously flushed with water or normal saline. Contaminated clothing should be removed and isolated in impervious containers. Inducing emesis is contraindicated because of the potential for rapid progression to coma or seizures. Gastric aspiration might be beneficial within about 30 minutes after ingestion of cyanide salts. Although older references question the efficacy of activated charcoal administration, a single dose of about 1 g of activated charcoal per kilogram of body weight may be administered to patients who have ingested cyanide salts and related compounds.

Antidotes

In the United States and some other countries, specific therapy consists of the administration of the antidotes found in the cyanide antidote kit. Once intravenous access has been established, amyl nitrite inhalation should be discontinued and sodium nitrite administered intravenously. The usual adult dose is 300 mg (one 10-mL ampoule of 3% solution). The pediatric dose for the average child is 0.12 to 0.33 mL/kg administered over absolutely no less than 5 minutes intravenously.

Sodium nitrite is a potent vasodilator, and rapid administration may cause significant hypotension, which can be avoided by initial slow administration, either (1) by slow intravenous push over absolutely no less than 5 minutes, or (2) by diluting the dose in 50 to 100 mL of 5% dextrose in water, initially beginning with a slow infusion rate, and then increasing to the most rapid rate possible without causing hypotension. Frequent blood pressure monitoring should be done during sodium nitrite administration.

Another potentially serious, although rare, adverse effect of sodium nitrite administration is induction of excessive methemoglobin levels. Induction of some level of methemoglobinemia has long been thought to be the mechanism of action of sodium nitrite because methemoglobin has a greater affinity for cyanide than cytochrome oxidase. This hypothesis has been questioned.

Excessive methemoglobin induction occurs most often in patients given excessive amounts of sodium nitrite, but it is rarely seen with therapeutic doses. Methemoglobin levels should be monitored, especially when multiple doses of sodium nitrite are required. Inducing levels greater than 30% to 40% must be avoided. The determinant of when “enough” sodium nitrite has been infused is the patient’s clinical response.

Sodium nitrite is followed by intravenous administration of sodium thiosulfate, in an adult dose of 12.5 g (one 50-mL ampoule of a 25% solution). The average pediatric dose is 1.65 mL/kg. No cases of significant adverse effects from sodium thiosulfate administration have been reported in humans, despite more than 50 years of clinical use of the drug. A continuous infusion of 1 g of sodium thiosulfate per hour for 24 hours was considered efficacious in one case of potassium cyanide ingestion poisoning.⁵²

In cases of smoke inhalation with known carbon monoxide and suspected cyanide poisoning, sodium thiosulfate and 100% supplemental O₂ can be administered initially if hydroxocobalamin is not available. Sodium nitrite administration should be withheld until the patient is at pressure in an HBO chamber, where dissolved plasma O₂ can adequately compensate for induced methemoglobinemia.⁸ When HBO was not immediately available for treatment of smoke inhalation patients, sodium nitrite was administered successfully without significant complications.⁵³

Second doses of sodium nitrite and sodium thiosulfate at one half the initial amounts may be administered 30 minutes after the first doses if clinical response is inadequate. With exposure to certain nitrile compounds, continued metabolic release of cyanide may cause prolonged poisoning requiring multiple antidote doses. If producing a satisfactory clinical response, sodium thiosulfate alone could be used in such cases because its inherent toxicity is low.

Alternate antidotes in clinical use in other parts of the world such as hydroxocobalamin (Cyanokit), dicobalt-ethylenediaminetetra-acetic acid (Kelocyanor), and 4-dimethylaminophenol (4-DMAP) are not available in the United States as of June 2006. A growing body of evidence, primarily from patients with combined carbon monoxide and cyanide poisoning from enclosed-space fire smoke inhalation, but also from patients with aliphatic nitrile or cyanide salt poisoning, indicates that hydroxocobalamin may be the cyanide antidote of choice.^{47,54,55}

Hydroxocobalamin is more rapidly acting than sodium thiosulfate, does not produce methemoglobinemia, which can impair oxygen transport as do 4-DMAP and the nitrites, does not cause hypotension as does sodium nitrite, and has a much better adverse effect and safety profile than do the nitrites, 4-DMAP and Kelocyanor.^{47,54} It has been shown to be safe and effective for decreasing low whole blood cyanide levels in volunteer heavy smokers and is an effective and safe cyanide antidote in a variety of experimental animal species.^{56,57} The only noted side effect in patients treated with hydroxocobalamin has been transient reddish-brown discoloration of the urine, sclera, mucous membranes, and skin from the color of the medication itself.^{47,54} Hydroxocobalamin can be combined with sodium thiosulfate in more severe poisoning cases because there is an antidotal synergy.^{47,54,57}

Because of its intense reddish-brown color and peak light absorption at 352 and 525 nm, hydroxocobalamin can interfere with automated colorimetric clinical chemistry measurements of aspartate aminotransferase, total bilirubin, creatinine, magnesium, and serum iron.⁵⁸

Elimination

Hemodialysis cannot be considered standard treatment for cyanide poisoning, but it has been efficaciously used as supportive therapy in a patient who developed renal failure secondary to rhabdomyolysis in the course of severe cyanide poisoning.¹⁶ One patient with severe acute

cyanide poisoning treated with supportive measures, antidotes, and charcoal hemoperfusion has also been reported.⁴ This patient was improving after antidotal and supportive therapy at the time that hemoperfusion was begun. Hemoperfusion has no place in the treatment of acute cyanide poisoning.

Disposition

Asymptomatic patients with apparent minimal exposure should be observed in a controlled setting for 4 to 6 hours. If exposure was to a nitrile compound, the onset of symptoms may be delayed for 12 hours or longer; in this situation, a longer period of observation and monitoring is necessary.

Patients who have serious symptoms (coma, seizures, shock, metabolic acidosis, cardiac arrhythmias, ischemic electrocardiographic changes, or hypoventilation) and all those administered antidotes should be admitted to an intensive care unit for clinical monitoring until all symptoms have resolved, or for a minimum period of 24 hours. Outpatient follow-up at intervals for a period of weeks should be arranged to screen for the possible development of rare delayed central nervous system effects.

Given the acute shortage of suitable organ donors, brain-dead poisoning victims should not be excluded as donors, if: (1) clinical and laboratory evidence shows true brain death (*not* central nervous system depression or lack of central nervous system activity due to the continued presence of the poison); (2) the poison itself has not irretrievably damaged or destroyed the organ under consideration for transplantation; and (3) the organ being considered for transplantation is not a reservoir, such that the transplanted organ itself might secondarily poison the transplant recipient. Organs have been successfully transplanted from brain-dead acute cyanide poisoning victims without causing secondary cyanide poisoning.^{59,60}

SODIUM AZIDE

Sodium azide is a white to colorless crystalline solid that is highly soluble in water and is used as a preservative in aqueous laboratory reagents and biologic fluids and in automobile airbags as a gas generator.⁶¹ It has also been investigated for use as an herbicide, insecticide, nematocide, fungicide, and bactericide and is used in the manufacturing of rubber, latex, wine, and Japanese beer, and as a chemical intermediate in lead azide production.⁶¹ Its use in automotive airbags has not resulted in sodium azide poisoning, but it has rarely caused relatively minor chemical burns by producing nitrogen gas and sodium oxide; the latter reacts with water to form corrosive sodium hydroxide.⁶¹

Sodium azide poisoning has most often occurred as a result of accidental or suicidal ingestion of colorless, odorless, tasteless laboratory solutions, which can be mistaken for water or normal saline, and has occurred in health care settings or laboratories.⁶¹⁻⁶³ Suicidal cases have generally been seen in individuals with access to the

chemical in laboratories because otherwise it has limited availability.^{63,64} One patient died after mistakenly ingesting 1 g of sodium azide obtained from a hospital but intended to be added as a preservative to a container for his 24-hour urine specimen.⁶⁵

The 2001 American Association of Poison Control Centers TESS³¹ does not have a specific listing for sodium azide. A recent systematic review covering the period of 1927 to 1999 found that a total of 38 publications constituted the knowledge base of sodium azide human health effects.⁶¹ Of these, 32 publications were case reports, 5 were occupational studies, and 1 paper was an experimental study of the use of sodium azide as a potential antihypertensive agent (since abandoned because of significant side effects).^{61,64} There were a total of 185 exposed people, with 116 from the experimental study.⁶¹ Adults were involved in 183 cases and children in 2 cases.

Of the 69 acute poisoning cases, 43 followed ingestion (26 survivors; 17 fatalities), 12 followed inhalation from occupational exposure (all 12 patients survived), 9 were exposed by the intravenous route from sodium azide contamination of hemodialysis apparatus (all 9 survived), and 5 patients had dermal exposure (4 survivors; 1 fatality).⁶¹ The dermal exposure fatality involved exposure to a metal azide during an explosion causing 45% total-body surface area burns.⁶¹ The hemodialysis patients exposed by the intravenous route developed hypotension, blurred vision, headache, nausea, vomiting, syncope, and cramping when ultrafilters used for preparation of dialysis fluid were pretreated with a preservative consisting of 0.25% sodium azide and 25% glycerin and not flushed.⁶⁶

Ingestion is the most common route of exposure in serious poisoning cases.⁶¹ Fatality is usually associated with doses greater than 700 mg (or 10–13 mg/kg), whereas nonfatal poisoning has been seen with doses ranging from 0.3 to 150 mg (or 0.004–2 mg/kg).⁶¹ In a series of four fatal and six nonfatal sodium azide poisoning cases, the lowest dose in survivors was 5 to 10 mg, and the highest dose was 80 mg.⁶⁷ The lowest fatal doses were 0.7 g in women and 1.2 to 2 g in men.⁶⁷

Sodium azide is rapidly absorbed from the gastrointestinal and respiratory tracts (as hydroazoic acid vapor).⁶¹ Its extent of dermal absorption is unclear, but a single fatal case from a warehouse accident has been reported.⁶¹ Sodium azide is metabolized by the liver and excreted by the kidneys, but human absorption, distribution, metabolism, and excretion kinetics data are not available,⁶¹ except for a half-life of about 2.5 hours calculated in a single fatal case.⁶⁸

Hypotension is the most common clinical effect, and the time between exposure and the onset of hypotension is somewhat predictive of survival.⁶¹ When hypotension occurs within minutes to 1 hour after exposure, it is a physiologic response, and the clinical course is most often benign. When the hypotension is delayed in onset more than 1 hour, it “. . . constitutes an ominous sign for death.”⁶¹

Other common clinical effects are nausea, vomiting, diarrhea, headache, dizziness, temporary vision loss, pal-

pitations, dyspnea, temporary loss of consciousness, and depressed sensorium.⁶¹ Markedly depressed sensorium, seizures, coma, hypothermia, cardiac dysrhythmias, chest pain, tachypnea, cyanosis, noncardiogenic pulmonary edema, acute respiratory distress syndrome (ARDS), metabolic acidosis, oliguria, and cardiorespiratory arrest are seen in severe poisoning cases.^{61,62,65,68}

The hypotensive effects are due to dilation of peripheral blood vessels, but it is unclear whether this effect is caused by the parent compound or its metabolism to nitric oxide.⁶¹ Sodium azide does inhibit heme-containing enzymes such as catalase, peroxidase, and cytochrome oxidase,^{61,69,70} but its lethality may be due instead to enhanced excitatory nervous transmission in the central nervous system, caused by the parent compound itself or by metabolically released nitric oxide.^{61,71}

One case of cardiomyopathy presenting as an acute myocardial infarction was reported in a previously healthy 29-year-old female student who mistakenly ingested 700 mL of a buffering solution containing 0.1% sodium azide.⁷² Nausea, weakness, and confusion occurred initially and prompted overnight observation in a hospital. These effects had resolved by the following morning, and she was discharged, only to develop exertional dyspnea over the following 24 hours and severe precordial chest pain radiating to the left arm 3 days after ingestion. Electrocardiogram and creatine kinase elevations indicated possible myocardial infarction. Cardiac catheterization and chest x-ray were consistent with cardiomyopathy. Over several hours, the patient developed episodes of ventricular tachycardia and refractory hypotension and died in asystolic arrest. At autopsy, histology of the left ventricle revealed cardiomyopathy but no monocellular infiltrates to suggest an inflammatory etiology.⁷² Chest pain for 6 months after survival of acute sodium azide poisoning has been reported in one patient who ingested 80 mg.⁶⁷

Sodium azide levels in blood are not readily available, and diagnosis and treatment decisions must be based on clinical grounds. Postmortem blood concentrations have ranged from 7.4 to 8.3 mg/L in one acutely fatal suicidal case to between 40 and 262 mg/L in other reported cases.⁶⁴ Interestingly, cyanide has been detected in the postmortem blood in three sodium azide fatalities (0.38 mg/L, 1.6 mg/L, and 9 mg/L), but it is not clear whether the cyanide production took place *in vivo* or in the postmortem remains.⁶⁴

Severe hypotension may be unresponsive to volume expansion and vasopressors.⁶¹ Phenobarbital had a protective effect against sodium azide poisoning in mice and rats, whereas diazepam and phenytoin did not.⁷¹ Phenobarbital should thus be considered for patients with seizures after sodium azide exposure not responsive to other anticonvulsants.

There is no specific antidote for sodium azide poisoning in current clinical use^{61,72} and only symptomatic and supportive treatment can be given.⁶³ The U.S. cyanide antidote kit containing amyl nitrite, sodium nitrite, and sodium thiosulfate has not been efficacious in human poisoning cases or in animal experiments.^{61,67,71,73}

Kelocyanor (dicobalt EDTA) and sodium thiosulfate alone have been ineffective for prevention of sodium azide poisoning in experimental animals.⁷¹

Hydroxocobalamin has not been administered to sodium azide-poisoned humans. An *in vitro* study in isolated rat mitochondria found that when hydroxocobalamin was added to sodium azide-inhibited mitochondria, cytochrome-*c* oxidase was less inhibited than when sodium azide was added alone.⁷⁴ This gives a potential theoretical mechanism of action for hydroxocobalamin in the treatment of sodium azide poisoning, and further studies should be pursued. When it is available, hydroxocobalamin could be administered to patients with life-threatening sodium azide poisoning because of its highly favorable safety profile. It is notably efficacious for reversing the severe hypotension seen in acute cyanide poisoning, and severe hypotension unresponsive to usual treatments is a hallmark of sodium azide poisoning.

At a Glance...

- The isocyanates are widely used precursors to polyurethane products, as well as carbamate insecticides.
- Methyl isocyanate was released at the worst industrial disaster in history on December 2 and 3, 1984, at Bhopal, India.
- Isocyanates are chemical compounds consisting of R-N=C=O groups, which react with compounds containing reactive hydrogen atoms to form polymers.
- Toxicity of the isocyanates varies inversely with molecular weight, related to volatility and vapor pressure.
- The most common occupational illness associated with the isocyanates is diisocyanate asthma, which has a distinct mechanism of toxicity as compared with atopic asthma.
- Management of isocyanate exposure is supportive; asthmatic symptoms should be managed as for atopic asthma.

The isocyanates are a diverse group of molecules that contain one or more R-N=C=O moieties, used most commonly in the synthesis of polyurethane plastics, foams, paints, and coatings, as well as in the production and degradation of carbamate insecticides. Regarding the latter, the isocyanates are known for the worst industrial disaster in history, in which thousands died in Bhopal, India in 1984 (discussed later).

Demand for polyurethanes, and thus their isocyanate precursors, is strong. Worldwide production of polyurethanes had been estimated at 2.2 to 3.4 million tons (2 to 3 million tonnes) in 2001; an automobile may contain 110 pounds (50 kg) of polyurethane and a residence 440 to 660 pounds (200–300 kg).¹

Because of their commercial ubiquity, clinically relevant toxicity, and historical infamy, the isocyanates merit awareness by the medical toxicologist. This chapter discusses four isocyanates of commercial importance: methyl isocyanate (MIC), methylene diphenyl diisocyanate (MDI), toluene-2,4 and 2,6 diisocyanate (TDI, or 2,4-TDI or 2,6-TDI), and hexamethylene diisocyanate (HDI).

PHYSICOCHEMICAL PROPERTIES

MIC (CAS 624-83-9) is most commonly associated with production and degradation of carbamate insecticides. At ambient conditions, it is a colorless liquid with a pungent odor and a high vapor pressure (348 mm Hg). Its odor threshold of 2.1 parts per million (ppm) is two orders of magnitude greater than its recommended exposure limits (see “Regulations”). Water solubility is 10% at 59° F (15° C). MIC reacts violently with water in an exothermic reaction producing polymeric MIC gas (perhaps creating trimers of MIC under the conditions

seen at Bhopal²). Flammability is high, with a flash point of 19° F (−7° C). Pyrolysis results in decomposition to hydrogen cyanide and carbon dioxide. Environmental degradation of MIC is prolonged in air, with an atmospheric half-life estimated at 3 months; water degradation is shorter, at a half-life of about 2 days.³

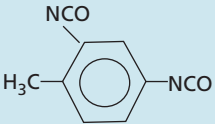

MDI (CAS101-68-8), TDI (CAS 584-84-9 and 91-08-7), and HDI (CAS 822-06-0) are known as diisocyanates, that is, molecules containing two isocyanate moieties. Their use is predominantly in the formation of polymers, namely polyurethane plastics and foams, by means of reaction with alcohols (polyols). At ambient conditions, MDI and 2,4-TDI are white-yellow solids, whereas 2,6-TDI and HDI are clear to pale yellow liquids. The vapor pressures of the diisocyanates (0.000005–0.5 mm Hg) are low. Water solubilities are low to insoluble. Flammabilities are low, with flash points above 200° F (93° C). The diisocyanates are less reactive with water than MIC, and under conditions of controlled water addition, they have the desirable effect of producing foams.⁴ In addition, the less toxic MDI has replaced TDI in many settings. Environmental degradation is more rapid than with MIC, with the diisocyanates having atmospheric half-lives of hours to 2 days, as well as “rapid” water degradation.³ Table 89-1 provides a comparison of these agents.

SOURCES OF EXPOSURE

MIC is both a crop pesticide reagent and an ingredient, as well as a degradation product of the pesticide metam-sodium. Air concentrations of MIC were found to be up to 2.5 ppb in the 72 hours following ground injection of metam-sodium for field fumigation in California.³ Cigarettes may contain four micrograms of MIC each, and workers who are in an environment at the threshold value for an 8-hour workday may be exposed to 460 µg daily.³ On the night of December 2 and 3, 1984, the introduction of water into two MIC storage tanks at the Union Carbide plant in Bhopal (capital of Madhya Pradesh, India, population 900,000) overwhelmed multiple safety systems and released about 27 tons of MIC into the environment within 1 to 2 hours, resulting in a mean estimated air concentration 1350 times the U.S. Occupational Safety and Health Administration (OSHA) limit (see “Regulations”).

The diisocyanates (MDI, TDI, HDI) are used in countless global industries, including adhesives, painting and varnishing, wire coating, vehicle building, mining, upholstery, plastics, rubber, insulation, and textiles.⁴ The major group of workers potentially exposed are those in the foam and rubber industry, who use the isocyanate monomers during manufacturing.

TABLE 89-1 Comparison of Common Isocyanates

COMPOUND	STRUCTURE	MOL. WT. (g/mol)	VAPOR PRESSURE (mm Hg) AT 77° F/25° C	ODOR THRESHOLD (ppm)	CONVERSION (ppm TO mg/m ³)*
Methyl isocyanate	CH ₃ N=C=O	57.05	348	2.1	1 ppm = 2.3 mg/m ³
Hexamethylene diisocyanate	OCN(C ₆ H ₁₂)NCO	168.22	0.03	0.001	1 ppm = 6.9 mg/m ³
Toluene diisocyanate (shown as 2,4-TDI)		174.15	0.05	0.17	1 ppm = 7.12 mg/m ³
Methylene diphenyl diisocyanate	[OCN(C ₆ H ₆) ₂]-CH ₂	250.25	5 × 10 ⁻⁶	0.4	1 ppm = 10.2 mg/m ³

*mg/m³ = ppm × mol. wt./24.45, under conditions of 1 atmosphere and 25° C.

TOXICITY

Mechanisms of isocyanate toxicity are incompletely understood. Much of the literature regarding the cellular and molecular toxicity of MIC followed from the acute, high-dose exposure in Bhopal. Most of the literature available concerning the diisocyanates focuses on the occupational asthma phenomenon (see “Clinical Manifestations”), a predominantly chronic, low-dose exposure.

MIC toxicity, despite the horrible disaster of 1984, remains enigmatic for several reasons. Although the Bhopal incident released mostly MIC (probably in trimerized form), it is likely that decomposition products such as hydrogen cyanide, nitrogen oxides, carbon monoxide, and other molecules (including reagents, etc.) played a role in the toxicity experienced by the Bhopal victims.⁵ Descriptions of “relief of symptoms” when sodium thiosulfate was administered to 30 Bhopal victims 2 months after the event prompted Indian authorities to recommend widespread thiosulfate treatment, although ultimately this was not carried out. Details of the reported response to delayed thiosulfate administration in these 30 victims are not known, and conclusions about efficacy cannot be drawn.

A two-part study conducted on rats by Jeevaratnam and Sriramachari^{6,7} examined the histopathologic manifestations of pulmonary MIC toxicity both by inhalational (232, 465, and 930 ppm) and subcutaneous (164.3, 328.6, and 657.2 mg/kg) routes. In the acute phase, concentration- and dose-dependent necrotizing bronchitis and pulmonary edema were seen by inhalation, whereas subcutaneous administration resulted in vascular endothelial damage and pulmonary edema, apparently leaving normal bronchial epithelium.⁶ The subacute and chronic phase (10 weeks) demonstrates a convergence of the inhalational and subcutaneous group tissue findings, both manifesting a diffuse interstitial pulmonary fibrosis.⁶

A burst of research activity in the immediate post-Bhopal era regarding the systemic toxicity of MIC

appears to have been short-lived, but quite interesting. Jeevaratnam and Sriramachari⁸ examined the non-pulmonary viscera of rats exposed to both inhalational and subcutaneous MIC and found vascular congestion, focal hepatocellular necrosis, and tubular rupture and degeneration in the kidney. Other authors have investigated in animal and in vitro models the inhibition of cardiac Na⁺/K⁺-ATPase in rabbits,⁹ binding to erythrocyte membrane sulfhydryl groups in rats,¹⁰ and changes in free amino acids in the brain and plasma of mice.¹¹ These data are not directly applicable to occupational exposures of much lower concentrations, particularly given the propensity of isocyanates to react with surface water and proteins, decreasing their absorption.

Issues of carcinogenicity and reproductive effects of MIC are unclear. The Agency for Toxic Substances and Disease Registry (ATSDR) of the Centers for Disease Control and Prevention (CDC) reports that MIC is not classified in terms of carcinogenicity, nor for reproductive effects, but makes mention of some of the observations at Bhopal, which included an apparent increase in stillbirths and spontaneous abortions.¹² Dhara and Dhara² cited a few epidemiologic, animal, and cytogenetic studies from the Bhopal experience that yielded no definitive conclusions for humans but do suggest the need for further observation.

The mechanisms of diisocyanate toxicity (see “Clinical Manifestations”) are likewise incompletely understood. Asthma induced by the diisocyanates differs mechanistically, yet less so clinically, from atopic asthma. This form of occupational asthma is of great concern because sensitization to subsequent lower exposure levels has been demonstrated. Diisocyanate asthma, in contrast to atopic asthma, appears to lack a consistent immunoglobulin E (IgE)-associated mechanism. The prevalence of diisocyanate-specific IgE in symptomatic patients has been reported to be less than 20%; furthermore, these antibodies have been found in asymptomatic patients, indicating a weak association with the disease state.^{4,13} Regarding the airway inflammatory

response, it appears that diisocyanate-induced asthma results in an increased neutrophil influx with increased interleukin-8 (IL-8) production, as compared with atopic asthma, which demonstrates relatively more eosinophils.¹³ The cellular immune response differs as well. Diisocyanate-induced asthma seems to invoke more of a helper T-cell subset 1 (T_H1) response (with a subsequent neutrophil, IL-8, and interferon- γ [IFN- γ] response), as compared with atopic asthma, which has a predominantly T_H2 -mediated response.¹⁴ Transmigration of these inflammatory and immune cells across endothelial and epithelial basement membranes is, in part, mediated by enzymes known as matrix metalloproteinases (MMPs). In a recent murine model by Lee and colleagues,¹⁵ in which bronchioalveolar lavage (BAL) fluid is examined after nebulized TDI exposure, MMP inhibitors are shown to blunt the migration of leukocytes and decrease the expression of adhesion molecules, interleukins, and tumor necrosis factor- α that are initiated after TDI exposure. Extrapulmonary sensitization (e.g., skin sensitization resulting in pulmonary effects) may also play a role in diisocyanate-induced asthma. As for immune recognition, the diisocyanates appear to haptinize with native protein in order to initiate a cellular response; in most models, albumin has been the carrier protein used. Wisniewski and coworkers¹⁶ examined HDI-exposed volunteers, through inhalational (20–30 parts per billion [ppb]) and skin (0.1% v/v) routes, and found that keratin 18 and keratin 10, both type I (acidic) keratins of the respiratory epithelium and skin, respectively, were conjugated to HDI and might play a role in antigen presentation. Genetics also appear to play a role; allelic variations of glutathione S-transferase appear to alter susceptibility to isocyanate hypersensitivity.¹⁷

Carcinogenesis and reproductive issues regarding the diisocyanates are also being investigated, but current knowledge regarding these in humans is limited. Bolognesi and colleagues¹⁸ provide a review of the evidence regarding TDI and MDI carcinogenesis and conclude that, although some short-term animal studies have shown gene mutations and chromosomal damage, the few epidemiologic studies produced have not been able to demonstrate that TDI and MDI are occupational carcinogens. As with MIC, the potential role of metabolic intermediates and adducts is undergoing continued study.

CLINICAL MANIFESTATIONS

The toxicity of the isocyanates will vary by the specific substance (e.g., MIC versus TDI), dose, route, and chronicity of the exposure. In humans, the predominant effects of the isocyanates are mucosal and respiratory, both upper and lower, consistent with an intermediate water solubility (see Chapter 9), and in some cases, dermal. A distinction should be made between the chronic effects of an acute exposure and the chronic effects of a chronic exposure, as provided by the examples of Bhopal and diisocyanate asthma, respectively (discussed subsequently).

Acute Exposure

Despite the confounders and limitations described, the largest acute human MIC exposure was the Bhopal incident. More than 200,000 people were exposed to MIC at this tragic event.¹⁹ The immediate (1 week) death toll has been estimated at 2500, thought to be due predominantly to acute pulmonary edema.²⁰ Early autopsy results revealed severe necrotizing lesions of the upper and lower respiratory tract as well as pulmonary edema. In survivors, respiratory symptoms were described as rhinorrhea, throat irritation, cough with frothy expectoration, and dyspnea. Chest films obtained 2.5 to 3 months after exposure in 903 subjects revealed only 65 that were thought to be associated with acute gas exposure,² although the immediate radiographic appearance in these patients is unknown. Ocular toxicity in the acute phase included symptoms of severe burning and photophobia associated with chemosis and corneal ulceration; only a few cases of iritis were seen, and blindness was not known to have occurred.²

Chronic effects of acute exposure to MIC resulted (and continue to result by some accounts) in much morbidity and mortality. The death toll is recently said to be greater than 6000, and the number of victims with chronic health effects greater than 50,000.⁵ Later pulmonary deaths may have been related to secondary infections,²⁰ as well as interstitial fibrosis and other structural changes,² consistent with findings from an animal model⁷ (see “Toxicity”). Beckett²¹ stratified 454 adults by distance from the incident site and found forced midexpiratory flow rate (FEF_{25–75}) reductions that correlate with distance from the incident, concluding that small airways obstruction may be attributed to gas exposure. Chronic ocular issues may include chronic conjunctivitis and corneal opacities.²² Chronic neurologic effects are reported, but these are not well defined, and associations may be stronger with a mass casualty event than with the chemical itself.² Reproductive and pediatric effects of MIC are discussed later.

Acute diisocyanate toxicity is predominantly pulmonary and may be subdivided into four entities: chemical bronchitis, hypersensitivity pneumonitis, asthma, and acute nonspecific airways disease.⁴ Chemical bronchitis is typically associated with an acute, higher-level exposure, resulting in marked upper respiratory and ocular irritation symptoms as well as cough, chest pain, and tightness; transitory or permanent changes in pulmonary function tests may be seen.⁴ High-level exposures would be expected to produce symptoms as seen with MIC, including pulmonary edema and death. Hypersensitivity pneumonitis is a rare presentation; in one series by Baur,²³ 16 patients were diagnosed clinically from 1780 isocyanate workers based on their symptoms of repeated episodes of fever, dyspnea, and malaise after a latency period of several hours after isocyanate exposure. Of those selected, 14 agreed to participate in the study, yielding the confirmatory findings of decreased diffusion capacity (10 patients), reticulonodular pattern on chest film (9 patients), and the presence of serum IgG to TDI-albumin (10 patients). Five patients underwent lung biopsy, revealing lymphohistiocytic infiltrates in all.

Diisocyanate asthma is the most common manifestation of diisocyanate-associated pulmonary disease, with the initial description in 1951 by Fuchs and Valade.⁴ Asthma associated with the diisocyanates may be subdivided into immediate, late-onset, and dual-onset forms. An interesting case series by Zammit-Tabona and colleagues²⁴ provides insight into these presentations. In their series, 11 foundry workers with exposure to MDI and symptoms consistent with asthma were subjected to a single inhalational MDI challenge at a concentration less than 0.02 ppm for 60 minutes. Seven patients, two of whom were atopic, developed asthmatic reactions as measured by spirometry (>20% fall in forced expiratory volume in 1 second [FEV₁]). One patient was discounted owing to response to formaldehyde challenge. The remaining six had late-onset reactions, with onset an average of 5 hours after the exposure; two of these patients also had immediate-onset reactions (before the end of the challenge). Four of the six patients also developed recurrent nocturnal asthmatic symptoms, away from any known exposure, for a period of 3 to 7 days after the single-dose challenge.

Chronic Exposure

Chronic MIC exposure and resulting effects are not well defined in the literature. In regard to chronic pulmonary diisocyanate exposure, the clinical effects may be divided into isocyanate-associated asthma and chronic nonspecific airways disease.⁴ Diisocyanate asthma may be diagnosed after several years of potential exposure; whether this phenomenon is due to the chronicity of the exposure and disease latency or to a delay in diagnosis²⁵ is unknown. Diisocyanate asthma may develop within months after exposure⁴; however, newer employees may have had exposures during previous jobs, confounding the time course.²⁶ Loss of sensitization after removal from exposure is a possibility in diisocyanate asthma. Mapp and colleagues²⁷ found that in a group of TDI-sensitized patients, provocation after increasing intervals of time following TDI exposure indicates a reversible increase in airway responsiveness. In a recent 30-year follow-up of workers at a single TDI factory unit, Ott and colleagues²⁶ reported an initial decline in FEV₁ within the first 2 years of reporting symptoms, but no acceleration of decline in lung function thereafter. These two studies seem to be in contrast to the findings of Padoan and associates,²⁸ in which 87 subjects with TDI-induced asthma were followed for 11 years. In this group, airway reactivity to methacholine challenge persisted even after 10 years of nonexposure, and the presenting FEV₁ and provocative dose were among the factors predictive of subsequent reactivity and decline in pulmonary function. All these considerations highlight the importance of early recognition of respiratory symptoms and removal of employees from further isocyanate exposure.

Case reports exist for diisocyanate-associated skin lesions in chronically exposed workers. Larsen and colleagues²⁹ reported on 10 nurses in an outpatient orthopedic clinic who worked with diisocyanate-

containing casting material. Patch testing to five types of diisocyanates yielded one patient with a “doubtful” reaction toward two types. Their conclusion that the diisocyanates are predominantly irritants rather than sensitizers stands in contrast to other animal studies and case reports identifying positive patch testing or IgE antibodies to isocyanates after dermal exposure.

Any potential carcinogenic risk after chronic diisocyanate exposure in humans is only theoretical at this time and is based on very heavy (e.g., 6 mg/m³) chronic inhalation exposures in animal models.^{18,30}

PRENATAL AND PEDIATRIC ISSUES

The reproductive effects of the isocyanates in humans are largely undefined, but some evidence for adverse effects exists at massive exposure doses. In the case of the Bhopal disaster, Dhara and Dhara² reported on a study indicating that a higher rate of miscarriages occurred in the affected area, as well as higher perinatal and neonatal mortality rates. In a recent letter,¹⁹ Ranjan and associates discussed their findings of a selective growth retardation in boys exposed in utero or as young children to the Bhopal disaster versus matched controls. Reproductive toxicity data regarding the diisocyanates are also limited, but reassuring. One study found a no observed adverse effect level (NOAEL) of about 0.3 ppm MDI in pregnant Wistar rats with regard to maternal and developmental toxicity.³¹ Other studies showed NOAELs in the range of 0.1 to 0.3 ppm TDI in CD rats in regard to reproductive toxicity.^{32,33}

ASSESSMENT

Diagnosis of isocyanate-associated disease is best defined in the occupational setting, particularly for diisocyanate-induced asthma. Important historical components include a suspected exposure and symptoms of airway hyperreactivity, including cough, wheezing, and shortness of breath; these may be delayed by several hours after each exposure and therefore may present as nocturnal asthma in day-shift workers. Fever and respiratory symptoms in exposed workers would suggest hypersensitivity pneumonitis. A full medical, occupational, and social history should be elicited, including personal and family history of pulmonary disease, potential sources of previous isocyanate exposure (and perhaps sensitization), and smoking status.

Pulmonary function testing begins with sequential peak expiratory flow measurements both during and away from a potential exposure. Inhalational challenge testing may be indicated and is divided into nonspecific bronchial hyperresponsiveness (NSBH) and specific bronchoprovocation testing (SBPT).³⁴ NSBH is performed by challenging the patient with a known airway reactant such as methacholine or histamine, whereas SBPT involves the use of the suspect diisocyanate itself. Generally, a 20% decrease in FEV₁ during either test supports a diagnosis of reactive airways^{4,28}; however, the SBPT is considered

the gold standard.³⁴ Nonspecific testing is often performed in lieu of SBPT because of the lack of availability of such tests at many centers. Many organizations have published guidelines on the diagnosis of occupational asthma, including that of the diisocyanates, and are included in a review by Bernstein and Jolly.³⁴

Laboratory evaluation for diisocyanate-associated asthma is not well-defined, although currently an area of research interest (see “Toxicity”). Other ancillary tests that may be useful include chest radiography, bronchoalveolar lavage, and biopsy, particularly in cases of suspected hypersensitivity pneumonitis.²³

MANAGEMENT

Treatment of isocyanate-associated disease, regardless of the specific moiety or the acuity, requires removal of the patient from the source of exposure, followed by surface decontamination as needed (see Chapter 2). Management of the patient’s airway and breathing takes precedence over further care. Co-inhalations should always be suspected, especially in the setting of fire (e.g., carbon monoxide, cyanide gas). Management in the disaster setting is addressed in Chapter 103. In cases of diisocyanate-associated asthma, acute treatment should follow that of standard principles for the atopic asthmatic. Removal of the worker from any further isocyanate exposure is required because the safe concentration for reexposure of sensitized individuals has not been defined.

PREVENTION

It is uncertain at what levels and duration of exposure diisocyanate-associated pulmonary disease develops.⁴ Although there are mandated exposure guidelines (see “Regulations”), some authors believe these to be too lenient. Baur³⁵ advises that although occupational exposure limits for the various diisocyanates in most Western countries are placed at about 10 ppb, a more appropriate “health-based” level based on current research would be 2.5 to 5 ppb.

Environmental monitoring is an important component of exposure prevention. There are several methods for detecting the presence of isocyanates, including colorimetry (wet and dry) and chromatography (thin layer, gas, and high-performance liquid).⁴ Each regulatory or advisory body, as discussed next, adopts an explicit method for standardizing detection of the environmental burden.

REGULATIONS AND EXPOSURE ADVISORIES

In the United States, multiple agencies, both governmental and private, dispense recommended worker exposure limits in multiple formats. In general, it is helpful to categorize these into “regulatory” (enforceable) and

TABLE 89-2 Regulatory and Advisory Limits for Representative Isocyanates

	OSHA PEL (ppb)	NIOSH REL (ppb)	NIOSH IDLH (ppb)	ACGIH TLV (ppb)	AIHA ERPG (ppb)
MIC	20 (TWA)	20 (TWA)	3000	20	25–5000
MDI	20 (C)	5 (C)	7500	5	N/A
TDI	20 (C)	None	2500	5	N/A
HDI	None	5 (TWA)	N/A	N/A	N/A

ACGIH, American Conference of Government and Industrial Hygienists; AIHA, American Industrial Hygiene Association; C, ceiling limit; ERPG, emergency response planning guidelines; HDI, hexamethylene diisocyanate; IDLH, immediate danger to life or health; MDI, methylene diphenyl diisocyanate; MIC, methyl isocyanate; N/A, not available; NIOSH, National Institute of Occupational Safety and Health; OSHA, Occupational Safety and Health Association; PEL, permissible exposure limit; ppb, parts per billion; REL, recommended exposure limit; TDI, toluene-2,4 and 2,6 diisocyanate; TLV, threshold limit value; TWA, threshold weighted average.

“advisory” types. OSHA provides regulatory values. The National Institute of Occupational Safety and Health (NIOSH), also a federal program, provides advisory limits. Private programs such as the American Conference of Government and Industrial Hygienists (ACGIH) and the American Industrial Hygiene Association (AIHA) also provide advisory limits. The AIHA guidelines are for emergency exposures only. These are summarized in Table 89-2 for MIC, MDI, TDI, and HDI.^{36,37}

There are also regulations at the state level, superseded at all times by federal regulation. Other nations have their own regulations. Refer to Chapter 82 for definitions and further details on regulatory agencies and promulgations.

ANTHONY J. SCALZO, MD ■ CAROLYN M. BLUME-ODOM, RN, BSN

At a Glance...

- Hydrofluoric acid is highly toxic by the dermal, inhalation, ocular, and oral routes.
- Symptoms and tissue effects may be delayed.
- HF exposure can induce systemic toxicity related to electrolyte abnormalities.
 - Hypocalcemia
 - Hypomagnesemia
 - Hyperkalemia
- Treatment is directed at rapid and complete deactivation of absorbed fluoride ion.
- Treatment options vary by site of exposure.
 - Dermal: initial water irrigation and use of calcium gluconate via various routes
 - Topical calcium gluconate gel
 - Subcutaneous intralesional calcium infiltration
 - Regional intravenous calcium infusion—Bier block technique
 - Intra-arterial calcium infusion
 - Ocular: water/normal saline irrigation, 1% calcium gluconate drops
 - Inhalation: fresh air and nebulized 2.5% calcium gluconate
 - Ingestion: cautious lavage with calcium gluconate, support for systemic complications

INTRODUCTION AND EPIDEMIOLOGY

Hydrofluoric acid (HF) is an aqueous solution of the inorganic acid of elemental fluorine. HF will dissolve anything that has glass or silica content as well as various metals, rubber, leather, and most organic materials including human tissue. In the industrial setting, HF is used to etch and frost glass, clean metal parts before electroplating, and etch silicon wafers in electronic semiconductor materials. HF is used in the petroleum industry to manufacture high-octane gasoline and in various metal processes, including pickling stainless steel, producing aluminum and uranium, and cleaning and removing rust from iron, copper, and brass.

The majority of inhalation exposures and those involving high concentrations are nearly exclusive to industry. Industrial exposures, though less frequent than home exposures, normally account for the majority of severe exposures accompanied by long-term morbidity and mortality. An 11-year investigation by the U.S. Occupational Safety and Health Administration (OSHA) of nine deaths attributed to HF indicated that unsafe work practices were contributing factors in all nine.¹

In the home setting, HF exposures can occur when rust removers are used with inadequate dermal protection. Consumer HF-containing products are most commonly rust removers and aluminum and chrome

cleaning products. The majority of exposures in the home setting involve the distal extremities, primarily the hands and fingers. A case of hydrofluoric acid burns to the hand has been reported after ignition of a compressed air duster containing 1,1-difluoroethane, which decomposes to HF at high temperatures.² Other products of concern to the lay public are wire wheel cleaners, which contain ammonium bifluoride in a concentration of 15.9%. As little as 2 mL of this type of product has proved fatal in toddlers when ingested.³

STRUCTURE-ACTIVITY RELATIONSHIPS

Hydrofluoric acid is a colorless, corrosive liquid or gas, which fumes at concentrations greater than 40% to 48%,⁴ boils at 19.5°C, and has an odor threshold in air of 0.5 to 3 ppm.⁵ The vapor pressure of HF gas over a concentrated solution (70% HF at 80°F) is relatively high at 150 mm Hg and thus resembles acetone and other volatile liquids.⁶ HF is miscible in water and in solution has virtually no odor as opposed to in gaseous form, where it has a strong, irritating odor. HF is manufactured from calcium fluoride (fluor spar), which is reacted with sulfuric acid to form HF gas⁷:

where CaF_2 = fluor spar and H_2SO_4 = sulfuric acid.

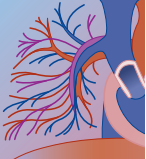

The gas is then cooled to be stored as anhydrous HF liquid, which by definition refers to concentrations greater than 99%. Most injuries from HF do not involve anhydrous HF but varying concentrations of >20% used in diverse industry applications or household products with lower concentrations. HF and additional free fluoride ions are also generated when ammonium bifluoride dissociates in aqueous solution:

where NH_4HF_2 = ammonium bifluoride.

PHARMACOLOGY AND TOXICOLOGY*Pathophysiology*

Concentrated solutions of HF are strong proton (H^+) donors that can cause coagulative necrosis similarly to other strong inorganic acids (e.g., HCl), while dilute solutions of HF are weak acids. HF is referred to as a binary hydride, and it has the highest bond dissociation energy, so it requires more energy to dissociate compared with other halogen group series acids (i.e., HF > hydrochloric acid [HCl] > hydrobromic acid [HBr] or > hydriodic acid [HI]). The reverse is true with regard to

strength of acidity (ability to donate a proton, or H^+). HF has a dissociation constant (K_d) of 3.53×10^{-4} , which is 1000 times less dissociated than HCl. It has a pK_a of 3.8.⁸ Cellular damage from the proton donated by HF causes initial tissue injury by dehydration and corrosion. It is the fluoride ion, however, that is responsible for the majority of tissue damage from HF. Fluoride ion has a permeability coefficient similar to that of water ($P = 1.4 \times 10^{-4}$ cm/sec).^{4,9} HF in the systemic circulation may dissociate to H^+ and free fluoride ions, which may cause severe acidosis as well as systemic fluorosis.^{8,10}

The presence of free fluoride ions results in a number of pathophysiologic effects. Fluoride ions are intensely electronegative and attract several cellular and systemic cations such as calcium and magnesium. In this process, biologically active calcium and magnesium are depleted at a rapid rate. Specifically, the binding of calcium may exceed the rate at which calcium can be mobilized from bone, and this process may lead to severe systemic hypocalcemia.¹¹ Fluoride ion exposure also results in low ionized calcium.^{12,13} In general, low ionized or low total calcium may be associated with significant neurologic effects including tetany and seizures as well as cardiovascular instability and other effects.¹⁴⁻¹⁶ Although the systemic depletion of calcium may be severe, in most cases of HF poisoning, clinical evidence of hypocalcemia such as tetany, Chvostek's sign, and Trousseau's sign may be absent.¹⁷ Some authors have described patients with leg cramping.¹⁸ Because of the rapid onset of hypocalcemia, early replacement of calcium is crucial in significant exposures and should not await laboratory confirmation. The electrocardiogram at the bedside may also offer clues, since hypocalcemia is a well-known cause of prolonged QT_c interval. One author described recurrent ventricular tachycardia in association with QT prolongation after an adult was exposed to 30% HF over 44% body surface area (BSA) and survived.¹⁹ The hypomagnesemia seen with HF poisoning may also cause prolonged QT and atypical ventricular tachycardia.²⁰ According to the World Health Organization (WHO) guidelines, increased likelihood of significant hypocalcemia may be suspected if the patient has a dermal burn of 1% BSA from HF concentrations of 50% or greater, any dermal burn of 5% BSA regardless of the concentration of HF, inhalation of HF vapors from solutions of greater than or equal to 60%, or even small ingestions of HF solutions including more dilute household products.^{21,22} In clinical practice, however, there are often exceptions to these guidelines.

Additionally, free fluoride ions inhibit many membrane and intracellular enzymes including those of the Krebs cycle and importantly the Na^+/K^+ -ATPase pump^{8,23} as well as enzymes that are magnesium or manganese dependent.²⁴ Inhibition of Krebs cycle enzymes may result in cellular energy failure, which contributes to cell death. Fluorides react with trace amounts of aluminum (Al^{3+}) to form AlF_4^- complexes that have been shown to activate G proteins in cell membranes, which may alter cell-signaling processes and lead to inflammation.²⁵ Fluoride ions also stimulate phospholipase A_2 , which may liberate arachidonic acid, the precursor for various

inflammatory eicosanoids.²⁵ On a more emergent level, fluoride reportedly stimulates adenylate cyclase,²⁶ which in the myocardium results in increased cyclic adenosine monophosphate (AMP) and may increase the possibility of arrhythmias.²⁰ Direct myocardial tissue injury is also possible from high myocardial fluoride levels in cases of fatal systemic fluorosis from serious dermal burns.¹⁰

Changes in potassium flux across membrane channels have been implicated in fluoride poisoning and are the subject of recent research on the use of amiodarone for its potassium channel blocking effects.²⁷ The Na^+/K^+ -ATPase system is responsible for pumping sodium ions out of the cell and potassium ions into the cell to maintain normal extracellular levels of each cation. When poisoned by fluoride ions, this pump will result in excess extracellular potassium, which exacerbates the hyperkalemic state. The resultant hyperkalemia is likely a contributory factor in enhancing myocardial irritability. The effects of hypocalcemia and dysfunction of the Na^+/K^+ -ATPase system on potassium flux may not be immediate. Delayed ventricular fibrillation, frequently described in severe dermal exposure, ingestions, and inhalation exposures to concentrated HF may be due to late-onset hyperkalemia.²³ Others report this arrhythmia in the absence of hyperkalemia.^{13,19} The mechanism of acute fluoride-induced sudden cardiac death from ventricular arrhythmias has been attributed to profound hypocalcemia, but in canine studies this lethal effect appears to be more temporally due to the elevation in serum potassium.²³ A large fraction of the increase in extracellular potassium may derive from transfer across the erythrocyte membrane of red blood cells in circulation that are exposed to the fluoride ion.²⁸ In vitro studies show that while fluoride ion decreases extracellular calcium, it increases intracellular calcium, which is believed to trigger calcium-dependent K^+ channels that allow for enhanced K^+ efflux and resultant hyperkalemia.²⁹ Moreover, in dogs this fluoride-induced hyperkalemia cannot be prevented by glucose, insulin, or bicarbonate.²³

From a pathophysiologic standpoint, the treatment of fluoride-induced hyperkalemia may depend on removal of fluoride as well as potassium. This is problematic at best. To some extent, the treatment of HF-induced hypocalcemia with intravenous (IV) calcium should help correct some effects of hyperkalemia. Although sodium bicarbonate administration may lower extracellular potassium and correct the acidosis of systemic HF poisoning, it also may lower ionized calcium.³⁰ Maintaining normal to supranormal extracellular calcium levels may diminish the likelihood of ventricular arrhythmias (ventricular fibrillation, or VF) in severe HF exposure.⁸ In one report, a 33-year-old man developed severe hypocalcemia (0.78 mmol/L ionized calcium), metabolic acidosis (pH 7.04), and several episodes of VF after ingesting HF. As much as 4 g of IV calcium chloride including 1 g/hr infusion were administered, yet the patient still had five episodes of VF. An ultrahigh dose of calcium at 200 mL/hr (20 g/hr calcium chloride) was subsequently infused and achieved an ionized calcium level of 4.34 mmol/L; no further VF was observed.⁸

The delayed pain characteristic of HF dermal exposures can be attributed to some of these pathophysiologic effects on potassium flux across the membrane but likely is more complex. Some authors have attributed pain as secondary to the precipitation of calcium fluoride and magnesium fluoride in deep tissues as well as hyperkalemia, which leads to neural stimulation.^{31,32} We question, however, the notion of attributing pain (nociceptive stimulus) to tissue deposition of insoluble calcium and magnesium salts of fluoride. The effective correction of pain due to fluoride toxicity employs calcium and possibly magnesium to complex with free fluoride ions. This process generates insoluble calcium fluoride or magnesium fluoride, yet is the very therapy that alleviates pain.

The authors believe that the neural stimulation theory from enhanced K^+ flux and in some cases extracellular hyperkalemia is more plausible. The stimulation of unmyelinated free nerve endings (C fibers) and later, slower conducting myelinated A- δ fibers in damaged tissue likely occurs after HF exposure. Fluoride-induced calcium deficiency at the cellular membrane allows enhanced outward K^+ flux through Ca^{2+} -dependent K^+ channels.^{29,33} Extracellular hyperkalemia at the cell membrane surface may not always translate to abnormal serum potassium even in severe or fatal human HF poisoning,^{22,34,35} but it may occur and be life threatening.^{18,23} Hyperkalemia is associated with peripheral neural depolarization as well as depolarization in muscle and excitable cardiac tissue.³⁶⁻³⁸ Mild to moderate hyperkalemia shifts the resting potential toward depolarization and there is an increase in conduction velocity in human atrial cells, whereas severe hyperkalemia may lead to a reduction in conduction velocity.³⁶ This discussion of potassium in no way diminishes the consequences of severe systemic hypocalcemia or hypomagnesemia seen in serious HF exposures. Hypocalcemia, especially in combination with hypomagnesemia, is a major contributing factor in myocardial irritability in many cases.

Enhanced potassium flux at the cellular level is probably insufficient explanation for the mechanism of pain. The molecular mechanism of pain, especially in damaged or inflamed tissue, is complex, and sodium channels, voltage-gated potassium channels (Kv), and a host of neuropeptides and excitatory amino acids are involved.³⁹ Protons (H^+) and lower tissue pH may stimulate a subpopulation of C fibers and contribute to pain.⁴⁰ Substance P (an 11-amino acid peptide), released from vesicles in sensory nerve fibers, also may contribute to pain.⁴¹ Hyperkalemia may signal increases in calcitonin gene-related peptide (CGRP), a known nociceptive neuropeptide, as evidenced by *in vitro* release of CGRP by potassium chloride.⁴² High extracellular potassium appears to enhance the release of glutamate in the central nervous system.^{43,44} Glutamate receptors are localized in the peripheral nervous system on nociceptive, afferent, unmyelinated C-fiber type nerves.⁴⁵ Studies in animal models of pain have shown that peripheral glutamate is involved in nociceptive transmission under normal conditions and with

inflammation.⁴⁶ Thus, inflamed and injured tissue having suffered the initial burn effects of the H^+ ions and subsequently the effects of fluoride ions will likely have exposed free unmyelinated nerve endings that will signal the pain sensation.⁴⁷

In summary, fluoride ion results in alterations of potassium flux with extracellular hyperkalemia, as well as hypocalcemia and hypomagnesemia, all of which contribute to altered membrane excitability of peripheral sensory nerves as well as cardiac tissue. These ion derangements, especially hyperkalemia, may herald the release of nociceptive peptides such as CGRP and glutamate, all of which play a role in the generation of pain. More research is needed at the molecular biologic level to further clarify these constructs.

Toxic Pathology and Clinical Effects

HF and related products may cause dermal, ocular, pulmonary, gastrointestinal (GI), and systemic injury. Unique exposure routes, however, include a case of intradermal injection of 5 mL of 7% HF in a suicide attempt with severe local and systemic effects including hypocalcemia,⁴⁸ and fulminant colitis following self-administration of an HF enema.⁴⁹ Nevertheless, most HF-related injuries that the emergency or occupational physician encounters are from dermal exposures with resultant injury largely dependent on the concentration of HF and extent of exposure. Oral and inhalation exposures, however, should be considered potentially fatal irrespective of HF concentration. Industrial exposures may involve exposure to anhydrous HF and varying concentrations below that to approximately 20% HF.

Household products usually contain HF in lower concentrations but may also cause injury from misuse or failure to use protective equipment. Household products used as rust removers and aluminum wheel cleaners for automobiles usually contain 6% to 12% and less than 20% HF.⁵⁰ Consumers may use these products without wearing gloves or protective garments, and the lack of immediate pain or irritation often is deceiving. Vinyl or rubber gloves are superior to latex, since HF attacks latex. Additionally, since moist skin appears to be more permeable to HF, a glove with a pinhole leak may allow HF to contact skin and the occlusive, moisture-retaining effect of the glove may enhance absorption.^{6,51} Other forms of fluoride that dissociate to HF upon contact with water include ammonium bifluoride found in automobile alloy wheel cleaners. Exposures, both dermal and inhalational, to ammonium bifluoride-containing products has resulted in deaths and serious morbidity including marked hypocalcemia, hypomagnesemia, and ventricular fibrillation in several pediatric patients.^{3,13,52}

Additional forms of fluoride that are significant for human health include sodium fluoride as found in fluoridated water supplies or dental products. Sodium fluoride tablets, which generally contain 0.25 to 1 mg of fluoride ion, have caused fluoride poisoning in children.^{53,54} As opposed to HF in household and automobile cleaners, the fluoride contained in toothpaste usually is not consumed in quantities sufficient to cause

toxicity with common daily use. Dental preparations containing fluoride include toothpaste and gels as well as mouthwashes, topical fluoride gels, and dental rinses that may induce minimal toxicity in accidental overdoses. The forms of fluoride found in these products usually release only small amounts of free fluoride anion, thus reducing the risk of acute toxicity.

Nevertheless, cases of fluoride poisoning have occurred with ingestion of fluoride rinses as well as large ingestions of toothpaste (4.5 to 9 ounces with 0.15% fluoride ion w/v) in small children.⁵⁵ Some consider approximately 5 mg/kg of F⁻ ion from dental products as “toxic,” with nausea, vomiting, diarrhea, and abdominal cramping likely to occur at this dose,⁵³ whereas others believe the toxic range is 5 to 10 mg/kg.⁵⁶ The estimated lethal dose of fluoride is in excess of 30 mg/kg.⁵⁷

In a series of 87 children, those who ingested up to 8.4 mg/kg from dental products had mild, self-limited primarily GI symptoms.⁵⁸ A 15-kg toddler who ingests a full 4.6-ounce tube of children’s fruit-flavored toothpaste, however, could be at risk for significant toxicity. This exposure can be calculated as follows:

A 4.6-ounce tube of a popular children’s flavored toothpaste contains 2.4% sodium fluoride and has 0.15% w/v of fluoride ion.
 4.6 ounces \times 29.57 mL/oz = 136.02 mL in the tube.
 136.02 mL \times 0.15 g/100 mL (0.15% w/v fluoride)
 = 204.03 mg of fluoride.
 204.03 mg fluoride in a 15-kg child = 13.6 mg/kg.

Serious poisoning due to fluoride-containing dental products has been reported. GI hemorrhage, hypocalcemia, hypomagnesemia, ventricular tachycardia, and ventricular fibrillation have been reported in a 43-year-old following an ingestion of up to 25 ounces of a topical fluoride gel containing 1.23% fluoride.⁵⁹ Death occurred following ingestion of 200 mg (16 mg/kg) of fluoride in a 3-year-old boy.⁶⁰ Subgingival irrigation of deep periodontal pockets with a 2% stannous fluoride (SnF₂) solution resulted in extensively erythematous mucosa of half of the hard palate and necrosis of the soft tissue close to the palatal aspect of two molars.⁶¹

Excessive fluoridation has also been associated with skeletal fluorosis.⁵ The American Academy of Pediatrics Committee on Nutrition and Fluoridation recommends that the optimal daily dose of fluoride effective in preventing dental caries is 0.05 to 0.07 mg/kg/day.⁶² Dental fluorosis, characterized by mottled teeth, has occurred with excessive fluoridation. There is evidence that levels of fluorosis have increased in part owing to widespread use of fluoridated water in food processing and dentifrices containing sodium fluoride used in combination with ingestion of fluoridated water.⁵

DERMAL TOXICITY

When in contact with skin, HF dissociates into hydrogen ions and free fluoride ions. There may be a latent period before a clinically evident burn is apparent, dependent on the concentration of the acid and the length of time it is in contact with the skin.⁶³⁻⁶⁵ Other mineral acids are

rapidly neutralized, whereas the process of tissue destruction may continue for days with HF.⁶⁶ Fluoride ions penetrate tissues deeply, causing tissue damage and the potential for systemic toxicity depending on the HF acid concentration.

In general, exposure to HF solutions of greater than 50% concentration results in immediate pain and tissue destruction.^{4,21,67} The skin appears blanched, and within 1 to 2 hours the dermal lines are obliterated by edema.⁶⁵ Even a small cutaneous exposure to greater than 50% HF can be rapidly fatal.^{17,68} Two cases of delayed death at 7 days and at 15 days resulting from multiple organ system failure have been reported following significant dermal burns from 70% HF.^{69,70} Dermal contact with concentrations of 20% to 50% HF usually result in a burn that develops within a few hours.³¹ In fact, concentrations greater than 20% HF have a potential for serious toxicity regardless of the degree of surface area involved.⁷¹ Contact with solutions of less than 20% HF concentration results in dermal injury that usually develops with a latent period of about 24 hours.⁷²

Hand and finger involvement is common in household product exposures⁷³⁻⁷⁶ as well as industrial-strength solutions of HF.^{4,77} The clinical presentation of exposure to strong HF solutions of greater than 20% begins with pain at the site that is characteristically intense⁷⁷ and often described by patients as “burning,” “deep,” “throbbing,” or “exquisite.”⁶⁴ Local erythema and edema may or may not be present initially, but later a pale, blanched appearance of the skin is apparent in more severe burns from concentrated HF (e.g., >50%).^{24,65,77} Extensive bullae and maceration of tissue may be seen.⁷⁴ Gray areas may develop and progress to frank necrosis and deep ulceration within 6 to 24 hours.²⁴

Since subungual tissue is lacking in stratum corneum, it is particularly susceptible to the penetration of fluoride ions, and exposure may result in a gray, black, or bluish discoloration of the nails.^{21,78} This is of clinical importance, since the nail bed is generally inaccessible to administration of topical calcium therapy.

Tissue fluoride may be extremely high at the site of the burn, but such burns also result in elevated serum fluoride levels. In a fatal industrial exposure to 70% HF over 9% BSA, the burn site had 303 μ g of fluoride per gram of dry tissue (normal, 0.2 to 0.8 μ g/g) and serum fluoride was measured at 4.17 μ g/mL (normal, 0.01 to 0.04 μ g/mL).¹⁰ In another case, a serum fluoride level of 21.3 μ g/mL (normal, 0 to 0.5 μ g/mL) was reported in a child who survived an 11% BSA burn from a combination product consisting of 8% hydrofluoric acid and 23% hydrochloric acid.²⁰ Urinary fluoride (toxic, >10 mg/L) is also used to document exposures.^{13,79}

Secondary contamination attendants to the victims of HF exposure has been reported in two emergency department (ED) personnel who developed respiratory and skin irritation from patients who had not been decontaminated prior to arrival.⁸⁰ In another case, all three members of an operating room team developed marked conjunctival and nasal irritation from presumably unbound fluoride present in tissue that they were debriding on the fifth day postinjury.⁶⁹

OCULAR TOXICITY

Ocular toxicity with concentrated HF solutions may be immediate or delayed.⁶⁷ Denuded corneal and conjunctival epithelium, corneal stromal edema, and conjunctival ischemia may be seen.⁸¹ Severe eyelid edema and conjunctival chemosis with decreased visual acuity has also been described in a worker sprayed with aerosolized and solid particles of HF.⁸² Even vapors of HF can cause ocular damage.^{83,84} Anhydrous HF may result in immediate damage and globe perforation necessitating enucleation.⁸⁵ Lid deformities, uveitis, and glaucoma have also been described.⁴

Delayed effects may be seen, as evidenced by a 25-year-old sprayed in the eye with HF who was treated in an ER and released, only to return 5 days later with a foreign body sensation in his affected eye. Examination revealed a corneal erosion measuring 4 × 5 mm accompanied by marked conjunctival injection, chemosis, and subconjunctival hemorrhages.⁸² In a 3-year-old child, initial symptoms of pain and redness resolved with irrigation alone after she had sprayed her eyes with a wire wheel cleaner containing an unknown percentage of phosphoric acid and hydrofluoric acid. Pain, however, returned in 4 days. She sustained bilateral corneal opacities, which were treated with topical antibiotics and corticosteroids under the care of an ophthalmologist. Her ocular examination was normal at 30 days postexposure.⁸⁶

INHALATION TOXICITY

Upon inhalation, HF has resulted in local pulmonary as well as systemic effects. Acute lethal inhalation exposures in humans have resulted in congestion, edema, or necrosis in the liver, kidneys, and spleen, as noted on autopsy.⁸⁷ The American Conference of Governmental Industrial Hygienists' (ACGIH) threshold limit value (TLV) and the OSHA permissible exposure limit (PEL) have both been set at 3 ppm or 2.6 mg/m³.⁸⁸ Since TLV is a ceiling threshold level and PEL is a time-weighted average over 8 hours, these standards are not very useful to the emergency physician confronted with a worker who has been exposed in a factory accident to HF at 100 or 150 ppm for a short time. Thus, some researchers have sought to define a short-term exposure limit (STEL) at which brief (≤10 minutes) exposures at higher levels might produce irritation but not serious or irreversible effects on the respiratory tract. In one such study, rats were used to derive an STEL for humans of 130 ppm for a 10 minute or less exposure.⁸⁸

Potroom workers in the aluminum smelting industry are at increased risk for inhalation of HF⁸⁹ and particulate fluoride salts,⁹⁰ which have caused inflammatory responses in the upper and lower respiratory tracts of healthy individuals at HF levels of less than 5 mg/m³.²⁵ In a volunteer study, 20 individuals exposed to HF at levels varying from 0.2 mg/m³ to 5.2 mg/m³ had elevated levels of plasma fluoride that correlated with increasing concentrations of HF. The authors also found that exposures above 2.5 mg/m³ were associated with pronounced upper respiratory tract symptoms and with increased neutrophils and tumor necrosis factor- α

(TNF- α) in nasal fluid.²⁵ In some cases, HF inhalation may result in pulmonary edema and severe lung injury¹ or death,⁹¹ whereas others report an adult respiratory distress syndrome (ARDS)-like syndrome necessitating prolonged intubation but with normal pulmonary function at outcome.⁹² Postmortem examination of tissue in fatal inhalation cases has revealed bronchi obstructed with mucus and blood and severely ulcerated, necrotizing tracheobronchitis with pseudomembrane formation.⁹¹

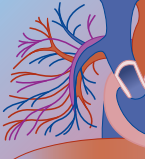

The sudden onset of asthma in an adult with no previous history has been reported immediately following an inhalation exposure to an 8% to 9% HF rust remover.⁹³ Chemical pneumonitis has been reported in a previously healthy 26-year-old woman who used three 10-ounce applications of an 8% HF-containing rust remover in an attempt to remove a stain in a bathtub. On presentation, she had shortness of breath, orthopnea, fever, nonproductive cough, severe right shoulder pain, and auscultated wheezes and crackles over her right thorax. A chest radiograph revealed a right lower lobe infiltrate. Over the ensuing 3 to 4 days, her respiratory status deteriorated and she was intubated, requiring a fraction of inspired oxygen (FiO₂) of 1.0 and positive end-expiratory pressure (PEEP) of 10 cm H₂O to maintain oxygen saturation above 70%. All cultures for bacteria, viruses, fungi, and mycobacteria were negative.⁹⁴

Respiratory symptoms may be persistent for months to years following inhalation of HF.⁹¹ While changes in respiratory function have been described with large exposures as mentioned above, there also appears to be an association between low-level HF exposure and a decline in chronic lung function as measured by forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV₁).^{25,89}

INGESTION TOXICITY

The toxicity of HF in oral ingestions is generally severe and rapid, with death occurring in less than 1 hour in some cases.^{4,22} This route of exposure is not uncommon, as reported by one regional poison center over a 2-year period. The authors found 1172 HF exposures 99 of which were human cases of ingestion.³⁴ All these ingestions involved products which contained 6% to 8% HF. Hypocalcemia was found in 4 of 29 cases in which calcium was measured, and all four of these patients were adults who intentionally drank 3 oz or more in a suicide attempt. Two of these patients died.

GI symptoms after HF ingestion include throat pain, nausea, vomiting, gastric pain, and hematemesis.^{8,34,35} Endoscopic studies show esophageal erythema and edema³⁵ as well as superficial ulcerations in the stomach in treated cases.⁸ Systemic symptoms are also likely with HF ingestion and may be life threatening. A survivor of two swallows of an 8% HF-containing rust remover developed severe hypocalcemia and received 1100 mg of calcium gluconate in the first few hours. Despite calcium replacement, the patient became hypotensive (BP 62/40, HR 140) and developed ventricular fibrillation for which she was defibrillated as many as 30 times³⁵; she ultimately survived neurologically intact.

Ingestion of ammonium bifluoride (NH_4HF_2) resulting in death in two children has been reported^{3,52} and survival in two others.¹³ In one case, a 3-year-old girl ingested an unknown quantity of a wheel cleaner containing NH_4HF_2 , which had been placed in a drinking cup. Within 20 minutes of ingestion she was obtunded, flaccid, and with circumoral cyanosis. She was intubated and treated with multiple doses of IV and nebulized calcium gluconate, but within 30 minutes of arrival she suffered bradysystolic arrest. Curiously, the QT_c interval remained normal until the time of the arrest. She could not be resuscitated, and postmortem examination revealed severe pulmonary hemorrhage as well as hemorrhagic necrosis of the pharynx, esophagus, and stomach.⁵² Both of two survivors of significant NH_4HF_2 ingestion displayed significant hypocalcemia (one, 4.2 mg/dL, and the other, 2.6 mg/dL; normal, 9 to 11 mg/dL) and one displayed severe hypomagnesemia (0.3 mg/dL; normal, 1.5 to 2.1 mg/dL). An electrocardiogram (ECG) available in the first case revealed a slightly prolonged QT_c (0.48 seconds) that prompted treatment with IV calcium. One patient developed delayed ventricular fibrillation at approximately 3.5 hours and the second at an estimated 6 to 7 hours postingestion.¹³ Urinary fluoride levels confirmed the exposure in both cases (77 and 110 mg/L; toxic, >10 mg/L).

DIAGNOSIS

Laboratory and Other Diagnostic Testing

Diagnosis of acute fluoride toxicity is based on clinical presentation and history of exposure. The onset of systemic toxicity may be rapid and abrupt; hence, treatment is best initiated prior to definitive knowledge of the electrolyte status of the patient. Frequent monitoring of calcium, magnesium, potassium, and phosphorus as well as arterial blood gas (ABG) levels is essential during evaluation and treatment of HF exposure. Hypocalcemia, hypomagnesemia, hyperkalemia, and acidosis are suggestive of HF toxicity. Renal and hepatic functions are important parameters to monitor, since toxicity to these organs may accompany systemic fluorosis.⁸⁵

Continuous cardiac monitoring and hourly serum calcium concentrations are essential during parenteral (i.e., subcutaneous, intravenous, or intra-arterial) calcium supplementation to guard against the risk of hypercalcemia associated with the inexact nature of dosing with calcium salts.²⁰

Serum and urinary fluoride levels may be used as indicators of severity of exposure, since neutralized fluoride is eliminated primarily by the renal system. Fluoride levels are not very useful in the management of acute overdose, and normal or reference values vary in the literature. For serum, the generally accepted "normal" range is 0.01 to 0.04 $\mu\text{g}/\text{mL}$; some use an upper reference limit of no more than 2 $\mu\text{mol}/\text{L}$. The normal range for urine fluoride varies from 0.2 to 3.2 mg/L (toxic, >10 mg/L).

Differential Diagnosis

Phosphoric acid may be present in products used for etching metals and creating semiconductor products. It may also burn the skin but does not have the delayed effects characteristic of HF. If the patient has severe pain in the extremities or other areas of the skin without noticeable redness early following exposure to unknown chemicals, HF toxicity should be considered.

MANAGEMENT

Regardless of the route of HF exposure, initial management is aimed at thorough decontamination to reduce the absorption of fluoride. This is followed by attempts at rapid and complete deactivation and neutralization of absorbed fluoride ion to prevent or minimize tissue damage and systemic toxicity.

Dermal Exposure

First aid for dermal exposure to HF is immediate removal of contaminated clothing, taking extreme caution to protect attending personnel from cross-contamination, and irrigation of the exposed site with copious amounts of water for a minimum of 15 to 20 minutes. Decontamination is followed by careful débridement of vesicles and bullae to allow topical neutralization efforts to be optimally effective.⁴

A wide variety of treatment options have been devised to treat tissue hypocalcemia by deactivating free fluoride ions at the site of injury, thereby promoting formation of a nontoxic, insoluble calcium salt. Selection of a treatment modality is based on the history of the exposure and clinical status of the patient (Fig. 90-1).

Initial topical neutralization should include massage of a 2.5% to 5% calcium gluconate gel into the burn site.^{64,75,85,95} An extemporaneous preparation of calcium gluconate gel 2.5% to 5% is formulated by adding 3.5 to 7 g of calcium gluconate powder to a 5-ounce tube of water-soluble surgical lubricant (e.g., K-Y Jelly).^{4,21} Alternatively, the gel may be formulated by adding 10 1-g calcium carbonate tablets (e.g., Tums antacid tablets), which have been crushed into a fine powder, to 20 mL of water-soluble surgical lubricant to create a slurry.⁹⁵ The calcium carbonate will not be fully dissolved. Some authors advocate formulating the gel with dimethyl sulfoxide (DMSO), since it is thought to enhance the absorption of calcium into underlying tissues^{20,96}; however, safety and efficacy of DMSO use have not been established.⁶⁶ Calcium chloride should not be used as a substitute for either the gluconate or the carbonate forms of calcium in topical applications owing to its potential for cellular toxicity and tissue irritation.⁹⁵ To facilitate application to the hands and digits, it is recommended to place 10 mL of the prepared gel inside a sterile surgical glove that is a half-size too large and insert the patient's hand into the glove.^{4,75,95} Bending the fingers intermittently ensures optimal contact between the gel and the treatment area and facilitates main-

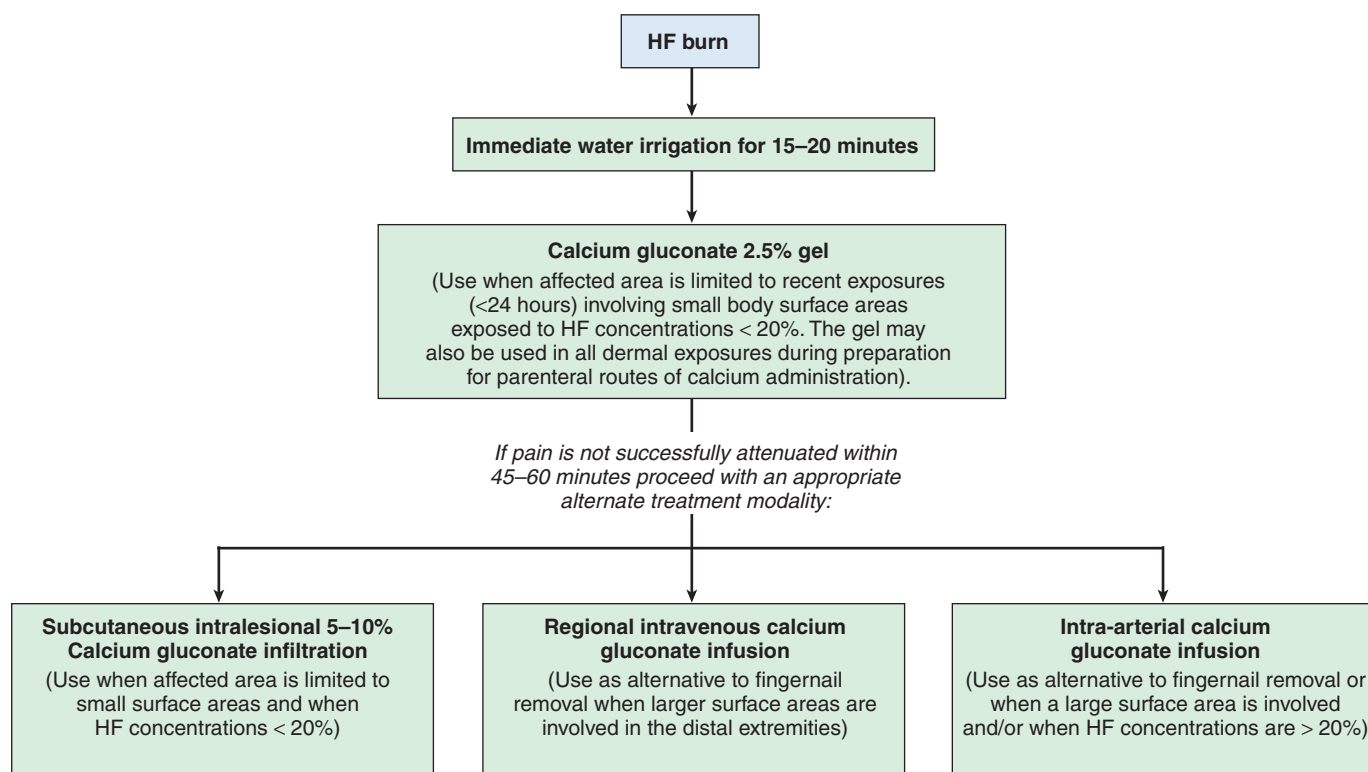

FIGURE 90-1 Dermal treatment of hydrofluoric acid burns.

tenance of joint mobility. If the patient obtains pain relief within 1 hour, liberal use of the gel can be continued for 3 to 4 days at 4- to 6-hour intervals⁸⁵ or whenever pain recurs.²¹ It is hypothesized that topical treatment with calcium pulls fluoride ions back across the skin by a diffusion gradient.⁹⁵ This rationale suggests that topical administration of calcium is more efficacious in recent exposures (<24 hours), where the fluoride ion may not have penetrated deeper tissue layers, or in extensive exposures while preparing for more invasive means of calcium delivery to the tissues.^{76,95}

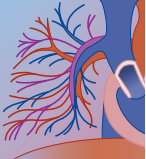

Topical applications to neutralize the fluoride ion may have limited success in extremely late presentations (>24 hours) or when the skin shows evidence of altered integrity such as a toughened outer coagulum and blisters that may limit the access of subcutaneous tissues to administered calcium.⁹⁵

When pain persists beyond 45 to 60 minutes of topical calcium neutralization^{7,65,66} or if severe burns from solutions greater than 20% HF are present on initial consultation,^{21,78,85,97} subcutaneous intralesional administration of calcium gluconate should be considered. Tissue destruction and associated pain may be minimized by subcutaneous intralesional administration of calcium gluconate, as introduced in 1932 by Freehagen and Wellmann,⁹⁸ with proven efficacy by Jones⁹⁹ in 1939.

A standard protocol in use, first described by Dibbell⁷⁸ in 1970, involves multiple subcutaneous intralesional injections of 10% calcium gluconate beneath the affected area by means of a 30-gauge needle to deliver a maximum volume of 0.5 mL/cm² of tissue, extending 5 mm beyond the injured site.^{4,65,72,78,100} Each injection of

0.5 mL of 10% calcium gluconate solution delivers 4.2 mg of elemental calcium, which has been estimated to neutralize 0.025 mL of 20% HF.¹⁰¹ A plastic surgeon or hand specialist should be consulted prior to attempting tissue infiltration. Subcutaneous injections into the tissues of the fingers must not be circumferential nor should they exceed 0.5 mL per affected digit owing to the possibility of the injection itself producing vascular impairment or of local compartment syndrome in already edematous tissue.⁶⁵ If local pain recurs, repeat injections^{21,78} may be warranted, with extension of the treated site beyond the recommended 5 mm.^{72,97} When tissues of the face are infiltrated, it is advised that a 5% calcium gluconate injection be used to reduce the risk of tissue irritation, potential scarring, and keloid formation.^{4,85} Administering large volumes of subcutaneous calcium gluconate in single or repeated injections should be avoided because it may result in hypercalcemia, decreased tissue perfusion, local compartment syndrome, and ischemia-induced necrosis.^{7,20,63} Calcium chloride should never be substituted for calcium gluconate in subcutaneous injections owing to the risk of tissue necrosis related to its hypertonicity.^{4,11,21}

Velvart¹⁰² recommends that subcutaneous calcium injections not be attempted when necrosis is apparent on presentation in favor of a more definitive treatment modality. The main disadvantage of subcutaneous infiltration is obvious discomfort to the patient. Since the end point of therapy is cessation of pain, the use of anesthesia has been discouraged during the infiltration procedure^{21,65,78} although parenteral morphine is often required. Local calcium infiltration may require removal

of fingernails to gain access to contaminated subungual structures that are easily penetrated by HF because of the lack of corneum stratum. In some instances, "burr holes" into the fingernails may be sufficient to deliver adequate calcium to underlying tissues.⁷ Fingernail removal is a disfiguring process that requires up to several months for regrowth, causing extended disability in occupations requiring the use of the hands and fingers. An alternative to fingernail removal is trimming the nail plate back to its attachment at the nailbed⁴ or injecting the nail bed via a lateral or volar route through the fat pad,⁷⁵ which is accomplished under digital nerve block. Instead of local injection and fingernail removal, one can infuse calcium locally. The decision to advance to more definitive modes of calcium delivery is warranted when fingernail removal is being considered or when there is lack of response to topical or subcutaneous injection.

Regional IV calcium infusion is a therapeutic option proposed for treatment of HF burns of the upper extremity to promote analgesia while minimizing tissue destruction.¹⁰³⁻¹⁰⁷ Success has been reported with HF injuries to the lower extremity.¹⁰⁸ Calcium gluconate, 10 mL of a 10% solution in 30 to 40 mL of normal saline, is injected intravenously into the affected limb by means of the Bier block technique. Ischemia of the limb is maintained with a tourniquet for 20 to 25 minutes to allow calcium to accumulate in tissues at the site of injury.¹⁰⁶ Some clinicians utilize a second tourniquet proximal to the first to prevent inadvertent systemic calcium administration. In the event of failure of regional IV calcium infusion, a second infusion should be attempted.^{103,107} Patients should have continuous cardiac monitoring and frequent serum calcium level measurements during Bier block-IV calcium infusion. Some authors advise regional IV calcium infusion as a viable alternative to subcutaneous intralesional infiltration owing to the discomfort imposed on the patient during infiltration without anesthesia and the need for fingernail removal in some instances.^{106,107} Adverse effects reported with regional IV calcium infusion have been limited to minor complaints of warmth and burning during the calcium infusion and discomfort during maintenance of tourniquet inflation.¹⁰⁶ Transient forearm fasciculation for up to 1 hour has been reported in one case.¹⁰⁶

An additional yet more invasive means of fluoride ion deactivation is delivery of calcium by an intra-arterial infusion method. This treatment modality is indicated for severe exposures to HF of greater than 20% concentration, late presentations (>24 hours) unresponsive to other therapies, extensive burn areas where available tissue space is limited for subcutaneous infiltration of calcium.⁷⁷ Aschinger and colleagues¹⁰⁹ introduced the procedure, specified for injuries to the distal extremities, in 1979, with modifications by Velvart¹⁰² in 1983 and Vance⁷⁷ in 1986. The technique for intra-arterial infusion involves the percutaneous insertion of a long catheter into the radial, ulnar, or brachial artery, as determined by the site of injury. The origin of vascular supply to the injured area is identified by digital subtraction

arteriography. A pressure transducer and monitor are used to confirm the position of the catheter; once the catheter is optimally in place, a dilute solution of calcium salts (10 mL of 10% calcium gluconate in 40 to 50 mL 5% dextrose) is infused over a 4-hour period by means of a pump apparatus. Treatments are repeated at 4-hour intervals until the patient remains pain free for a 4-hour period. Continuous cardiac monitoring, vital signs, and calcium levels are closely observed during intra-arterial calcium infusion.

Lin and colleagues¹¹⁰ recommend modifying the above procedure by continuously infusing calcium over a 12-hour period using an ambulatory infusion pump. This modification offers the patient additional comfort and mobility during the treatment period while maintaining excellent clinical efficacy.

Intra-arterial calcium infusion enables the delivery of large volumes of calcium to the injured site without impairment of surrounding structures or induction of local tissue toxicity.^{77,102} Some toxicologists and vascular hand surgeons with extensive experience in the use of intra-arterial calcium infusion may consider this technique earlier in the course of management, while taking necessary precautions including continuous arterial waveform monitoring. This technique is most appropriate when it is advantageous to administer large amounts of calcium to the burn site in the case of extensive burns from highly concentrated HF accompanied by a considerable risk of hypocalcemia and systemic toxicity.

A single 10-mL intra-arterial infusion of 10% calcium gluconate delivers 84 mg (4.7 mEq) of elemental calcium to tissues injured by HF.⁷⁷ The infusion is painless to the patient and avoids the need for fingernail removal. Case reports have demonstrated proven efficacy for pain relief up to 24 hours after the injury with intra-arterial infusion.¹⁰² When intra-arterial infusion is employed early in the course of treatment, initial tissue débridement should be conservative, since rejuvenation of avital tissue has been noted.¹⁰² Despite its advantages, intra-arterial infusion has significant drawbacks in that it requires hospitalization, specialized equipment, and coordination by a vascular surgeon experienced in the technique.⁷⁷ Complications include local arterial spasm, arteritis, and soft tissue loss.⁷⁷ Siegel and Heard¹⁰⁵ reported nerve palsies, carpal tunnel syndrome, and persistent increased sensitivity to cold and paresthesias from their experience in treating 38 extremities in 28 patients.

Ocular Exposure

The speed with which irrigation is instituted is the most important factor in preventing damage from ocular exposure to HF. An immediate *single* irrigation with tap water or isotonic NaCl for 15 to 20 minutes is the best initial first aid and should be instituted immediately at the scene. Multiple or prolonged irrigations are discouraged on the basis of studies in rabbit eyes which indicate that multiple irrigations can increase the rate of corneal ulceration from 6% to 40%.⁸¹ Although the pH of the burn surface may rapidly return to normal after initial irrigation, deeper tissues may remain at con-

siderable risk for serious injury. Some clinicians recommend that once the patient is in the ED, an additional 5 to 10 minutes of irrigation with a 1% calcium gluconate solution should be instituted to ensure that adequate decontamination has been achieved and that remaining fluoride ion on the surface of the eye is neutralized.^{21,85} Calcium gluconate 1% drops should be instilled every 2 to 3 hours for up to 2 to 3 days,^{82,84,85} accompanied by conventional use of cycloplegics and antimicrobial agents when necessary. Efficacy of this treatment has been demonstrated in several cases involving HF concentrations of up to 49%.⁸⁴ The use of corticosteroid agents is proposed by some clinicians to lessen fibroblast formation in the cornea.^{85,111} Systemic analgesic agents are helpful in controlling the pain associated with ocular exposure to HF. An ophthalmology consultation and examination are highly advisable for all patients with ocular exposure to HF.

It is not feasible to extrapolate treatment for dermal HF burns to the eye.^{81,86} Many irrigants that have been suggested as immediate first aid in dermal exposures (e.g., Hyamine 0.2% and Zephiran 0.05%) can induce additional toxicity to the eye.⁸¹

Other irrigant solutions have been proposed for the treatment of ocular exposure to HF. Hatai⁸⁶ suggested the use of milk or lactated Ringer's solution as appropriate eye irrigants, since both have physiologic compatibility with the eye and both have a divalent calcium ion. Further research is needed to evaluate their efficacy.

Water, isotonic sodium chloride (NaCl), and isotonic magnesium chloride (MgCl₂) when available are the best irrigating solutions for HF exposures to the eye in an experimental rabbit model.⁸¹

Inhalation Exposure

Inhalation exposure to HF is most common in industrial settings. Multiple organ systems are at risk, since HF fumes at concentrations greater than 40% to 48%. Rapid removal from the contaminated environment is key to reducing morbidity and mortality. Rescue personnel should wear self-contained breathing apparatus (SCBA) and containment suits to prevent exposure. To patients in respiratory distress, 100% humidified oxygen should be administered immediately, followed by administration of a 2.5% to 3% calcium gluconate solution in normal saline with 100% oxygen via nebulization.^{7,85} HF inhalation is accompanied by a significant risk for immediate or delayed-onset pulmonary edema, especially with prolonged exposure or exposure to high concentrations. If there is evidence of pulmonary edema, the patient should be placed on intermittent positive pressure breathing (IPPB) with PEEP and calcium should be delivered per nebulization.⁸⁵ In a reported case, 5% calcium gluconate per IPPB was employed utilizing a nebulizer after an inhalation exposure to 100% HF. Chest films and computed tomographic (CT) scan were normal at 21 days postexposure when the patient was discharged.⁹² Patients exposed to HF by inhalation may require intubation and mechanical ventilation, especially when exposed to concentrations exceeding 60%.⁶ Inhaled HF

is rapidly introduced into the liver and kidneys via the blood stream and is accompanied by a high risk for systemic toxicity.⁸⁵ It is essential to maintain an adequate airway and closely monitor serum calcium, magnesium, and potassium levels; arterial blood gases (ABGs); and O₂ saturation. Continuous observation for 24 to 48 hours after inhalation exposure to HF in a health care facility is suggested.

Some clinicians recommend the early use of corticosteroids to prevent noncardiogenic pulmonary edema and to control the inflammatory response.^{85,98} Since there is not complete agreement about this recommendation, the use of steroids as a standard regimen remains controversial.

Oral Exposure

Oral exposure to HF results in rapid systemic absorption even with dilute solutions and is associated with a high risk for systemic toxicity. Simple dilution with a demulcent will not arrest the progression of tissue damage or the development of systemic toxicity when HF preparations are ingested. Induced emesis is contraindicated, as is neutralization with oral sodium bicarbonate.²¹ Recommended first aid is oral administration of 1 to 2 cupfuls of milk or water. Milk is preferred owing to the presence of calcium ions,³⁵ though milk of magnesia may be given for its available magnesium ions and its demulcent effect on oral and gastric mucosa. To the authors' knowledge, there are no reports of benefit from activated charcoal in the management of oral exposures to HF.

Treatment in the ED may include cautious nasogastric lavage with a small-bore nasogastric tube to remove residual HF if this can be performed within 60 to 90 minutes of ingestion and perforation has not occurred.^{4,21} It has been advocated to add 10% calcium gluconate to the lavage fluid to help bind fluoride present in the GI tract.^{4,13} Lavage with 20 mL of calcium chloride in 1000 mL of normal saline has been initiated after ingestion of 10% HF.⁸ Chan and Duggin⁸ contend that it does not matter which form of calcium is used for lavage so long as enough calcium is provided to bind available fluoride. In a rare case of a self-administered concentrated HF enema, calcium carbonate enemas were given to bind intraluminal fluoride ion.⁴⁹ A gastroenterology/surgery consultation and examination are highly advisable for all patients with significant or symptomatic oral exposure to HF.

Systemic Toxicity: Fluoride-induced Electrolyte and Cardiac Abnormalities

Systemic toxicity should be anticipated with any ingestion or inhalation of HF and with any dermal exposure involving a large surface area or a high concentration of HF. Continuous cardiac monitoring, hourly electrolyte values, and frequent ABG determinations are essential during the acute phase of systemic toxicity. IV access is essential for the supplementation of depleted electrolytes and sodium bicarbonate.

HYPOCALCEMIA

Hypocalcemia has been associated with a prolonged QT_c interval and ventricular fibrillation. In adults, a slow IV, prophylactic infusion of 20 mL of 10% calcium gluconate is recommended when systemic toxicity is anticipated.⁸⁵ Continuous cardiac monitoring is indicated, since too rapid calcium administration may induce cardiac arrhythmias, most notably bradycardia. Prior to calcium administration, a serum calcium level should be drawn but the initial prophylactic infusion should not be delayed pending results. Calcium should be infused until the level reaches the upper limit of normal in an effort to prevent ventricular fibrillation related to hypocalcemia in myocardial tissue.^{20,21,24} Some clinicians propose the substitution of chloride salt for calcium gluconate, since it provides increased amounts of calcium ion. Calcium chloride however, has a potential for irritation and is best delivered by a central line. In addition, calcium chloride is acidifying and so should not be used when acidosis coincides with hypocalcemia. It is important to note that attempts to increase extracellular calcium through supplementation may exacerbate potassium efflux, so treatment of hypocalcemia may confound hyperkalemia in the setting of systemic fluorosis.²³

HYPERKALEMIA

Hyperkalemia may precipitate the development of peaked T waves and cardiac arrhythmias. Aggressive measures such as hemodialysis may be required to achieve normalization of potassium levels.^{23,35} Although there are recent reports of the use of cation exchange resins (e.g., Kayexalate) for hyperkalemia,¹¹² no one has reported such use to treat the hyperkalemia of HF exposure. Considering the time delay in rise of extracellular potassium, this may be an intervention to consider in advance of the anticipated hyperkalemia seen in significant HF exposures.

HYPOMAGNESEMIA

Hypomagnesemia is associated with QT prolongation and ventricular arrhythmias. Correction of hypomagnesemia is achieved with IV magnesium sulfate.

ACIDOSIS

Sodium bicarbonate may be used to correct acidosis. Inducing a slight metabolic alkalosis with sodium bicarbonate is indicated to enhance the excretion of fluoride ions in the urine.³¹

ALTERNATE FORMS OF FLUORIDE AND RELATED TOXICITY

With exposures to oral forms of fluoride including toothpastes, oral rinses, dentifrices, and oral supplements, it is important to establish the type and the amount of the fluoride salt present in the product as well as the amount ingested. Table 90-1 gives a partial listing of fluoride salts and the amount of elemental fluoride in each.

When ingested amounts of elemental fluoride exceed 5 to 8 mg/kg,⁵⁸ provision of calcium in the form of milk

TABLE 90-1 Elemental Fluoride Amounts in Common Fluoride Salts

SALTS OR PRODUCT	ELEMENTAL FLUORIDE
Sodium fluoride (NaF), 2.2 mg	1 mg
Stannous fluoride (SnF ₂), 4.1 mg	1 mg
Sodium monofluorophosphate (MFP) 7.6 mg	1 mg
Fluoride toothpaste	Maximum of 1 mg per gram of toothpaste The maximum allowable amount of elemental fluoride in a tube of toothpaste is 260 mg
Oral nutritional supplements	0.25 to 1.0 mg per tablet or milliliter of product

and dairy products or calcium-containing antacid tablets will bind fluoride in the stomach. Fluoride salts dissociate in the acidic environment of the stomach to form HF acid, which causes GI irritation. When large amounts of fluoride salts are ingested, there is a risk of systemic fluoride toxicity, but this is rarely the case in accidental ingestion.

TEE L. GUIDOTTI, MD, MPH

At a Glance...

- Severe acute hydrogen sulfide poisoning can be seen in a variety of settings but is most commonly observed in the oil and gas industry.
- High concentrations of hydrogen sulfide may cause “knockdown,” a sudden loss of consciousness, which may be accompanied by apnea.
- Unprotected rescuers are at high risk of death. Self-contained breathing apparatus should always be worn during rescue attempts.
- In addition to altered consciousness, hydrogen sulfide sometimes causes pulmonary edema and keratoconjunctivitis (“gas eye”).
- Laboratory studies are rarely available for confirmation; therefore, the diagnosis is based on history and clinical grounds.
- Supportive care, with attention to the airway, is critical.
- Sodium nitrite, a component of the Taylor cyanide kit, is a useful antidote for hydrogen sulfide but only if given promptly. Hyperbaric oxygen may also be effective in severe cases.

Hydrogen sulfide (H_2S) has been recognized as an occupational hazard since the time of Ramazzini in the 18th century. H_2S is among the most common causes of fatal gas inhalation exposures in the workplace and is mostly a problem today in the oil and gas industry, in swine confinement facilities, and in manure collection systems. H_2S is generated in municipal sewers and sewage treatment plants, pulp and paper operations (in Kraft and especially sulfite mill technologies), construction zones in wetlands (such as marshes), asphalt roofing, and pelt processing (in which soaking in sulfide solution loosens hair for removal), and may be a hazard in confined spaces in which organic material, such as fish or offal, has decayed or in which inorganic sulfides may be reduced.¹⁻⁶ H_2S may be both an occupational and a potential community environmental health risk in areas with geothermal activity and hot springs, such as Rotorua, New Zealand.⁷

H_2S is the principal hazard in the “sour gas industry,” that part of the natural gas industry extracting sulfur-containing natural gas. Organic sulfur is reduced to hydrogen sulfide during the prolonged degradation process of organic material underground that forms natural gas and petroleum. Sour gas is distributed in oil and gas fields worldwide but is concentrated in western Canada, Texas and the Gulf Coast, Michigan, the Middle East (including Saudi Arabia and Abu Dhabi), central Asia (including Kazakhstan, Iran, and Pakistan), and Russia. Most sour gas falls between 2% and 35% H_2S , but some wells in the Canadian province of Alberta exceed 98%.⁸⁻¹²

MECHANISM OF ACTION

The primary toxicity of H_2S is conventionally assumed to result from inhibition of cytochrome-*c* oxidase and possibly other heme-containing macromolecules by aqueous sulfide.^{13,14} H_2S is classified as a cellular asphyxiant, together with carbon monoxide, cyanide, and azide. H_2S interacts with a number of enzymes and other macromolecules, including hemoglobin and myoglobin. The effect of H_2S in disrupting cytochrome-*c* oxidase activity is the same as oxygen deprivation or asphyxiation except that it may act more quickly. This is thought to be the primary mechanism of action of the characteristic reversible neurotoxicity associated with H_2S , the sudden loss of consciousness called “knockdown.”⁶

The mechanism of action of H_2S is often attributed to inhibition of cytochrome-*c* oxidase and therefore to a mechanism identical to that of cyanide.¹⁵ However, there are clearly other mechanisms.¹⁶ One lethal end point of H_2S exposure is respiratory paralysis, a dose-dependent reduction in ventilatory drive resulting in apnea, which follows an initial hyperpnea.¹⁷ Infusion of the sulfide ion alone into the circulation mimics the systemic effects of H_2S inhalation. The apneic response to H_2S is not enhanced by intra-arterial injection of sulfide into the carotid artery, which delivers blood directly to the brain, compared with intravenous injection into the femoral artery, in which mixing occurs in the general circulation. The apneic response can also be blocked by paralysis of the vagal nerve by lidocaine or by infusion of sodium bicarbonate solution, in the absence of acidosis. These findings strongly suggest that a peripheral receptor in the lung is responsible for the apneic response.¹⁸ Hydrogen sulfide may also be a neuromodulator, and so toxic exposure may involve direct functional effects as well as cell toxicity.^{16,19,20}

Pulmonary edema and mucosal irritation, particular of the eye, are nonspecific irritant effects of hydrogen sulfide, reflecting its chemical reactivity.²¹

TOXICOKINETICS

H_2S is poorly soluble in water. Exposure occurs exclusively by the inhalation route, and to date all described toxicity incidents have involved exposure in the gaseous phase. H_2S is inhaled and enters the circulation directly across the alveolar-capillary barrier. Once absorbed, H_2S dissociates in part into hydrosulfide ion, HS^- , then is spontaneously transformed into sulfide [S^{2-}] and then sulfate [SO_4^{2-}]. Some H_2S remains as free H_2S in blood, and this fraction appears to interact with metalloproteins, disulfide-containing proteins, and thio-S-methyl-

transferase, forming methyl sulfides. The sulfide ion binds to heme compounds and is itself metabolized by oxidation to sulfate. Sulfate is then excreted by the kidney or lost in intermediary metabolism. Little is known of the toxicokinetics of H₂S and sulfide.²²

CLINICAL PRESENTATION

Pathophysiology

It has been known for many years that H₂S has potent neurotoxic properties. Respiratory paralysis may occur if exposure is prolonged, presumably as a direct consequence of sulfide toxicity inhibiting brainstem respiratory nuclei. However, the studies cited on apnea,^{16,18} supported by studies suggesting a chemoreceptor response,²⁰ suggest that there are other pathways that affect central activity.

Animal studies of the toxicity of H₂S are often difficult to interpret. Exposure to H₂S is known to increase levels of taurine in cerebrospinal fluid, for example, but it is not clear whether this is a toxic effect or a protective effect because taurine may act on neurons to reduce the neurotoxicity of some agents.²³ Likewise, H₂S is known to increase serum glucose levels in postpartum rats, but an aggravating effect on diabetes has not been suggested in the literature on human toxicity.²⁴ Chronic low-level exposure to H₂S is associated with abnormal proliferation and ramification of Purkinje cells in the cerebellum of rats, but there is no comparable human exposure outcome with which to compare these observations.²⁴

In healthy, fit human volunteers, exposure to H₂S as low as 5 ppm during exercise (30 minutes) is associated with an early shift from aerobic to anaerobic metabolism, as indicated by increasing blood lactate levels, but without symptoms.²⁵ This observation precipitated a review of occupational exposure levels in the United Kingdom.²⁶

In the past, there was a controversy over whether sulfhemoglobin occurs after high-level H₂S exposure, but the weight of evidence is that it does not.¹⁴

Manifestations

ACUTE TOXICITY

Acute central neurotoxicity, pulmonary edema, and the mucosal effects are the characteristic features of acute toxicity of H₂S. Odor perception, olfactory paralysis, and keratoconjunctivitis are the characteristic effects of H₂S at lower concentrations.^{3,5,6,9,11,21} In addition to the effect of olfactory paralysis, which is an effect at higher exposure levels (>100 ppm), olfactory fatigue occurs at lower, ambient levels, so that the person exposed may not be as aware of the odor because of habituation, even though there is no toxic effect on olfaction. See Table 91-1 for health effects of hydrogen sulfide at various exposure levels.

H₂S-induced acute central toxicity leading to reversible unconsciousness is sudden and is colloquially called a “knockdown.”⁶ Knockdowns can be acutely fatal as a consequence of respiratory paralysis and cellular anoxia. Very high concentrations (500–1000 ppm) are associated with a knockdown. This is an abrupt loss of

TABLE 91-1 Health Effects of Hydrogen Sulfide at Various Exposure Levels

CONCENTRATION (ppm)	EFFECTS
0.01–0.3	Odor threshold (highly variable)
1–5	Moderate offensive odor, may be associated with nausea, tearing of the eyes, headaches, or loss of sleep with prolonged exposure; healthy young male subjects experience no decline in maximal physical work capacity.
10	8-hour occupational exposure limit in Alberta, OSHA PEL
15	15-minute occupational exposure limit in Alberta
20	Ceiling occupational exposure limit evacuation level in Alberta; odor very strong
20–50	Keratoconjunctivitis (eye irritation) and lung irritation. Possible eye damage after several days of exposure; may cause digestive upset and loss of appetite
100	Eye and lung irritation; olfactory paralysis, odor disappears
150–200	Sense of smell paralyzed; severe eye and lung irritation
250–500	Pulmonary edema may occur, especially if prolonged
500	Serious damage to eyes within 30 minutes; severe lung irritation; unconsciousness and death within 4 to 8 hours; amnesia for period of exposure; knockdown
1000	Breathing may stop within one or two breaths; immediate collapse

OSHA, Occupational Safety and Health Administration; PEL, permissible exposure limit.
From Guidotti TL: Hydrogen sulfide. *Occup Med* 1996;46(5):367–371.

consciousness and collapse, described by those who witness it as appearing much like turning off the switch on a mechanical doll. A knockdown may be fatal if exposure is prolonged. If exposure is transient, as usually happens in the oil patch, recovery may be equally rapid and apparently complete.^{9,27} Some veteran oilfield workers have returned to what they were doing without reporting the event and without treatment, considering the experience all in a day's work.

Central effects observed after a knockdown might represent primary toxicity of H₂S, secondary effects from low-level cellular anoxia, or the sequelae of acute brain injury. The long-term central effects of a knockdown in any given case may represent an episode of toxic anoxia, or even a secondary traumatic injury. In at least one case, focal cortical necrosis was documented following a knockdown in which the patient never recovered consciousness.

H₂S is irritating to mucous membranes, although this feature of H₂S exposure may have been overly emphasized in the literature.²⁶ H₂S penetrates deeply into the respiratory tract because its solubility is relatively low, rendering it capable of causing alveolar injury leading to acute pulmonary edema.

The irritant effect is also seen in the upper airway; experimental studies suggest that the olfactory mucosa do not recover as fast as the bronchial epithelium. Recently, this pattern of toxicity was demonstrated to be attributable to selective toxicity of olfactory mucosa in the nasal passages.²⁸ Human subjects exposed to transient high levels of H₂S have been reported to show deficits on standardized tests of smell and taste years later, suggesting that the effect may be a permanent sequela under some circumstances.²⁹

Pulmonary edema is also a well-recognized acute effect of H₂S toxicity, especially when exposure is prolonged. Older studies suggest that 20% of cases of H₂S toxicity reaching the emergency department showed evidence of pulmonary edema.⁹ Experimental studies have shown that although H₂S at high concentrations produces a marked alveolitis and profuse edema, it is only moderately cytotoxic for pulmonary cells and does not seem to disrupt the basement membrane of the alveolar endothelium. Thus, the ultimate prognosis for recovery and remodeling may be good if the patient can be supported through the acute episode.^{9,30,31} Acute inhalation of H₂S may be fatal, depending on the concentration and duration of exposure and the duration of anoxia. In one series of 152 cases from China, an overall mortality rate of 5% was reported.^{30,32}

It is not clear whether hydrogen sulfide exposure is associated with chronic respiratory sequelae. Exposure in the short term does not appear to be associated with reduced lung function or increased airways reactivity.^{33,34} However, other studies have suggested that a reduction in residual volume is a subclinical effect.³⁵ Cross-sectional studies of sewer workers, who are exposed to hydrogen sulfide, suggest that after accounting for smoking, lung function is significantly reduced and may show an accelerated rate of decline among age groups.³¹ A single case report has suggested interstitial fibrosis, but this has not been observed in other studies or case series.³⁶

Prolonged anoxia, which might be due in these incidents to respiratory paralysis, pulmonary edema, or asphyxia in a confined space, results in a severe metabolic acidosis that further complicates resuscitation. Overwhelming exposure may be associated at autopsy with skin and organ discoloration, pulmonary edema, and renal tubular necrosis.^{5,6}

Most standards for the protection of occupational and community populations are based on prevention of keratoconjunctivitis (eye irritation) and respiratory tract irritation. The slope of the exposure–response relationships for these conditions is not as steep as it is for central nervous system effects.³⁷

“Gas eye,” or keratoconjunctivitis, is a superficial inflammation of the cornea and conjunctiva that is often recurrent in workers in sour gas plant who are exposed for prolonged periods to relatively low concentrations. A peculiar feature of this effect is that it can be associated with reversible chromatic distortion and visual changes. It has been suggested that the corneal epithelium develops a fine punctate stain and becomes edematous, and that small vesicles form that act as a diffraction grating. This results in a colored halo surrounding the object. This effect is sometimes accompanied by blepharo-

spasm, tearing, and photophobia. In the viscous rayon industry, this problem is encountered with carbon disulfide exposure.^{5,21,37}

There are few data on teratogenicity, mutagenicity, or carcinogenicity for H₂S, largely because it is so toxic. In animal studies, H₂S appeared unlikely to cause reproductive toxicity after exposures that are plausible in occupational and workplace situations.^{38,39} Exposure to 75 ppm is reported to prolong delivery time of gravid rat dams at the time of parturition, and rat pups exposed at the same level in utero or neonatally showed only minor delays in ear and hair development.³⁸ Exposure to lower levels, although still toxic in human context, has been shown to elevate circulating glucose in maternal rats, with secondary metabolic effects in the offspring.²⁴ H₂S appears to enhance the mutagenicity of peroxide but is not genotoxic alone.⁴⁰ Evidence for cancer in human populations is weak. Studies of residents of Rotorua, which is a largely Maori community and cultural center, have observed an excess of cancers of the sinus overall (which may be confounded by wood dust exposure in Rotorua’s extensive native craft industry) and of lung cancer in Maori women, which was not completely explained by higher smoking rates but which was accompanied by a statistically significant deficit among Maori men.⁴¹

Laboratory Features

The management of H₂S toxicity does not depend on laboratory confirmation or monitoring sulfide levels.⁴²⁻⁵⁰

Sulfide measurements can be made on postmortem brain tissue, but this is currently a research tool that has not been validated for forensic use in humans.⁵¹ Blood sulfide levels are not diagnostic of H₂S toxicity, must be performed within 2 hours of exposure, but are seldom available, are subject to many limitations, and are not available on an emergency basis.⁵

Urinary thiosulfate levels show promise as a biologic exposure indicator in the monitoring of occupational exposure but are profoundly influenced by diet and have not been validated for human toxicity.⁵

The partial pressure of oxygen in arterial blood may be normal in H₂S toxicity, unless there is pulmonary edema or another reason for respiratory compromise. Metabolic acidosis and a low arteriovenous oxygen difference may indicate anoxia at the cellular level and may correlate with severity of toxicity, but this has not been documented.

The chest film may show evidence of noncardiogenic pulmonary edema.⁵

TREATMENT

Treatment of transient exposures, and of knockdowns in which the worker has regained consciousness, is not specific.⁵² Removal from exposure is critical, of course. Unlike cyanide intoxication, there is no evidence that H₂S intoxication would confer a risk on the rescuer during mouth-to-mouth resuscitation.⁵

Patients should be observed for pulmonary edema overnight, and metabolic acidosis should be treated.¹³ Because workers may encounter H₂S while performing

hazardous tasks, incidental injuries may require treatment.⁵³ Overwhelming exposures and prolonged knockdowns may require aggressive treatment, but the circumstances in which these exposures occur often lead to delays in transport and treatment.

Combined treatment with hyperbaric oxygen and nitrite has emerged as the treatment of choice, but the literature remains anecdotal, reflecting experience acquired one case at a time.^{2,14,44,54-60} Increased oxygen tension may overcome some of the physiologic disadvantages of nitrite treatment.

Empirically, nitrite treatment alone has been used successfully in managing acute cases, but its mechanism of action remains uncertain. Nitrite treatment is based on the observation that H₂S resembles cyanide in that both bind reversibly to cytochromes, although there appear to be differences at a biochemical level.¹³ The theory is that methemoglobin generated by nitrite would displace the sulfide, as it does cyanide, and regenerate the active cytochrome oxidase.⁵⁸ Although methemoglobin is more effective in binding sulfide than oxyhemoglobin, the complex between sulfide and methemoglobin does not last long enough to make much difference. The sulfide disappears quickly from the circulation under conditions of good oxygenation anyway. The evidence suggests that nitrite can only be effective within the first few minutes after exposure and may actually slow sulfide removal thereafter. There are also reasons to believe that the methemoglobin hypothesis is insufficient to explain the action of nitrite even in the first few minutes. A further practical problem with this approach is that it may add to the anoxic burden that already may exist from the cytochrome poisoning, respiratory paralysis due to central toxicity, and ventilation-perfusion mismatch associated with pulmonary edema. It may also induce hypotension and further complicate the anoxia with hypoperfusion. Administration of nitrites is usually begun with inhalation of amyl nitrite perles (for 30 seconds out of every minute) followed by sodium nitrite intravenously, in the same dosages as for cyanide poisoning. The literature suggests infusion of 300 mg of fluid containing 10 mL of 3% NaNO₂ over 4 minutes, titrating the drop in blood pressure to maintain systolic pressure above 80 mm Hg (10.6 kPa).^{13,55-58} In children, the recommended intravenous treatment dose would be as for cyanide intoxication (see Chapter 88). Because of the potential for inducing hypotension in a child, however, such treatment should only be considered in cases in which the cause is indisputably hydrogen sulfide exposure and the patient is not already recovering. Because hydrogen sulfide is primarily an occupational exposure, occasional episodes of toxicity may occur in adolescents³⁰ but would be extremely rare in children.

Treatment with oxygen and supportive care alone has been recommended in order to avoid further complicating the toxic effects with iatrogenic anoxia and nitrite toxicity. However, confirmation that oxygen therapy alone works is limited to anecdotal reports and experimental studies with H₂S-exposed mice did not show increased survival with oxygen alone.

Hyperbaric oxygen therapy is an attractive and logical option for treating H₂S intoxication, and anecdotal evidence suggests that it may be effective.⁵⁹ The utility of oxygen is probably related to the oxygenation of marginally anoxic tissues and the displacement of sulfide from binding sites on cytochrome-*c* oxidase, but this has not been worked out. By the nature of such poisoning incidents, it is difficult to perform clinical trials and to compare therapies. A series of three treatments at 2.5 atmospheres for 90 minutes each has been recommended.⁶⁰ Given the low morbidity of hyperbaric oxygen treatment in skilled hands,⁶¹ it is a prudent intervention if facilities are available.^{62,63} Outcomes are not guaranteed, and neurologic sequelae may still occur following treatment.⁴⁶

Decontamination is not required for the protection of health providers and bystanders. However, the foul odor of hydrogen sulfide may complicate management and cause anxiety among other patients. Removal of clothing and simple skin washing with soap and water should remove the odor from the patient. Airing outdoors should greatly reduce the odor from clothing.

Many antidotes to H₂S intoxication have been proposed, but few have shown efficacy. Ascorbate has been proposed to reverse methemoglobinemia, but because this is not the problem in sulfide toxicity, this intervention, although benign, is unlikely to be useful.⁶³

Sodium thiosulfate has been proposed as a treatment for H₂S intoxication on analogy to its role in cyanide toxicity, but its efficacy has not been demonstrated, and the rationale is in question. Sulfide is oxidized and excreted sufficiently rapidly by the body that clearance is not the problem. Thiosulfate is a metabolite of sulfide and not a substrate for enzymatic oxidation, which destroys the toxic moiety, in the case of cyanide intoxication.^{5,13}

There is evidence that the respiratory paralysis observed in some fatal knockdowns is associated with monoamine oxidase inhibition.⁶⁴ This inhibition is reversed by dithiothreitol (DTT), which also displaces sulfide from brain tissue *in vitro* after exposure in animals.⁶⁵ DTT has also been found to be protective if given to animals as pretreatment before exposure. These observations have led to efforts to use this agent and other thiol compounds as specific antidotes. In practice, however, these approaches have been disappointing.

Pretreatment with several agents is associated with increased survival in animals: pyruvate,⁶⁶ α -ketocarboxylic acids,⁶⁷ bicarbonate,¹⁸ and glucose (unpublished observation). To date, these pretreatments have not led to successful therapeutic or prophylactic interventions.

DISPOSITION

Patients presenting to the emergency department after significant acute hydrogen sulfide exposure should be admitted or observed for several hours in most cases, owing to the substantial risk of development for pulmonary edema.

The prognosis for recovery after exposure to hydrogen sulfide is an area of controversy. The evidence is strong for neurologic sequelae following knockdown, in the context of acute high exposure, but weak for effects associated with chronic, low-level exposure.

Chronic Sequelae of Acute Exposure

Chronic central nervous system effects after repeated or prolonged knockdowns have not been adequately studied. The available evidence strongly suggests that knockdowns are sometimes, if not usually, associated with chronic neurologic sequelae.^{4,32,37,42-46} However, case series describing these effects may be confounded by effects of head trauma during falls, anoxia from apnea, or seizure activity. Extrapyramidal symptoms resembling Parkinson's diseases may appear during recovery from an H₂S-induced coma.⁴⁶⁻⁴⁸

Experimental studies on mice do suggest a cumulative effect in reducing brain cytochrome-*c* oxidase activity. Experimental studies also help to localize the effects of H₂S in the brain and appear to suggest anoxia as the mechanism. The available animal evidence points to injury to the cerebral cortex, cerebellum, and possibly brainstem and spinal cord at concentrations approaching those humans might encounter. The lesions are similar to those seen in oxygen deficiency and in poisoning by other cytochrome oxidase inhibitors.^{17,42,47}

Chronic Effects of Lower-Level Exposure

Although there is sufficient evidence to conclude that a chronic toxicity syndrome exists as a sequela of knockdown, the evidence to date is weak for the conclusion that a chronic toxicity syndrome exists as a result of long-term, low-level exposure. Ecological studies of residents of Rotorua suggest some excess morbidity in both the central and peripheral nervous systems, but the pattern is not consistent, being strongest for mononeuritis. There was an elevated risk for cardiovascular disease but a reduced frequency of stroke and evidence for an elevated prevalence of high blood pressure. Other potential confounders include mercury (which was not measured) and other sulfides (not reported).⁴¹

Kilburn and colleagues have published data⁴⁸ suggesting neurobehavioral effects observed in populations exposed to low levels of H₂S, including single exposures below 1.0 or 0.5 ppm. The subjects consisted primarily of litigants, involved in a lawsuit for compensation for damages arising out of their exposure. The studies describe a pattern of poor recall, delayed reaction time, unilateral (not bilateral) changes in visual performance, and abnormal balance (requiring special technology to detect). The group has described similarly nonspecific patterns for other potential hazards. In these studies to date, the effects of litigation, posttraumatic stress, anticipation of compensation, and test bias cannot easily be ruled out. Neurobehavioral testing is also easily confounded by effects of learning, practice, motivation, sleep, education, distraction, depressed mood, and stress. The wide range of "normal" performance on these tests renders them rather insensitive and nonspecific in identifying neurotoxic outcomes, limitations freely acknowledged in the neurobehavioral literature. This literature is therefore difficult to interpret.

The Medical Diagnostic Review, a population-based prevalence survey and clinical screening conducted in

southern Alberta in the mid-1980s, found no evidence of an excess in prevalence of neurologic signs and findings, both soft and hard, in populations living downwind of sour gas facilities.⁴⁹ Animal studies show no evidence of behavioral change after exposures of less than 80 ppm, a concentration that is effectively much higher in rats than humans because upper airway clearance is less in the rat.⁵⁰

Other properties of H₂S have been difficult to assess because mucosal irritation and cellular anoxia dominate the clinical picture. Secondary effects may be overlooked in the more obvious acute toxicity profile of H₂S. Respiratory, cardiac, eye, and host defense disorders emerge as the most likely secondary effects to be associated with H₂S, but the evidence remains inconclusive.^{11,37}

PREVENTION

H₂S is heavier than air. Workers entering a depression or confined space in which the gas has collected are likely to be at highest risk, although potentially lethal exposures can and do take place in the open air. Personal protection required is the self-contained breathing apparatus (SCBA).⁶⁸ In the past, tympanic membrane defects (perforated eardrums) excluded workers from certification for SCBA gear, on the grounds that H₂S could bypass the SCBA; this is not supported by the evidence and no longer recommended.⁶⁹

H₂S is very odorous, with a low olfactory threshold, from less than 0.01 to 0.3 ppm. By 1 to 5 ppm, the odor is very offensive, like rotten eggs. However, the gas has poor warning properties at high exposure levels. As with most strong odors, workers may become accustomed to them in the short term, a phenomenon known as *olfactory fatigue*. There is also a specific mechanism known as olfactory paralysis that results in loss of the ability to perceive the odor, owing to neurotoxicity affecting the olfactory bulb and fibers. In relatively high concentrations (about 100 ppm), H₂S paralyzes the olfactory mechanism, preventing perception of any smell. This removes the primary warning sign of H₂S exposure and the principal warning to, say, oilfield workers caught in a plume.^{5,6,14,27,69,70}

As in most such incidents, casualties usually occur in twos or more, as would-be rescuers rush to save their coworkers and in their haste neglect to protect themselves with an SCBA. Intensive training and ready availability of personal protective equipment are required to prevent such situations.⁶⁸

Although there have been no documented cases of serious, irreversible injury or death in the public attributed to Alberta's sour gas industry, there have been a number of occupational fatalities arising from H₂S exposure in Alberta.¹² As a consequence, the oil and gas industry, the Alberta Government, and representatives of local residents and public agencies have developed an elaborate network of stakeholder organizations and public consultation mechanisms, which have been a model for other jurisdictions. Other locations where H₂S is a prominent hazard include Texas, Louisiana, and Iran. When a well blowout releases substantial quantities of sour gas, the usual management strategy is to ignite the gas, so that combustion converts the H₂S to less toxic

sulfur dioxide, notwithstanding the recognized irritant effects of this agent. This protects the community and nearby workers and allows crews to get closer to cap or shut down the well.

The OSHA Permissible Exposure Limit and the NIOSH Recommended Exposure Limit for H₂S are both 10 ppm, 8-hour time-weighted average. OSHA also has a short-term standard of 15 ppm. Alberta has adopted the same set of standards as occupational exposure levels and in addition has a ceiling of 20 ppm and an evacuation standard for the general population of 5 ppm.^{6,71} Studies on normal volunteers during exercise suggest that 5 ppm of H₂S is easily tolerated and results in minimal detectable physiologic change.²⁵ In the absence of definitive studies of community residents or low-level exposure of workers, this is the best evidence available that current occupational exposure standards are probably adequate, bearing in mind that time-weighted averages are generally of less significance than peak exposures for this agent for neurotoxicity but may be more suitable for irritant effects.

The encroachment of communities on industrial sites and oil and gas fields that were once relatively isolated, together with economic incentives to site wells and facilities where deposits exist in urban locations, has resulted in many conflicts in land use and regulatory requirements for emergency planning to protect residents and create setbacks, or buffer zones, between gas facilities and populated areas. The Alberta Energy and Utilities Board and its predecessor agencies have been particularly proactive in emergency planning based on projected concentrations generated by computer models in the event of an uncontrolled release. Because of the nature of incidents involving H₂S, emergency response usually involves high levels in uncontrolled situations requiring rescue. Table 91-2 summarizes acute exposure levels proposed for both emergency planning and response purposes.

The exposure–response curve for lethality is extremely steep for hydrogen sulfide.^{6,72} Among inhaled toxic substances, H₂S gives little margin of safety. One can visualize an encounter with concentrations of H₂S

TABLE 91-2 Guidelines for Emergency Planning and Response

GUIDELINE	CONCENTRATION (ppm)		INTERPRETATION
Emergency response planning guidelines (ERPGs)	Note: Concentrations are modeled for planning purposes.		Source: American Industrial Hygiene Association, 2004. ERPGs are intended to guide land use and resource planners and to determine appropriate emergency response contingencies for communities near facilities. They assume exposure of the general population, including more susceptible individuals.
ERPG-1	0.1		Exposure for up to 1 hour without experiencing "other than mild transient adverse health effects or perceiving a clearly defined objectionable odor."
ERPG-2	30		Exposure for up to 1 hour without developing "irreversible or other serious health effects or symptoms that could impair an individual's ability to take protective action."
ERPG-3	100		Maximum airborne concentration "below which it is believed nearly all individuals could be exposed for up to one hour without experiencing or developing life-threatening health effects."
Acute exposure guideline levels (AEGs)	Note: In actual uncontrolled incidents, it may not be possible to measure exposure.		Source: U.S. Environmental Protection Agency, Office of Pollution Prevention and Toxics, 2002. Intended to be guidelines in context of emergency response only: once-in-a-lifetime, short-term exposure to airborne chemicals that are acutely toxic. (Note: the significant figures in which AEGs are given far exceed the accuracy of exposure assessment in most real uncontrolled incidents.)
AEG 1	10 min	0.75	"Concentrations above which predicted that general population, including susceptible individuals, could experience notable discomfort, irritation or certain asymptomatic non-sensory effects that are not disabling and that are transient and reversible."
	30 min	0.60	
	60 min	0.51	
	4 hr	0.36	
	8 hr	0.33	
AEG 2	10 min	41	"Concentrations above which predicted that general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape."
	30 min	32	
	60 min	27	
	4 hr	20	
	8 hr	17	
AEG 3	10 min	76	"Concentrations above which predicted that general population, including susceptible individuals, could experience life-threatening health effects or death."

above 500 ppm as being much like hitting a wall, with the degree of damage having much more to do with concentration, analogous to the speed with which one hits the wall, than with the duration of contact with the wall. Concentration is much more important than duration of exposure. Fatal exposures to hydrogen sulfide in humans, for example, may in theory take place at 150 ppm for 6 hours (concentration-time product = 0.252) or 650 ppm for 8.5 minutes (0.005). This means that, for H₂S, higher concentrations are much more toxic, even with proportionally shorter exposure levels. This also appears to be true for experimental pulmonary edema induced in the rat. Many current models for risk assessment use a concentration-time constant for lethality of the general form Cⁿ × t, where n ranges from 1.43 to more than 4.36; the empirical evidence favors the higher exponents. Occupational exposure levels based on time-weighted averages do not take this into account.^{6,72}

Sour gas, the accepted term in the oil patch for natural gas containing H₂S, contains more than natural gas and hydrogen sulfide. The process stream contains variable amounts of methyl mercaptans (CH₃SH, [CH₃]₂S, and [CH₃]₂S₂), carbonyl sulfide (COS) and carbon disulfide (CS₂), and some trace metals. Mercaptans are also added to natural gas as a safety measure to ensure detection of leaks. Production also involves exposure to a variety of production chemicals incidental to gas exposure.^{8,73} Flaring introduces numerous other products of incomplete combustion and has become a particularly controversial issue in Alberta in recent years. A major study of downwind exposure to emissions from gas facilities and effects on animals is under way, and findings are expected to be available in the near future.

WILLIAM J. LEWANDER, MD ■ ALFRED ALEGUAS, JR., RPH, BSPHarm, PHARMD

At a Glance...

- Patients should be evaluated for pulmonary, gastrointestinal, and CNS toxicity.
- Management is primarily symptomatic and supportive.
- Radiographic findings do not always correlate with clinical presentation.
- All symptomatic or suicidal patients should be admitted.
- Patients who remain asymptomatic for 6 hours with normal radiographic findings may be considered for discharge.

Hydrocarbons are a group of organic compounds composed primarily of hydrogen and carbon. Common hydrocarbons are derived either directly from plants (e.g., pine oil) or from petroleum distillates. Although often mixtures, petroleum distillates are of three basic types: aliphatic, halogenated, and aromatic hydrocarbons. Aromatic and halogenated hydrocarbons are discussed in other chapters. Petroleum distillates are produced from the fractional distillation of crude petroleum and contain various amounts of aliphatic (straight chain) and aromatic (cyclic) hydrocarbons. Those classified predominantly as aliphatic hydrocarbons are discussed here. Some examples are kerosene, gasoline, mineral spirits, naphtha, mineral seal oil, diesel oil, and fuel oil (see Table 73-1). Turpentine is a hydrocarbon made from pine oil.

EPIDEMIOLOGY

Hydrocarbon exposures are frequent and account for an inordinate number of health care visits and hospital admissions. The American Association of Poison Control Centers reported 59,132 hydrocarbon exposures in 2002.¹ Twenty-two percent of exposed individuals required treatment in a health care facility, and nearly 22% of these patients were considered to have suffered exposures of moderate or major severity. Nearly half of all exposures occur in children younger than 6 years of age, and the vast majority of exposures are unintentional. Nevertheless, intentional exposures are not uncommon and frequently have greater potential for toxicity. Fifteen deaths were reported as a result of hydrocarbon exposure in 2002.¹

Petroleum distillates continue to be the most commonly reported cause of hydrocarbon poisoning, accounting for more than 39,000 exposures. Unmarked, poorly stored containers and an attractive aroma or color may account for the high percentage of exposures among young children. In adults, poisoning is most often by intentional ingestion, occupational exposure, or inadvertent aspiration when siphoning fuels. Adult

ingestions generally involve larger volumes along with a greater likelihood of co-ingested toxins. The most common route of exposure is by ingestion, but inhalation, cutaneous, and intravenous exposures have been reported. Nearly one quarter require treatment in a health care facility. The most commonly ingested products in this group in order of frequency are (1) gasoline, (2) lubricating oil, (3) mineral spirits, (4) lighter fluid or naphtha, (5) lamp oil, and (6) kerosene.¹

PATHOPHYSIOLOGY

Petroleum distillates are potent solvents, capable of destroying lipid-containing cell membranes. The toxicity of petroleum distillates is mainly a result of their potential to cause a fulminant and sometimes fatal pneumonitis when aspirated. Central nervous system (CNS), gastrointestinal (GI), hepatic, renal, cardiovascular, and hematologic toxicity may also occur. Cutaneous toxicity may occur with prolonged dermal exposure. After oral ingestion, pulmonary toxicity occurs from aspiration rather than by GI absorption. Aspiration may occur when the hydrocarbon is initially ingested or during vomiting. Although vomiting often precedes and results in aspiration, lack of vomiting does not preclude the possibility that aspiration has occurred. The potential for aspiration is determined by the physical properties of viscosity, surface tension, and volatility. The risk of aspiration involving any particular petroleum distillate increases with low viscosity, low surface tension, and high volatility.² However, the single most important property determining aspiration potential is viscosity, the tendency to resist flow. Low viscosity allows penetration further into the distal airways. Viscosity is measured in Saybolt seconds universal (SSU). Substances with an SSU value greater than 100 have a low aspiration potential (e.g., mineral and fuel oil), whereas those with an SSU value of less than 45 have a high potential for aspiration (e.g., gasoline, kerosene, mineral seal oil). Low surface tension may allow the petroleum distillate to spread from the upper GI tract to the trachea, and high volatility (i.e., tendency of a liquid to become a gas) increases the likelihood of pulmonary absorption and risk of CNS depression that can blunt the gag reflex. When aspirated, petroleum distillates dissolve surfactant, resulting in alveolar collapse, ventilation-perfusion mismatch, and subsequent hypoxemia.²⁻⁴ Bronchospasm and direct capillary damage lead to a chemical pneumonitis and hemorrhagic bronchitis and alveolitis that peak in intensity at about 3 days.⁵ A late process of alveolar proliferation and thickening may occur, peaking at about 10 days.⁵ Upper airway injury may occur and includes hyperemia, mucosal irritation, and inflammation

of the oropharynx. A case of epiglottitis has been reported after gasoline ingestion.⁶

Systemic toxicity is uncommon after ingestion or aspiration but may develop if a petroleum distillate contains toxic additives, if it is a vehicle for more toxic substances, or if a massive ingestion has occurred. The specific toxin involved determines whether cardiovascular, renal, hepatic, or hematologic toxicity ensues.⁷ Petroleum distillate inhalation abuse (e.g., gasoline sniffing) does not produce a chemical pneumonitis but instead leads to complex CNS toxicity caused by the combined effects of its many constituents (e.g., aromatic hydrocarbons, naphthenes, and tetraethyl lead).^{8,9}

Plant Hydrocarbons (Terpenes)

Terpenes are aliphatic or cyclic hydrocarbons and include turpentine, pine oil, and camphor. Pine oil, a component of many household cleaners, is a product of pine trees and is composed primarily of terpene alcohols. It is normally present in cleaners in concentrations of 20% to 35% and occasionally as high as 60% in products such as Pine Sol. Turpentine is a distillate from pine trees and is commonly used as a solvent for paints and varnishes. Camphor is discussed in Chapter 99.

Pine oil is well absorbed from the GI tract and is metabolized by the epoxide pathway and excreted in the urine.¹⁰ The volume of distribution is thought to be quite large, with the highest concentrations found in the brain, lungs, and kidneys.

Turpentine is also readily absorbed through the GI tract and lungs¹¹ and distributed throughout the body. The highest concentrations are found in the liver, spleen, kidneys, and brain.¹² The details of turpentine metabolism remain unclear. Elimination of turpentine and its metabolites is primarily by the kidneys.

Because of the terpenes' lower volatility and higher viscosity, the risk of aspiration is somewhat less than with the more volatile or less viscous hydrocarbons. In addition to the aspiration risk, pine oil and turpentine produce more CNS and GI symptoms than do the aliphatic hydrocarbons. Ingestions of turpentine exceeding 2 mL/kg are potentially toxic.¹¹ Although adults have survived pine oil ingestions of up to 500 g,¹³ the commonly cited lethal dose is 60 to 120 g. In children, the minimum lethal dose is probably 14 g.¹⁰

CLINICAL PRESENTATION

The initial signs and symptoms following petroleum distillate ingestion usually involve three main organ systems: pulmonary, GI, and CNS. The majority of children who present to health care facilities after a petroleum distillate exposure remain asymptomatic. Patients who aspirate generally demonstrate initial symptoms (e.g., coughing, gasping, and choking) within 30 minutes; these reach peak intensity between 24 and 48 hours after exposure.¹⁴ During the first 24 hours, tachypnea with grunting respirations, nasal flaring, retractions, and

cyanosis may develop or may be delayed as long as 2 days.⁴ The characteristic odor of the petroleum distillate may be apparent on the breath. Although auscultation may reveal rales, rhonchi, and wheezing, lower airway involvement cannot be predicted by initially normal findings on examination. Hemoptysis and pulmonary edema may be observed in severe cases. Laboratory evaluation (e.g., arterial blood gases, pulse oximetry) may reveal hypoxemia (from ventilation-perfusion mismatching) and early hypocarbia. This may progress to hypercarbia and acidosis. As many as 75% of hospitalized patients demonstrate chest film abnormalities. These abnormalities occur within 2 hours in up to 88% of patients and in 98% by 12 hours.^{7,15,16} Common early changes include unilateral and bilateral basilar infiltrates, punctate perihilar densities, and localized areas of atelectasis.¹⁵⁻¹⁸ Pneumatocoles are infrequent but when they occur are delayed in onset (e.g., 3 to 15 days) and resolution (e.g., 15 days to 21 months).¹⁹ Pleural effusion, pneumothorax, pneumomediastinum, pneumopericardium, and subcutaneous emphysema may develop.^{15,17,20,21} Symptoms correlate poorly with radiographic findings, and both may be delayed in onset.^{7,22} It is best to treat patients rather than rely on the absence of or delayed resolution of radiographic findings. Although fever and leukocytosis may be noted in as many as 15% to 20% of victims during the first 48 hours, their persistence suggests bacterial superinfection.¹⁴

GI symptoms are common and include local irritation of the oropharynx, nausea, vomiting, and abdominal pain. Vomiting appears to increase the likelihood of aspiration.^{17,23} CNS toxicity may occur in the presence of aspiration-induced hypoxemia, large ingestions, or toxic additives (e.g., aromatic hydrocarbons). Symptoms range from lethargy (91%) or somnolence (5%) to coma (3%) and seizures (1%).^{7,24}

Cardiovascular toxicity is uncommon, but both fatal dysrhythmias and myocardial dysfunction have been reported.²⁵ Dysrhythmias and sudden death after siphoning gasoline may be attributed to hypoxia or absorption after aspiration resulting in myocardial sensitization to endogenous catecholamines.^{7,22} A 19-month-old girl developed severe, reversible myocardial dysfunction after ingesting paint thinner.²⁴ Isolated case reports of acute renal tubular necrosis,^{26,27} supraglottitis,²⁸ severe burns after prolonged immersion in gasoline,²⁹ and hemoglobinuria secondary to intravascular hemolysis have been reported.^{28,30} One case report associated turpentine ingestion with hemorrhagic cystitis.³¹ Both inhalation abuse and parenteral administration of petroleum distillates have been reported to cause toxicity. CNS manifestations of inhalation abuse include confusion, dizziness, agitation, incoordination, and coma.^{7,8,32,33} Inhalation of leaded gasoline has also been associated with the development of organic lead poisoning.^{8,9,32,33} Parenteral administration has resulted in thrombophlebitis, cellulitis, and necrotizing myositis with compartment syndrome. Systemic toxicity includes seizures, hemorrhagic pneumonitis, pulmonary edema, and febrile reactions.³⁴⁻³⁶

Systemic toxicity of pine oil and turpentine ingestion primarily consists of GI irritation and CNS depression. Signs and symptoms include nausea, vomiting, diarrhea, weakness, somnolence, or agitation. Severe cases may present as stupor or coma; seizures are uncommon.³⁷ When systemic toxicity occurs, it usually develops within 2 to 3 hours of the exposure. GI and CNS symptoms generally resolve within 12 hours in moderately severe exposures. Dysuria and hematuria thought to be secondary to hemorrhagic cystitis have been reported in a turpentine ingestion 12 to 72 hours after exposure.³¹

DIAGNOSTIC EVALUATION

All symptomatic patients should receive a medical evaluation. A thorough history should include product identification, approximate amount, concentration, time of ingestion, and symptoms before presentation. The physical examination should focus on the vital signs and mental status, and the pulmonary and GI systems. If significant aspiration has occurred, respiratory symptoms should develop within 6 hours and reach peak intensity 24 to 48 hours after exposure.¹⁴ Pulse oximetry should be performed and a chest film obtained. Laboratory evaluation for symptomatic patients and for those who have ingested concomitant toxins may include arterial blood gas determination; complete blood count; determinations of electrolytes, glucose, blood urea nitrogen, and creatinine; urinalysis; and liver function tests. A directed toxic screen may help confirm the presence of toxic additives or other concomitant ingestions. Patients without symptoms for 6 hours after exposure remain asymptomatic.¹⁴

The distinctive odors of pine oil and turpentine and a thorough history and physical examination are the keys to diagnosis. The examination should focus on the pulmonary, GI, and central nervous systems. No specific laboratory tests help determine severity.¹¹ If aspiration is suspected, an arterial blood gas determination and appropriately timed chest radiograph should be obtained.

MANAGEMENT

Clinical and radiographic assessment of a patient's respiratory status determines initial management. Patients who remain asymptomatic with normal findings on chest films (obtained 4 or more hours after exposure) may be discharged after 6 hours of observation. Patients who are symptomatic, who have abnormal findings on chest films, or who have suicidal intent should be hospitalized. Gastric decontamination is not recommended for petroleum distillate ingestions because absorption and systemic toxicity are minimal, and spontaneous or induced vomiting increases the risk of aspiration and pneumonitis.³⁸⁻⁴⁰

Patients who have ingested toxic additives or other toxins with systemic toxicity should be considered for gastric decontamination. This decision is complex, often must be individualized, and should be made after con-

sultation with the regional poison center. The incidence of aspiration pneumonitis may be increased by either gastric lavage or ipecac-induced emesis. Either method is acceptable in an awake, alert patient.^{16,38} When GI decontamination is indicated in patients with altered mental status, the airway should first be protected by endotracheal intubation. Activated charcoal is indicated only if an adsorbable toxic additive or concomitant ingestion has occurred. Clothing that has been contaminated should be carefully removed, and contaminated skin washed with soap and water.⁷

Patients with respiratory symptoms should be given oxygen, placed on cardiopulmonary and pulse oximetry monitors, and have intravenous access established. An arterial blood gas determination and chest film should be obtained. Findings on chest films do not always correlate with the clinical status of the patient. The need for intubation should be based on the clinical assessment of respiratory distress. Continuous positive airway pressure may be necessary to maintain oxygenation, and bronchospasm should be treated with noncardioselective bronchodilators because of potential myocardial sensitization to catecholamines.⁴¹ Supportive care of serious petroleum distillate pneumonitis includes careful monitoring of fluid and electrolyte balance, continuous pulse oximetry, and serial chest films. Complete blood counts with differential and sputum Gram staining and cultures help identify bacterial superinfection. The regional poison center should be consulted. Fever and leukocytosis secondary to chemical pneumonitis are commonly noted during the first 24 to 48 hours, and prophylactic antibiotics should not be instituted.^{39,42,43} Treatment with antibiotics should be provided only to patients with documented bacterial pneumonia (e.g., Gram staining or culture of sputum or tracheal aspirate) or worsening of chest film findings, chest pain, leukocytosis, and fever after the first 40 hours.^{7,22} Several animal and clinical investigations have failed to demonstrate any benefit from corticosteroid treatment. Two animal studies indicate they may be harmful⁴²⁻⁴⁵; therefore, corticosteroids should not be administered.

Several reports document the efficacy of both extracorporeal membrane oxygenation and high-frequency jet ventilation as alternative therapies when conventional treatment for respiratory failure is unsuccessful.⁴⁶⁻⁴⁹

Most patients with petroleum distillate poisoning recover fully with supportive care. The majority have no significant sequelae despite the report of minor pulmonary function abnormalities in as many as 82% of asymptomatic survivors of aspiration pneumonitis.²⁰ Long-term follow-up with pulmonary testing should be considered. When indicated, psychiatric consultation should be obtained and poison prevention education given before discharge.

With plant hydrocarbons, the time and amount of ingestion, evidence of aspiration, and patient's level of consciousness largely determine treatment. A fully alert patient who is seen within 2 hours of ingesting greater than 2 mL/kg of turpentine should be considered for GI decontamination. Although not clearly defined

for pine oil, lavage is generally recommended for ingestions of greater than 5 mL in adults.⁵⁰ Airway protection is recommended for all but the alert patients because of the risk of aspiration. Activated charcoal is not useful, and the apparent large volume of distribution of terpenes precludes the use of hemodialysis or hemoperfusion.

Disposition

Medical disposition is based on clinical toxicity and time since ingestion. Patients who are either asymptomatic or who have only mild GI or CNS symptoms after 6 hours are unlikely to develop serious complications. All patients with evidence of significant toxicity (i.e., pulmonary or CNS) should be admitted for symptomatic and supportive care.

ROBERT B. PALMER, PHD ■ SCOTT D. PHILLIPS, MD

At a Glance...

- Chlorinated hydrocarbons generally share three acute health effects: dermatitis, narcosis, and the ability to induce cardiac arrhythmias.
- One of these compounds, carbon tetrachloride, was banned in the United States because of its propensity for hepatotoxicity and carcinogenesis.
- Trichloroethylene and tetrachloroethylene (perchloroethylene) continue to be employed as industrial solvents and the latter as a dry cleaning agent.
- Most of these compounds are highly volatile but generally not flammable—some have been used for fire extinguishing.
- CNS toxicity is prominent and may result from accidental exposure or intentional abuse. Seizures and coma are possible.
- Cardiac toxicity has been attributed to membrane stabilization and “sensitization” to catecholamines, although other mechanisms may play a role. Sudden sniffing deaths may occur.
- Carbon tetrachloride may cause hepatic necrosis. Other chlorinated hydrocarbons may cause fatty liver.
- Defatting of the skin may lead to chronic irritant dermatitis.
- Removal from exposure and supportive care is indicated in the treatment of disease caused by chlorinated hydrocarbons.

Compounds of only carbon, hydrogen, and chlorine are collectively known as *chlorinated hydrocarbons*. These compounds are used for a variety of industrial and medical purposes, including degreasing solvents in manufacture and topical anesthetics. Chlorinated hydrocarbons are not naturally occurring. Human exposures to these compounds are typically either the result of solvent abuse or occupational or environmental in nature. Although the specific toxicity profiles for the individual chlorinated hydrocarbons vary, essentially all these compounds share three fundamental acute effects: dermatitis, narcosis, and the potential to induce cardiac dysrhythmias. Literally hundreds of compounds are classifiable as chlorinated hydrocarbons, but the most commonly encountered are chlorinated derivatives of methane, ethane, and ethylene (Table 93-1). These compounds are the focus of this chapter.

Trichloromethane (chloroform) was first used as a veterinary anesthetic in 1847; its first reported use in human surgery came later that same year.^{1,2} Chloroform was the anesthetic agent of choice for nearly a century until the post–World War II era when compounds less toxic to the heart and liver were developed. Chloroform has also gained notoriety as an anesthetic agent used for murder or to incapacitate people for nefarious purposes.³ More recent medical applications of chloroform include topical use in herpes labialis, where it was shown to decrease time to scab formation when

compared with control.⁴ Warmed (40° C) chloroform has also been used to liquefy cholesterol gallstones.⁴

Other medical applications for chlorinated hydrocarbons include the use of small oral doses of carbon tetrachloride as an antihelminthic agent to treat hookworm infection in the 1920s. Despite its efficacy, use of carbon tetrachloride for this purpose was associated with hepatic necrosis, renal injury, and gastrointestinal hemorrhage, especially in alcoholics and malnourished children. Because of this, carbon tetrachloride was replaced with tetrachloroethylene for the management of both hookworm and pinworm. Tens of thousands of cases were treated with tetrachloroethylene, and only mild adverse effects, such as giddiness and lightheadedness, were reported. Chloroform, as part of “Hermann’s mixture” (chloroform, eucalyptus oil, and castor oil), was also employed in the management of hookworm infestation.⁵

In addition to its former use as an antihelminthic agent, carbon tetrachloride saw widespread industrial use as a degreasing solvent, dry cleaning agent, grain fumigant, and as fire extinguisher component.⁶ However, as a result of its potential toxicity, household use of carbon tetrachloride was banned in 1970, and its use as a grain fumigant was discontinued in the United States in 1985.⁶ The principal contemporary use of carbon tetrachloride is as an intermediate in the synthesis of chlorofluorocarbon refrigerants.⁷

The two-carbon (ethane and ethene) chlorinated derivatives have been used extensively as degreasing solvents, in the preparation of many insecticidal fumigants, and in dry cleaning. Trichloroethylene is also used in the textile industry for removing basting threads and as a swelling agent for dyeing polyester as well as a diluent for paints and varnishes. Trichloroethylene has also seen use as an inhaled anesthetic and is known to have poor muscle relaxant but excellent analgesic properties.^{4,6} In the past, trichloroethylene was used in the extraction of olive oil; however, the use of this solvent in the food industry was eliminated in 1975.⁸ Tetrachloroethylene is still used in American veterinary medicine as an antihelminthic and is available in capsules ranging from 0.2 to 5.0 mL and marketed by Parke Davis as NemaWorm. The antihelminthic activity of tetrachloroethylene is reportedly due to the ability of the compound to interfere with the release of lysosomal enzymes in the gut of nematodes. This results in paralysis of the parasitic worms, breaking their adhesion to the intestinal wall.⁹

PHYSICOCHEMICAL PROPERTIES

The chlorinated hydrocarbons discussed in this chapter are small aliphatic (acyclic open chain) organic com-

pounds. They are typically clear colorless liquids, although trichloroethylene may be dyed blue. As is typical of halogenated organic solvents, the chlorinated hydrocarbons are poorly miscible in water but highly miscible with other less polar organics such as diethyl ether. They are most often quite volatile, a property that led to their use as inhaled anesthetic agents, and have a characteristic sweet chloroform-like odor, which most patients did not find objectionable. Inhalation of high concentrations of chlorinated hydrocarbons is irritating to the mucosa. Although workers generally cannot detect concentrations of chlorinated hydrocarbons at the recommended workplace standard levels, they are typically able to smell these compounds at airborne concentrations at the immediate danger to life and health (IDLH) level.

In general, vapor pressure decreases and boiling point increases with increasing molecular weight. Therefore, in progressing from chloromethane (a gas), to dichloromethane, to chloroform, and ultimately to carbon tetrachloride, volatility steadily decreases. Despite their volatility (i.e., ease of going from liquid to vapor), the chlorinated hydrocarbons are generally not flammable. The exceptions to this rule are 1,2-dichloroethane and 1,2-dichloroethylene, which are flammable. Interestingly, although trichloroethane liquid is not flammable and no flashpoint has been defined using traditional methods, the vapor of this compound will burn. However, it takes an enormous amount of energy to ignite trichloroethane, and once ignited, the compound will not sustain combustion. In the presence of an open flame, chlorinated hydrocarbons such as methylene chloride decompose without burning and can be converted to phosgene and hydrogen chloride. Many of the chlorinated hydrocarbon solvents of industrial importance are photolabile. For example, chloroform is subject to photochemical decomposition to phosgene and hydrogen chloride. Chemical stabilizers such as small amounts of ethanol, triethylamine, or epichlorohydrin are often added to prevent degradation of the solvent in the presence of light.¹⁰

The number of chlorine atoms that can be added to a chlorinated hydrocarbon is determined by the number of hydrogen atoms on the unsubstituted hydrocarbon (i.e., the chlorine atoms replace only the hydrogen atoms of the hydrocarbon). The simplest chlorinated hydrocarbons are the chloromethanes. This series of compounds is created by progressively adding one to four chlorine atoms to methane (CH₄). The chloromethane series includes, in order of fewest to greatest number of chlorines, chloromethane, dichloromethane (methylene chloride), trichloromethane (chloroform), and tetrachloromethane (carbon tetrachloride) (see Table 93-1). The chloroethane series is based on substitution of ethane (CH₃CH₃) with chlorine. These compounds contain two carbon atoms connected by a single bond. The carbon skeleton of the chloroethylenes, although also composed of two carbons, is based on ethylene (ethene; CH₂CH₂), in which the two carbon atoms are joined with a double bond. Therefore, the chloroethane derivatives contain one to six chlorine atoms, whereas

FIGURE 93-1 Chemical structures of *cis*- and *trans*- isomers of 1,2-dichloroethylene.

the chloroethylenes bear a maximum of four chlorine atoms. Chlorinated derivatives of three (propane), four (butane), and five (pentane) carbon chains also exist but are less commonly encountered and will therefore not be discussed further.

Various isomers (compounds with the same molecular formula but different arrangements of atoms) can be formed from the chloroethanes and chloroethylenes when two or more chlorine atoms are present on the molecule. Isomerism is not possible in the chloromethane series because there is only a single carbon atom. The chloroethane isomers may have the chlorine atoms distributed on one or both carbon atoms in any combination. This is also true in the chloroethylene series, in which up to four chlorine atoms may be added. Notably, within the chloroethylenes, an additional form of isomerism, “geometric” or “*cis*-/*trans*” isomerism, is also possible because of the double bond prohibiting rotation about the carbon–carbon bond. This lack of available rotation results in the molecule having defined, noninterchangeable sides. In the 1,2-dichloroethylenes, both chlorines may be on the same side of the double bond (*cis*-) or on opposite sides of the double bond (*trans*-) (Fig. 93-1). Isomerism can result in differences in biologic activity. When examined in inhalation studies in rats, the *trans*-1,2-dichloroethylene isomer is twice as potent as an anesthetic than the *cis*-1,2-dichloroethylene isomer.¹¹ These two isomers cannot interconvert without breaking the carbon–carbon double bond. Further, subchronic dosing studies in animals indicate that 1,1-dichloroethane is about five times less injurious than 1,2-dichloroethane.¹² Geometric isomerism is not possible in the chloroethanes because there is free rotation around the carbon–carbon single bond.

EXPOSURE

Historically, significant exposures to chlorinated hydrocarbons occurred as a result of medicinal applications (e.g., as inhaled anesthetics and antihelminthic agents). However, this route of exposure has been largely mitigated by bans on the use of these agents as anesthetics, surgical disinfectants, and food extraction solvents. Currently, most exposures are the result of industrial contact from activities requiring large volumes of degreasing solvents (e.g., aircraft manufacture), in the manufacture and use of large volumes of paints and varnishes, or from work in the dry cleaning industry. Extensive industrial use of the chlorinated hydrocarbons has resulted in the release of these compounds into the environment where they may leach into ground water.

Most chlorinated hydrocarbon exposures generally fall into one of three broad categories: (1) very large acute exposure as a result of solvent abuse, (2) chronic higher concentration occupational exposure, and (3) chronic low-level exposure as a result of contamination of ground water supplies or other environmental sources.

TOXICOKINETICS

Absorption

Absorption of chlorinated hydrocarbons after ingestion is variable but can be significant. The one-carbon chloromethane compounds tend to be well-absorbed after ingestion. Absorption is increased further with physical exertion in the case of methylene chloride and with alcohol consumption after both inhalation and ingestion of carbon tetrachloride.^{13,14} Serious toxicity from chlorinated hydrocarbon ingestion is typically the result of large volume deliberate (i.e., suicidal) ingestions. Ingestion of these compounds as a result of low-level drinking water contamination does not cause acute toxic effects.

Inhalation is the primary route of exposure to the chlorinated hydrocarbons both occupationally and as a result of abuse. Because of their volatility, the chlorinated hydrocarbons are easily inhaled, and because of their lipophilicity, they are typically well absorbed. In fact, about 70% of an inhaled dose of methylene chloride is absorbed.¹⁵

As a general rule, absorption through intact skin is inefficient, although transdermal penetration through damaged skin may be more efficient. Most chlorinated hydrocarbons are not transdermally absorbed to levels of clinical significance unless contact is prolonged and an impermeable barrier prevents evaporation. The most significant exception to this rule is carbon tetrachloride, for which amounts capable of causing adverse health effects may be absorbed through the skin.¹⁶ Gastrointestinal effects, as well as liver damage and kidney failure, have been reported in individuals using a topically applied lotion containing carbon tetrachloride.¹⁶ Chloroform and methylene chloride are also percutaneously absorbed to a somewhat greater extent than other chlorinated hydrocarbons, but to a lesser degree than is seen with carbon tetrachloride. Percutaneous absorption can also be increased by trapping the liquid against the skin with clothing or gloves. Tetrachloroethylene is absorbed through the skin only to a very limited degree.

Although a single dermal exposure to a chlorinated hydrocarbon may not represent a toxicologic hazard, repeated dermal exposures to certain substances may become significant.¹⁷ This is illustrated by the observation that application of dichloroethane to the skin of guinea pigs causes blood levels of trichloroethylene to increase.¹⁸

Distribution

After absorption, chlorinated hydrocarbons are rapidly distributed to body tissues. As a result of their lipophilic

character, large concentrations tend to be deposited in the fat, brain, and blood.¹⁷ It is also notable that the lipophilic character of chlorinated hydrocarbon compounds such as chloroform and trichloroethylene allows some crossing of the placenta and potential exposure of the fetus.¹⁷ Placental crossing is also known to occur with chloroform and dichloroethane exposure.^{4,17} As expected from the partitioning of the chlorinated hydrocarbons into lipophilic tissues, their volumes of distribution are relatively large, ranging from about 2.6 L/kg for chloroform to about 10 L/kg for trichloroethylene.^{19,20}

Metabolism and Elimination

The chlorinated hydrocarbons are eliminated from the body through two fundamental routes: exhaled air and hepatic metabolism. That portion eliminated from the lungs is largely as unchanged parent compound, although some is first metabolically converted to carbon dioxide. The extent of biotransformation is variable by compound and exposure dose. Species dependence also exists in the clearance of chlorinated hydrocarbons because some animals have more active metabolic pathways than others, which makes interspecies comparisons problematic.²¹ For example, scaling of metabolic parameters for tetrachloroethylene determined in mice overestimates human metabolism.²²

The main metabolic routes are oxidative transformation through the cytochrome P-450 systems and subsequent conjugation (Fig. 93-2). The P-450 enzymes involved exist primarily in the liver and kidneys, although they are also present to a lesser extent in the lungs and gastrointestinal tract. The initial oxidative transformation creates a reactive intermediate that is then conjugated with a polar moiety such as glutathione or glucuronic acid in order to create a more water-soluble compound that can be eliminated from the body. The kinetics of these enzymatic transformations is not always linear in humans.²²

Other enzyme systems may also be involved with the biotransformation of chlorinated hydrocarbons. For example, ethanol changes the metabolism of trichloroethylene, suggesting that alcohol dehydrogenase may also be involved in its elimination.²⁰ The influences of aliphatic alcohols on the effects of chlorinated hydrocarbons containing a carbon-carbon double bond have been studied. It appears that the alcohols may influence the hepatotoxicity of some chlorinated hydrocarbons.²³ A secondary metabolic pathway also exists for methylene chloride and involves a glutathione transferase-dependent pathway, which produces carbon dioxide, formaldehyde, and formic acid.^{24,25}

The initial metabolic activation is the proposed source of toxicity for many of the chlorinated hydrocarbons (see Fig. 93-2). Hepatic P-450 enzymes oxidatively convert the chlorinated hydrocarbon to free radicals. These reactive radicals may then combine with molecular oxygen to form peroxy radicals, or they may react with endogenous lipids to form lipid radicals. By their very nature, free radicals are highly unstable and react essentially as soon as they are created. Therefore, the toxic effects of these

FIGURE 93-2 An abbreviated metabolic scheme for trichloroethylene.

reactive metabolites typically occur at or near their site of production. Additional significant clinical effects may result from the individual toxicities of the metabolites. For example, about 25% to 34% of an absorbed dose of methylene chloride is metabolically converted to carbon monoxide.¹⁵ This biotransformation takes place primarily in the liver but also occurs to a lesser extent in the kidneys and lungs and is mediated by the 2E1 isozyme of the cytochrome P-450 system.^{26,27} This pathway is also saturable in the presence of high substrate (methylene chloride) concentrations.²⁵ Carbon monoxide and carboxyhemoglobin may be formed for several hours after cessation of exposure.^{25,28} The two-carbon compounds, 1,1,1-trichloroethane, trichloroethylene, and tetrachloroethylene, undergo biotransformation to form trichloroacetic acid and trichloroethanol, which are excreted in the urine in both free and conjugated forms.²⁹⁻³¹ In addition,

both trichloroacetic acid and dichloroacetic acid, which may be hepatotoxic, are produced.³²

As a general rule, there is relatively little bioaccumulation of the chlorinated hydrocarbons in adipose tissues unless chronic high-concentration exposure has been maintained. Trichloroethylene's elimination follows a two-compartment model, with the first elimination half-life being about 0.5 to 3 hours and the second about 22 to 30 hours.^{33,34} However, it is known that adipose tissues can act as a reservoir for trichloroethylene deposition.³⁵ The extent of significant adipose deposition seems to correlate well with long-term high-concentration occupational exposure; however, ongoing exposure could not be excluded. One report describes an individual with exhaled trichloroethylene breath concentrations of 135 ng/L (1.8 mg/day) 4 years after the last exposure to the compound following a 20-year

occupational exposure.³⁶ The elimination half-life of the chlorinated hydrocarbons may also vary by route of administration. A half-life of 72 hours is observed after inhalation of tetrachloroethylene, whereas the half-life is about doubled (144 hours) when the compound is ingested.^{19,30}

The extended elimination profile seen with tetrachloroethylene actually affects the minority of the inhaled dose. With acute exposure to most chlorinated hydrocarbons, a large portion of the dose is excreted as unchanged parent compound in the air expired from the lungs.^{37,38} In the case of methylene chloride, the saturability of the enzymatic conversion to carbon monoxide has a dramatic effect on the elimination of the compound. A dose-dependent elimination of methylene chloride is observed, with low-dose exposures being principally eliminated through the lungs as carbon monoxide while a greater proportion of unchanged parent methylene chloride is exhaled in the setting of larger exposures.³⁹

EFFECTS ON BODY SYSTEMS

Central Nervous

Chlorinated hydrocarbons exert dose-dependent effects on the central nervous system (CNS), where the dose is a function of both the duration of exposure and the concentration of the substance. The effects of these compounds are not mediated by interaction with any specific CNS receptor. Rather, the mechanism of toxicity appears to be alteration of neurotransmission as a result of direct effect to nerve cell membranes by the chlorinated hydrocarbons,^{40,41} which may be temporary or permanent.⁴² In animal models, low-dose exposures to chlorinated hydrocarbons produce minimal histologic evidence of damage to nerve cells.⁴³ In high-dose exposure, the histologic results are equivocal.⁴³ No specific pathologic changes in the CNS are seen as a result of death from chlorinated hydrocarbon exposure. Rather, alterations in the CNS observed at autopsy are typically the result of underlying disease.⁴⁴

Acute high-level exposures can be encountered in cases of solvent abusers or with large accidental releases of chlorinated hydrocarbon solvents in a workplace. Chronic high-level exposure is really only germane in the circumstance of long-term solvent inhalation abuse. Chronic low-level exposure is typically the result of routine occupational encounters with solvents in the course of normal work procedures. Chronic very-low-concentration exposures, as would be seen from drinking ground water contaminated with small amounts of chlorinated hydrocarbon solvents, are not expected to have any effects on the CNS.

Acute high-level exposure typically causes CNS depression, dizziness, narcosis, nausea, vomiting, seizures, coma, and possibly death from respiratory failure. Because there is no discrete receptor and no requirement for metabolic activation of the chlorinated hydrocarbon to exert effects on the CNS, onset of effects is rapid.

Likewise, because effects are not the result of a covalent drug-receptor interaction, recovery from intoxication is typically rapid and, except when very high doses are abused chronically or significant hypoxic insult is incurred, recovery is usually fairly prompt and complete. Most deaths associated with acute high doses are caused by either narcosis and apnea or cardiac arrest, which is discussed in greater detail under Cardiovascular.

Chronic high-dose exposure to chlorinated hydrocarbons, most frequently as a result of long-term solvent abuse, may have substantial effects on the CNS. The primary pathologic change to the CNS from solvent abuse is degeneration of the white matter (leukoencephalopathy).⁴⁵ Other CNS changes observed at autopsy in the brains of toluene abusers include substantial atrophy and mottling of the white matter, as well as myelin and oligodendrocyte loss with relative axonal preservation.⁴⁵ These conditions are characterized for toluene, not chlorinated hydrocarbon, abuse, and it is known from animal studies that some differences in specific neurologic effects may exist between the individual solvents.⁴⁶ However, a pathologic picture similar to that seen with toluene abuse may occur in cases of chronic chlorinated hydrocarbon abuse. Metabolites may also contribute to CNS effects, especially in the case of metabolically produced carbon monoxide from significant methylene chloride exposure.⁴⁷

Chronic exposure to chlorinated hydrocarbons at lower levels is most frequently associated with occupational settings. The CNS depression and narcosis seen with acute high-dose exposure is generally not seen with chronic low-dose exposures. The occurrence of solvent-induced encephalopathy from low-dose exposure is a matter of some debate. Several epidemiologic studies have looked for cognitive dysfunction in workers exposed to individual and mixtures of solvents with batteries of psychometric tests.⁴⁸⁻⁵⁰ However, these studies are often difficult to interpret because of confounders such as simultaneous exposure to multiple chemicals, including alcohol use, and have not consistently and definitively shown any predictable CNS dysfunction with this exposure paradigm.

Cardiovascular

The effects of chlorinated hydrocarbons on the cardiovascular system are visible on heart rate, contractility, and conduction. In general, the effects on all three of these parameters are dose-dependent depressive clinical effects. These depressant effects are likely at least twofold in etiology. First, the chlorinated hydrocarbons exert solvent-like effects that alter the fluidity of myocardial cell membranes, causing direct myocardial depression of contractility.^{51,52} Second, because of their lipophilic character, the chlorinated hydrocarbons readily cross the blood-brain barrier and disrupt the neuronal control of both heart rate and contractility. In fact, trichloroethylene (TCE) was once used as an inhaled agent for human anesthesia but was abandoned because of its cardiac depressant effects, which caused excessive bradycardia and hypotension.⁵²

The effects of chlorinated hydrocarbons on cardiac conduction are slightly more complex but can be considered to fall into two basic categories: depression and sensitization. The depressant effects are the result of the solvents acting to stabilize the myocardial cell membranes to depolarization.⁵³ This increased membrane stability blocks conduction impulse transmission resulting in an increased risk for dysrhythmias. In vitro evidence also suggests that some depressant activity appears to be the result of the ability of the chlorinated hydrocarbons to attenuate calcium dynamics in cardiac myocytes during excitation-contraction coupling.⁵⁴ The potency of the tested compounds to inhibit calcium dynamics in the cardiac myocytes expressed as IC_{50} correlated strongly ($r = 0.9829$) with compound lipophilicity expressed as octanol:water partition coefficient.⁵⁴

Sudden death in humans following large exposure to chlorinated hydrocarbons has been reported numerous times and is often referred to as "sensitization." Often, those afflicted by sudden death are solvent abusers, although death following occupational exposures to some solvents has occurred.^{55,56} The strong link between solvent abuse and sudden death was the genesis of the descriptive term *sudden sniffing death*, which is sometimes used to refer to this condition. Postmortem examination of people who died under such circumstances is often without adequate anatomic abnormality to alternatively explain death. The demise is sudden and often without apparent neurologic involvement such as seizures, so it seems likely that the cause of death is a dysrhythmia-associated sudden cardiac arrest. As such, the concept of "myocardial sensitization" has been offered as an explanation. The actual pathophysiology of myocardial sensitization is poorly understood. The general theory is that the myocardium becomes more responsive to the effects of systemic catecholamines, including endogenously released epinephrine, and that any excess catecholamine exposure causes irritability of the myocardium, resulting in dysrhythmias. Hypoxia may be an alternative explanation.

Perhaps the most widely cited study of myocardial sensitization from halogenated hydrocarbon inhalation was reported in 1971 by Reinhardt and colleagues.⁵⁷ Due to the frequency with which it is cited in other works, this study deserves a brief discussion. In this investigation, the potential of 13 compounds to produce dysrhythmias in a dog model was examined. Nine of the test compounds were fluorocarbon derivatives (Freon), seven of which were also chlorinated; two compounds (isobutane and propane) were simple hydrocarbons; one was an aliphatic ether (dimethyl ether); and the last was vinyl chloride. Two exposure circumstances were used and designated "standard exposure" (test compound inhaled over 10 minutes) and "short-term exposure" (high concentration of test compound inhaled for 30 seconds accompanied by a stimulus to frighten the animal in order to stimulate endogenous epinephrine release).

In the standard exposure experiment, the animals were equipped with continuous electrocardiographic monitors and received an intravenous injection of epinephrine (0.008 mg/kg over 9 seconds) followed by

the desired dose of test compound through mask inhalation. Midway through a 10-minute inhalation of test compound, a "challenge injection" of epinephrine was given, and the electrocardiogram was observed for the development of alterations in cardiac rhythm. The short-term exposure experiments were conducted in a similar fashion, except a high concentration of test compound was inhaled by the animal for only 30 seconds, and an external stimulus was applied to frighten the animal. The external stimulus used was a loud recording of noises such as sirens, gongs, and jet takeoffs. The authors examined the electrocardiographic data for the presence of marked responses, which they defined as development of a dysrhythmia considered to pose a serious threat or ending in cardiac arrest. In the standard exposure group, marked responses were seen only with higher concentrations of test compound, although not every animal who received the higher-dose test compound developed a marked response. The total number of dogs used in each phase of the experiment ranged from 6 to 13. Of the 367 dog exposures studied in the standard exposure experiments, 111 cases of marked response were reported, of which 14 were ventricular fibrillation and cardiac arrest. Alternatively stated, a cardiac arrest rate of only 3.8% was observed. In the short-term study, 66 dog exposures provided 9 marked responses, none of which were ventricular fibrillation or cardiac arrest. Notably, two animals manifested a bigeminal rhythm with areas of the electrocardiogram suggestive of multiple ventricular beats. The authors further indicated that the potential activity of a given compound depended at least partly on the specific halogen atoms present in the test compound. Those compounds that contained chlorine atoms produced the greatest degree of effect, whereas those halogenated only with fluorine were less effective. No brominated or iodinated compounds were studied. The nonhalogenated compounds produced a marked response rate similar to that seen with the halogenated compounds.

The authors suggested that smaller doses of epinephrine were required to induce life-threatening dysrhythmias or cardiac arrest following exposure to the test compounds. Other investigators have indicated that the concentrations of epinephrine required to cause cardiac dysrhythmias with exposure to inhaled chlorinated hydrocarbons are within the physiologic range.⁵⁸ However, even with the significantly higher doses of epinephrine used in Reinhardt's dog study, none of the animals in the short-term exposure group suffered cardiac arrest. The cardiotoxicity associated with inhaled chlorinated hydrocarbons appears to be exacerbated in the setting of hypoxia and hypercarbia.^{57,59} A lack of protective effect against development of cardiac dysrhythmias because of tolerance with long-term use has been suggested as support for the theory of myocardial sensitization. Although the principle of myocardial sensitization has been proposed in human cases of sudden death from solvent abuse, definitive data are lacking.

Several other factors may be either responsible or at least contributory to sudden death in chlorinated hydro-

carbon exposures. For example, chronic solvent abuse is associated with the development of cardiomyopathy, which is a known substrate for dysrhythmias. This may explain the lack of tolerance to cardiac dysrhythmias in people with a long-standing history of solvent abuse. Hypoxia and hypercarbia also put patients at greater risk for potentially lethal cardiac dysrhythmias; and hypoxia, anoxia, and suffocation all result from excessive oxygen displacement or positioning following loss of consciousness when chlorinated solvents are inhaled in large quantities. Finally, depression of sinus node impulse generation can be induced, leading to profound bradycardia with subsequent ventricular escape rhythms. In short, sudden death associated with inhalation of high concentrations of chlorinated hydrocarbon solvents, especially solvent abuse, is probably multifactorial, and myocardial sensitization to endogenous catecholamines is likely not the sole etiology.

When victims of sudden sniffing death are examined at autopsy, both gross and microscopic examinations are frequently normal. This has been demonstrated not only in animals but also in human cases.^{57,60} Two papers have also examined the postmortem tissue concentrations of trichloroethylene in cases of human death following acute occupational exposure.^{55,56} In one of the

listed cases, a brain trichloroethylene concentration of 2.5 mg/100 g was detected 33 days after death demonstrating the significant partitioning of the solvent into the CNS.⁵⁵

Liver

Chlorinated hydrocarbons, especially carbon tetrachloride and chloroform, are known to cause centrilobular hepatic necrosis and hepatomegaly.¹⁷ The destruction of liver cells, which may progress to involve the entire hepatic lobule, requires the metabolic activation of the chlorinated hydrocarbon (Fig. 93-3). The metabolically produced radicals are highly reactive, so the site of toxic effect is the liver because this is the site of radical production. The two most significant effects of free radical production are steatosis and carcinogenesis. Free radicals bind components of hepatocytes, resulting in inhibition of lipoprotein secretion.^{17,43} This causes an accumulation of fatty tissues in the liver, resulting in steatosis. When radicals react with DNA, the resulting adducts may be carcinogenic.

Although other chlorinated hydrocarbons do not cause hepatic necrosis, many induce fatty changes in the liver. Even though the fatty changes are typically

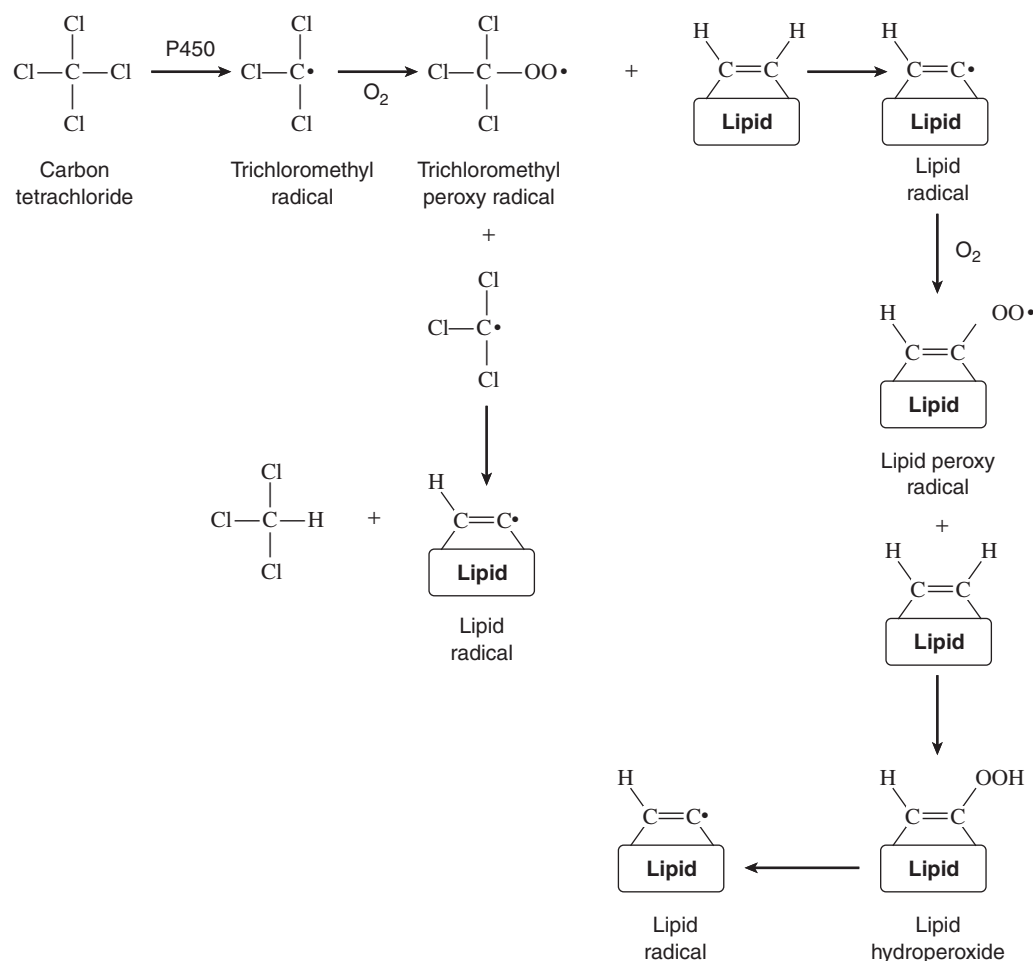

FIGURE 93-3 Metabolic activation of carbon tetrachloride to form free radical species.

reversible, it is a matter of some discussion as to whether or not the fatty changes are a prelude to hepatocyte death. The significance of the damage and ultimate prognosis for recovery are based on several factors. Among these factors are the magnitudes of exposure, underlying liver health, and presence or absence of other hepatotoxins. It is also important to realize that the extent of CNS involvement is not necessarily predictive of liver or kidney injury.

Kidney

Renal damage may also be associated with exposure to some of the chlorinated hydrocarbons. Reported toxic effects of chlorinated hydrocarbon poisoning on the kidney include azotemia, oliguria, anuria, ketonuria, acute tubular necrosis, and renal failure.^{61,62} Granular casts and red blood cells have also been seen in the urine after chloroform exposure.³⁷ Although inadequate to explain all cases of renal injury that have been reported after exposure to chlorinated hydrocarbons, at least part of the mechanism of injury in the kidney is likely the same as in the liver: production of reactive free radical and other reactive metabolites in the kidney by P-450-mediated oxidation.⁶³ It has been suggested that occupational exposure to chlorinated solvents is linked to glomerulonephritis, but this association has not been clearly defined.^{61,62} Renal failure has been reported after dermal exposure to carbon tetrachloride.¹⁶

Dermal

Because chlorinated hydrocarbon solvents are very hydrophobic, they tend to dissolve the lipids in the epidermis. This defatting of the skin surface often leads to a chronic irritant dermatitis. Most chlorinated hydrocarbon solvents are mild irritants. However, repeated or prolonged dermal contact may produce inflammation or burns. Trapping of solvents such as chloroform and methylene chloride under jewelry like rings and watches results in an almost immediate burning sensation on the contacted skin. Skin exposed to chlorinated hydrocarbon solvents may become hyperkeratotic, scaly, or thickened, and painful cracks or fissures may also be present.¹⁴ Tetrachloroethylene (perchloroethylene) is a much stronger irritant than the other chlorinated hydrocarbon solvents, and even brief contact with this compound can result in blistering and burns.¹⁴

Beyond simply the discomfort associated with solvent-caused dermatitis, the violation of the integrity of the skin as a barrier may also have significant clinical consequences. Dermal absorption of chlorinated hydrocarbon solvents alone is generally insufficient to cause systemic illness. However, when the skin is no longer intact, absorption of solvents may be greater, potentially leading to systemic effects. Dermal absorption of some important chlorinated hydrocarbon compounds may be clinically significant through the contribution of this route of exposure to the total-body burden of the compounds. In addition, although the chlorinated hydrocarbons are not themselves allergenic, it is possible that destruction of

the skin by these solvents may make the skin more permeable to sensitizing agents with which the exposed individual may be working.

Effects of chlorinated hydrocarbon exposure on the skin may also be systemic. Development of local scleroderma on the volar surfaces of the forearms and dorsal surfaces of the ankles in a 26-year-old woman with a history of working with tetrachloroethylene was reported, although this patient also worked with other solvents and this association remains elusive.⁶⁴

Exposure to trichloroethylene is associated with a unique toxicity known as “degreaser’s flush.” This condition is manifested by flushing of the face after ingestion of ethanol in people with chronic exposure to trichloroethylene vapor. The flushing is a result of vasodilation of the superficial blood vessels on the face. The exact mechanism of this effect is unclear, but it may be due to the direct effects of the trichloroethylene metabolites chloral hydrate and trichloroacetic acid on the vasculature.

The time course of degreaser’s flush is predictable. Typically, red blotches develop on the nose and malar eminences within about 30 minutes after the individual ingests alcohol. The blotches increase in size and then become confluent, resulting in a generalized flushing of the face and neck, which peaks within about an hour. The flushing then gradually diminishes to disappearance over the course of the subsequent hour. In daily drinkers of alcohol, degreaser’s flush is generally not observed until after about 3 weeks of daily exposure to trichloroethylene vapor. Notably, once established, the flushing reaction may occur with ethanol ingestion as much as 3 weeks after the last trichloroethylene vapor exposure.

Ocular

Like the skin, damage to the eye as a result of ocular chlorinated hydrocarbon exposure is largely due to delipification. Most often, the result of ocular exposure is mild chemical conjunctivitis, although direct application of high-concentration liquid chlorinated solvents may cause pain or burning with corneal dulling.¹⁴ Diplopia, visual blurring, and blindness have also been reported with contact with bulk chlorinated hydrocarbon solvents.¹⁴ Punctate staining of the epithelium may be seen with fluorescent examination. Unless serious chemical burns result, the damage is generally reversible. Both carbon tetrachloride and tetrachloroethylene have been implicated in development of optic neuritis, although this is not universally supported in the literature.⁴²

Blepharospasm has been reported after exposure to high concentrations of chloroform vapor.⁶ However, most cases of exposure to airborne chlorinated hydrocarbons do not result in persistent ocular damage even when the solvent concentrations are quite high.

Systemically absorbed chlorinated hydrocarbons do not typically cause ocular toxicity. However, development of blue-gray corneal opacities was observed in a dog model after systemic, but not intraocular, administration

of dichloroethane.¹⁷ No reports of similar systemically mediated ocular effects in humans exist.

Pulmonary

Exposure of the lungs to chlorinated hydrocarbons must be divided into two distinct situations: aspiration and inhalation. The effects on the lungs from these two different routes of exposure are quite different. With aspiration of liquid solvent, potentially severe chemical pneumonitis is the primary concern. This is largely due to the solubility of lung surfactant in the chlorinated hydrocarbon solvent leading to profound inflammation of the lung. In contrast, inhalation of solvent vapor does not typically cause this sort of injury, although massive inhalation has caused pulmonary hemorrhage.^{14,65} Even though respiratory arrest may be seen with large inhalation exposures to chlorinated hydrocarbons, the mechanism is typically CNS depression (solvent narcosis) rather than direct damage to the lung.

Because of the volatility of the chlorinated hydrocarbon solvents, the lungs represent a major exposure pathway. Although metabolism by P-450 enzymes in the Clara cells may produce some reactive metabolites, the lungs are not a principal target organ for chlorinated hydrocarbon toxicity.⁶⁶ Pulmonary irritation is possible, and is expected with high-concentration exposures. Very large pulmonary exposures to some compounds, including methylene chloride, may produce chemical pneumonitis or noncardiogenic pulmonary edema.^{14,67,68}

Teratogenicity and Carcinogenicity

The association of reproductive effects, including teratogenicity, and carcinogenicity with exposure to the chlorinated hydrocarbon compounds is a topic that is hotly debated. Vinyl chloride, which is not discussed in this chapter, is an International Association for Research on Cancer (IARC) class 1 compound, and knowledge of this association fuels concern about the cancer-causing potential of other chlorinated hydrocarbons. Conflicting data between studies, as well as significant species dependence in observed effects, make evaluation and comparison of much of the data difficult. Interpretation of the human epidemiologic data is further hindered by the presence of confounders such as simultaneous significant exposure to other potentially toxic compounds, poor quality of exposure measurements, and recall bias.

Perhaps the simplest case is that for 1,1,1-trichloroethane. Data suggest no teratogenic effects in laboratory animals or humans; further, carcinogenicity of this compound has not been demonstrated in humans. Animal data suggest that tetrachloroethylene is fetotoxic, and both tetrachloroethylene and trichloroethylene have been reported to cause developmental abnormalities in animals.^{69,70} However, these observations do not seem to translate to human epidemiologic investigations. No adverse effects on reproduction have been shown in humans after exposure to tetrachloroethylene. Although trichloroethylene exposure is a suggested culprit in human cases of birth defects and

increased rates of spontaneous abortion, inadequate data regarding the amounts of other compounds to which the mothers were exposed is missing, making establishment of a link impossible.^{69,70} Although associations between exposure to tetrachloroethylene and development of malignancy (leukemia as well as liver, esophageal, and urinary tract tumors) and also between trichloroethylene and other cancers (non-Hodgkin's lymphoma, hepatic and renal cancers) have been alleged, the epidemiologic data are not sufficient to establish a definitive connection.^{71,72} Impurities in the chlorinated hydrocarbon solvents may significantly influence evaluation of cancer-causing potential. One study reported development of pulmonary tumors in mice exposed to trichloroethylene; however, the trichloroethylene used in the experiments may have been contaminated with trace amounts of the stabilizer epichlorohydrin, a known carcinogen.⁷³ Tetrachloroethylene and trichloroethylene are both classified as IARC 2A compounds, whereas 1,1,1-trichloroethane is IARC class 3 based on animal studies. Concerns about possible adverse health effects have resulted in published efforts describing methods to limit occupational exposure to chlorinated hydrocarbon solvents and influence both technologic innovation and legislation on industrial metal degreasing.⁷⁴

The case of association is modestly stronger for adverse reproductive effects and carcinogenicity with exposure to the one-carbon chlorinated derivatives. Although methylene chloride and chloroform have not been shown to be teratogenic in some animal models, chloroform is highly embryotoxic and causes changes in sperm morphology in animals.^{14,75} Chloroform readily crosses the placenta.⁷⁶ Two cases of eclamptic toxemia were reported in pregnant women who worked in a laboratory where chloroform was used, although the association was circumstantial.⁷⁷

The situation for carbon tetrachloride is similar. This compound also crosses the placenta and has been detected in cord blood in exposed humans.^{69,76} Carbon tetrachloride has been reported to be both fetotoxic and teratogenic in rats.⁷⁸ Other investigators have not observed teratogenic effects in rats or rabbits.⁶⁹ At carbon tetrachloride doses of 0.1 and 0.01 of the LD₅₀ given to mice on days 1, 6, and 11 of gestation, no evidence of teratogenicity or fetotoxicity was observed.⁷⁹ Carcinogenicity of other compounds may be enhanced by exposure to carbon tetrachloride.⁸⁰ Methylene chloride, chloroform, and carbon tetrachloride are all classified as IARC class 2B. Except for vinyl chloride, the data in animals suggest an association with development of cancer; data in humans are inadequate to establish causality.

DIAGNOSIS

Although patients presenting with acute chlorinated hydrocarbon toxicity may be quite ill, the signs and symptoms are nonspecific. Further, specific laboratory assays for the detection of chlorinated hydrocarbons are not routinely available in most hospital laboratories but

are from certain reference laboratories. Therefore, to diagnose chlorinated hydrocarbon toxicity, it is necessary to obtain a history of exposure. In cases of acute occupational exposure, container labels or material safety data sheets may be available. Additional helpful information, such as air monitoring results, may be available from local emergency medical services personnel or fire department hazardous materials teams who responded to the incident. Cases of chronic exposure in which no immediate life threats exist may be more challenging to reconcile. Such incidents require careful physical examination along with a detailed history and differential diagnosis. Although it is most often essentially impossible to determine exact dose, especially in chronic exposure circumstances, some topics that should be addressed include the conditions of use, temperature, ventilation systems and other workplace controls in place, use of personal protective equipment, and whether the agent is aerosolized or used as bulk solvent. In the evaluation of less critical patients presenting with possible chronic toxicity, the history must include not only workplace exposure but also potential household and hobby sources such as home improvement, automotive repair, art, and cleaning activities.

In general, chlorinated hydrocarbons are CNS depressants, although this diminished level of consciousness may be preceded by an initial brief period of CNS excitation. The exact effects on the CNS and the time course of onset are largely dose dependent. Dose is determined by duration of exposure, concentration of the solvent, and minute ventilation volume. Individual susceptibility may also play a role in the development of specific signs and symptoms.

Large inhalation exposures are typically manifested by headache, fatigue, lethargy, nausea, and abdominal discomfort. Continued exposure may result in a progression to ataxia, stupor, coma, and death. Higher concentration exposures are generally associated with more rapid onset of more significant signs and symptoms. In some rare cases, coma and death may occur within minutes. Fortunately, with removal from the source of exposure, recovery is typically rapid provided the victim has not suffered serious trauma or hypoxic insult. Because of its prolonged elimination time, recovery may be somewhat slower after exposure to high concentrations of tetrachloroethylene.

Clinical presentation after ingestion of chlorinated hydrocarbon solvents is analogous to that seen with inhalation. However, the CNS depression may be delayed in onset with ingestion as a result of the time lag required for systemic absorption. In cases of large ingestions of trichloroethylene or tetrachloroethylene, onset of neurologic signs and symptoms may be delayed for several hours. As previously stated, trichloroethylene is eliminated very slowly. Therefore, prolonged coma may result after significant ingestions. Furthermore, it is possible that cardiac dysrhythmias may develop hours after ingestion of trichloroethylene when CNS depression is present or after significant methylene chloride exposure as a result of carbon monoxide production. One other special case that must be kept in mind is the potential for metabolic production of carbon monoxide

from significant exposures to dichloromethane. Although recovery may be slightly slower than with inhalation, recovery from chlorinated hydrocarbon poisoning as a result of ingestion is typically complete within about 24 hours in the absence of secondary effects such as aspiration, hypoxia, or carbon monoxide production.

MANAGEMENT

The initial approach to the medical management of acute chlorinated hydrocarbon toxicity is appropriate supportive care. As toxic exposure to this class of compounds is associated with substantial CNS and respiratory depression, as well as the possibility of oropharyngeal edema due to chemical burns, early and aggressive airway management is paramount. In these situations, as well as in cases of large ingestions, protection of the airway with endotracheal intubation is appropriate. Pulse oximetry and cardiac monitoring should be initiated and intravenous access obtained with crystalloid fluids. Baseline laboratory evaluation of acid–base status, electrolytes, and renal and hepatic function is appropriate. Chest radiography to assess endotracheal tube placement or the possibility of aspiration is indicated if clinically appropriate. Interestingly, some chlorinated hydrocarbons are radiopaque, which may assist in locating significant depots. In cases of significant methylene chloride exposure, absorption may be prolonged; therefore, serial carboxyhemoglobin determinations are appropriate until a definitive downward trend is demonstrated. Chlorinated hydrocarbon toxicity frequently causes profound diarrhea, which may exacerbate electrolyte imbalances. As such, fluid intake and output should be monitored closely as significant volumes of fluid and associated electrolytes may need to be replaced.

There is no specific antidotal therapy for chlorinated hydrocarbon intoxication. As such, treatment is symptomatic and supportive using standard basic and advanced life support interventions. Dysrhythmias resulting from chlorinated hydrocarbon toxicity should be managed according to standard advanced cardiac life support protocols. Many sources recommend that clinicians avoid the use of catecholamines such as epinephrine during the course of resuscitation of chlorinated hydrocarbon–induced cardiac arrest because of the possibility of myocardial sensitization to endogenous catecholamines. However, because myocardial sensitization has not been definitively shown to be the principal mechanism for sudden death associated with chlorinated hydrocarbon exposure and because administration of catecholamines such as epinephrine and dopamine is a standard resuscitative measure, complete avoidance of these therapies may be unwise.

Decontamination and Prevention of Absorption

External decontamination after exposure to chlorinated hydrocarbons is necessary to limit continued absorption by the victim as well as to protect the rescuers. Largely as

a result of the volatility of these compounds, simple decontamination techniques are quite effective. Removal of clothing followed by washing with copious amounts of water is the management of choice. Addition of soap to the decontamination rinse may assist in increasing the solubility of the chlorinated hydrocarbon compounds in the decontamination water. As with most liquid chemicals, the possibility of enhancement of absorption through vasodilation as a result of using scrubbing brushes or hot decontamination water exists with chlorinated hydrocarbon solvents. However, these compounds are sufficiently volatile and their percutaneous absorption generally low enough that this concern is largely theoretical. Special attention should be given to the decontamination of open wounds and mucous membranes.

Gastric decontamination after ingestion of chlorinated hydrocarbons should be undertaken on a carefully considered case-by-case basis. Induction of emesis is contraindicated because these compounds are commonly associated with CNS depression. Gastric aspiration may be considered in cases of large carbon tetrachloride or chloroform ingestion presenting shortly after ingestion in an attempt to limit the risk for hepatic damage. Administration of a single dose of activated charcoal may be considered, especially in cases of polysubstance ingestion. However, the clinician should remain mindful that the efficacy of activated charcoal has not been proved in cases of chlorinated hydrocarbon ingestion and that the potential for CNS depression, emesis, and aspiration exists.

There are no specific antidotes for toxic exposure to chlorinated hydrocarbons. *N*-acetylcysteine (NAC) is beneficial in preventing damage due to acetaminophen intoxication as well as in cases of fulminant hepatic failure.^{81,82} There are several proposed mechanisms of action for the hepatoprotective effects of NAC, including acting as both a glutathione precursor and a glutathione surrogate. Based on this theory, case reports have suggested using NAC to assist in minimizing hepatic damage as a result of acute carbon tetrachloride exposure.⁸³ Additional case reports suggest benefit from hyperbaric oxygen therapy in cases of methylene chloride or carbon tetrachloride poisoning.^{28,38}

Enhancement of elimination from the gastrointestinal tract using methods such as whole-bowel irrigation is not appropriate for toxic ingestions of chlorinated hydrocarbons. Because chlorinated hydrocarbons are eliminated largely through the lungs, hyperventilation may be beneficial. A case report of tetrachloroethylene poisoning suggested some benefit in accelerated clearance with hyperventilation.³⁰ Because of the large volumes of distribution, clearance of the chlorinated hydrocarbons using hemodialysis is generally ineffective. However, in cases of chlorinated hydrocarbon-induced renal failure, hemodialysis may be necessary and should be continued until renal function normalizes.

Disposition

In cases of toxicity after inhalation of chlorinated hydrocarbons, cessation of symptoms and complete

recovery are expected shortly after termination of the exposure. Typically, if the patient is asymptomatic, discharge is appropriate as soon as any alterations in mental status clear. The oral pathway may require a longer observation period. Depending on the circumstances of the exposure, discussion of safety practices at the worksite or referral for psychiatric evaluation may be warranted.

Patients with persistent CNS depression, cardiac dysrhythmias, or pulmonary involvement should be admitted until the clinical picture resolves. Further, in the event of a significant exposure, admission, with serial clinical and laboratory evaluations, is recommended. Renal and hepatic injury typically resolves with generalized supportive care and returns to baseline within days to weeks.

DANA B. MIRKIN, MD

At a Glance...

- Being highly lipophilic, all can produce narcosis if inhaled in high concentration, with CNS depressant effects that compare with those of general anesthetics
- The major aromatic compounds of toxicologic importance are toluene, benzene, styrene, ethylbenzene, trimethylbenzene, and xylene.
- The toxicity of the aromatic hydrocarbons is variable. Some, such as benzene, are highly toxic, affecting the CNS, bone marrow, and other vital organs.
- Many of the aromatic compounds are metabolized by cytochrome P450 isozymes.
- Metabolites of aromatic compounds are excreted in urine, making biological monitoring for occupational exposures relatively simple. In contrast, analysis of aromatics and their metabolites in blood is difficult.
- Treatment of severe exposure is supportive and includes the provision of fresh air or oxygen. There is probably little role for gastrointestinal decontamination since aromatics are not well adsorbed by activated charcoal.

Aromatic hydrocarbons are benzene derivatives; they constitute more than 50% of the different chemicals in common use.^{1,2} Aromatic solvents are found widely in many diverse occupations and products, in degreasing operations, lacquers manufacturing, printing, electronics and rubber (especially tire) manufacturing, paints, resins, pharmaceuticals, and glues and adhesives. They are liquids that typically exhibit high vapor pressures and low boiling points that rise with increasing molecular weight. This group of compounds has chemical structures of unsaturated cyclic compounds with the benzene ring as its basis. Benzene is the simplest homolog within the group.

Aromatic hydrocarbons are divided into the *benzene* group (one ring), the *naphthalene* group (two rings), and the *anthracene* group (three rings). *Polycyclic aromatic hydrocarbons* (polynuclear aromatic hydrocarbons) have multifused benzene rings.³ This chapter reviews only the aromatic hydrocarbons in the benzene (single-ring) group, specifically benzene and its common derivatives, styrene, toluene, and xylene. These four compounds have historically been used as solvents, antiknock agents in motor fuel, and process intermediates and feedstock for chemical synthesis.

Although originally derived from coal tar, the main source of aromatic organic compounds today is petroleum.

The term *aromatic* originally stemmed from the pleasant odor characteristic of the earlier recognized compounds in the group; these substances were used in perfumes and flavorings. However, some aromatic hydrocarbons are odorless.

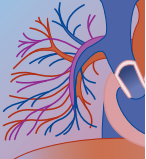

Aromatic solvents are characterized by nonpolarity and high lipid solubility. Structurally, their molecules are flat, with reactive electron clouds above and below the ring. The aromatic solvents have historically been found as mixtures in occupational settings, such as combinations of toluene, benzene, styrene, ethylbenzene, trimethylbenzene, and xylene.

Exposure to aromatic solvents occurs through contact with vapor or liquid with absorption through inhalation or the skin. Acute inhalational exposure to high airborne concentrations can produce dizziness, syncope, confusion, euphoria, respiratory irritation, and in some instances, coma through direct neurotoxicity (solvent narcosis). Inhalational exposure to high airborne concentrations may also sensitize the myocardium to catecholamines, both endogenous and exogenous, leading to potentially dangerous dysrhythmias, once dubbed "sudden sniffing death syndrome." Their individual toxicity correlates with physical chemical properties, inherent toxicity, and clinical pharmacokinetics, including metabolite production. Some aromatics, such as benzene and styrene, have metabolites that are their primary toxins.

BENZENE

Benzene, CAS registry 71-43-2, also referred to as annulene, benzeen (Dutch), benzen (Polish), benzol, benzole, benzolo (Italian), bicarburet of hydrogen, coal naphtha, cyclohexatriene, fenzen (Czech), phene, phenyl hydride, pyrobenzol, pyrobenzole, and Polystream, is a clear, colorless to yellow liquid. Its odor threshold is 1.54 to 4.68 ppm, with a taste threshold in water of 0.5 to 4.5 mg/L. The molecular weight is 78.11.^{4,5} Benzene in mixtures deviates from Raoult's law. Its vapor concentration is frequently higher than would be expected based on the concentration of benzene found in a solvent or hydrocarbon mixture. This is especially true of mixtures of hydrocarbons or solvents containing more than 5% benzene, from which substantial exposures to benzene vapors might occur during routine use.⁶

Benzene, a highly flammable liquid, was first discovered in 1825 by Michael Faraday, who isolated it from a liquid condensed from compressed oil gas.⁷ The heating of coal in a "by-product coke oven" resulted in the extraction of benzene, a significant by-product that, because of its low cost, excellent solvent properties, and rapid rate of evaporation, was used to make solutions of rubber or inks. Benzene was also involved in the chemical synthesis of dyes or halobenzene derivatives and other chemicals.⁸ In the 19th century, benzene was a common household degreasing agent and used in the dry-cleaning industry until its flammability, rather than its toxicity, led to its replacement by chlorinated

hydrocarbon solvents. Benzene was one of the first cancer chemotherapeutic agents recommended for the treatment of leukemia. The rationale for this astonishing treatment was that leukopenia occurred in some cases of benzene poisoning. However, "benzene therapy" was short-lived because of the complex action of the substance on the blood and the ensuing toxicity.⁹

Today, benzene is a widely used chemical with an annual production ranging from 10 to 30 billion pounds.^{10,11}

Recently, the mandatory decrease of lead alkyls in gasoline has led to an increase in the aromatic hydrocarbon content of gasoline to maintain high octane levels and antiknock properties. In the United States, gasoline typically contains less than 2% benzene by volume, but in other countries, benzene concentrations can be as high as 5%.¹¹

Human exposure to benzene takes place in factories, refineries, and other industrial settings. Although only a relatively small number of individuals are occupationally exposed to benzene, the general population is exposed to benzene contained in gasoline, automobile exhaust, and diesel fuel. Benzene is present in cigarette smoke, and smoking is the main source of benzene exposure for many people.⁷ It is found naturally in the environment at low concentrations.¹² For example, a hen's egg contains 35 to 133 μg of benzene. Many other foods (haddock fillet, red beans, blue cheese, cheddar cheese, pineapple, roasted filberts, potato tubers, cooked chicken, tomatoes, strawberries, black currants, roasted peanuts, soybean milk, codfish) also contain benzene in minute quantities. However, the exposure to benzene through normal dietary intake is not considered to be significant for the general population. Intakes per day from other exposures include smoking (1800 μg), passive smoke (50 μg), filling a gas tank (10 μg), driving or riding in a car (40 μg), and breathing outdoor air (120 μg).^{10,13}

In 1897, Santesson, a professor of pharmacology at the University of Stockholm, first reported the deaths from aplastic anemia of four female industrial workers who used a benzene-based rubber cement in the course of their work in a tire factory. Subsequently, Selling at Johns Hopkins (1910) substantiated his suspicion that benzene was the cause of aplastic anemia among workers in a canning factory, inducing leukopenia and marrow aplasia in rabbits by injecting them with benzene (subcutaneously, 1 mL/kg daily). Weiskotten (1920) at Syracuse University College of Medicine administered benzene by inhalation to rabbits (240 ppm) and produced similar results. Confirmed by subsequent studies, the direct relationship between benzene exposure and aplastic anemia was established.¹⁴

Acceptance of the cause-and-effect association between benzene exposure and leukemia was, however, slower in gaining acceptance after initial case reports by LeNoir and Claude in 1897 and Delore and Borgomano in 1928⁷ because few cases of leukemia were observed compared with reports of aplastic anemia associated with benzene exposure during that period. Nevertheless, Vigliani (1938) described benzene toxicity and classified it into four groups: (1) typical aplastic anemia, (2) atypical aplastic anemia with the bone marrow appearing

to be quite active in the formation of undifferentiated cells, (3) atypical aplastic anemia in which the marrow appeared to be either "hyperplastic" or "metaplastic," and (4) aleukemic leukemia.¹⁴

A cottage industry in shoemaking existed in Turkey, with families making shoes in their poorly ventilated homes. A petroleum-based solvent was used as a base for the glue until 1955 to 1960, when a change was made to a benzene-based glue. Professor M. Aksoy of the Department of Hematology at the University of Istanbul recognized an unusual number of cases of aplastic anemia and leukemia among his clinic patients. Aware of Vigliani's work, he studied the shoemakers of Istanbul, a cohort that numbered 28,500, and initially described 217 cases of bone marrow depression and 26 cases of leukemia (1971). He detected several cases of "preleukemia" and subsequently reported that of 51 cases of pancytopenia, 13 developed leukemia (1972).¹⁴

U.S. agencies, such as the Occupational Safety and Health Administration (OSHA) and the National Institute of Occupational Safety and Health (NIOSH) conducted further studies that established benzene as a leukemogen; those agencies and others attempted to determine acceptable levels of workplace exposure.¹⁵ A scientific consensus group (International Agency for Research on Cancer, IARC) concluded in 1982 that benzene was etiologically related to the development of acute nonlymphocytic leukemia based on epidemiologic studies.¹⁶

Later, a retrospective study was conducted on a well-defined cohort of workers in Ohio who were engaged in the manufacture of a rubberized material termed *Pliofilm*, in which benzene was used as a solvent for the rubber. The study showed elevated risks for leukemia associated with benzene exposure and argued that the risk was cumulative with prolonged exposure.¹⁴

Despite criticism of the Pliofilm study, subsequent analyses have supported the role of benzene as a leukemogen, and the argument has since revolved around estimates of risk.

An opportunity to use a larger cohort of benzene-exposed workers, which might be a better source of data for relating dose to leukemogenesis, arose in China where Dr. S-N. Yin of the Institute of Health of the Chinese Academy of Medical Sciences studied more than 500,000 workers demonstrating yet again the associations between benzene exposure and aplastic anemia and leukemia. Although the average benzene exposure concentration of the entire exposed cohort was determined to be 5.6 ppm, ranges of exposure among subcohorts of workers developing aplastic anemia and leukemia were found to be much higher, 29 to 361 ppm over varying periods of time.

A joint effort on the part of Dr. Yin's group and the U.S. National Cancer Institute (NCI) involving almost 75,000 exposed workers and 36,000 controls demonstrated significantly elevated levels of acute myelogenous leukemia (AML), myelodysplastic syndrome (MDS), and aplastic anemia associated with benzene exposure at levels below 10 ppm. However, the accuracy of exposure measurements and estimates in the Chinese cohorts

have since been questioned, and exposure levels may have been much higher than originally reported.¹⁷ The controversy regarding a “safe” level for occupational exposure continues.

The benzene ring is not a structure that readily binds covalently to glutathione, proteins, DNA, and RNA. It requires metabolic activation to a more reactive structure beginning with conversion to an epoxide (i.e., benzene oxide). Benzene oxide, in equilibrium with its oxepin form, is further metabolized to hydroquinone and catechol, which can then be readily converted to a benzoquinone (*ortho*- or *para*-), the ultimate toxic metabolite of benzene. Another potentially toxic metabolite, muconaldehyde, may arise from opening of the benzene oxide ring.^{9,15}

The mechanisms by which benzene produces bone marrow damage involve several targets of benzene metabolites. These include inhibition of spindle formation, which impairs mitosis; inhibition of the synthesis of interleukin-1, an essential factor in normal bone marrow function; covalent binding to proteins and DNA, forming adducts; inhibition of DNA polymerase contributing to irreversible changes in DNA; and chromosome damage, observed in MDS. Although the impact of these and other possible effects may have differential significance in the development of benzene toxicity, all appear to occur in the course of the development of benzene-induced hemopathies.⁸

Upon inhalation of benzene vapors, respiratory uptake varies from 47% to 80%; dermal absorption from liquid ranges from 0.05% to 0.2%. Absorption data for oral exposure are not available for humans; however, in animals, absorption rates following oral ingestion of benzene have been found to be 90% to 100%.¹¹

Benzene is distributed throughout the body after absorption into the blood. Because it is lipophilic, a high distribution to fatty tissue is expected. Benzene crosses the human placenta and is present in the cord blood in amounts equal to or greater than that in maternal blood.⁴

After inhalational exposure, most benzene is excreted unchanged in exhaled air. Absorbed benzene is rapidly detected in all organs. Its excretion involves a biphasic urinary excretion of conjugated derivatives (sulfates and glucuronides) with a half-life of 0.7 hours. The half-life of benzene in lipid tissues is about 24 hours.

Metabolism of benzene occurs primarily in the liver, although metabolism in bone marrow is also believed to play an important role in myelotoxicity. After rapid absorption from the lungs, benzene undergoes both phase I and II biotransformation in the liver. The primary phase I biotransformation of benzene involves cytochrome P-450 2E1-catalyzed (CYP2E1) conversion initially to phenol and subsequently to hydroquinone and catechol.¹⁸

The opening of the benzene ring, to eventually form muconic acid, appears to include a number of intermediates that arise from muconaldehyde.¹⁹

The many urinary metabolites of benzene include sulfate and glucuronic acid conjugates of the hydroxylated ring metabolites, several glutathione derivatives,

and muconic acid. At least one residue of a DNA adduct (7-phenylguanine) has been reported.¹⁹

Factors that alter the metabolism of benzene have the potential to influence its hematopoietic toxicity and carcinogenicity. Current research centers on the identification of risk factors for susceptibility to benzene toxicity, and there is evidence that metabolic susceptibility and genetic predisposition may play a major role. Metabolism and disposition are among the most important determinants of benzene toxicity. This variability results from intrinsic differences in the activities of xenobiotic metabolizing enzymes (so-called genetic polymorphisms). Variable factors in sensitivity include (1) hepatic CYP2E1, a major enzyme of the cytochrome P-450 family involved in benzene oxidation; (2) conjugating enzymes such as glutathione transferases; and (3) comparative activity of myeloperoxidase and myeloreductase (NQO1) in bone marrow. Benzene toxicity is thought to be exerted through oxidation metabolites formed in the liver primarily through pathways mediated by the cytochrome P-450 family of enzymes; benzene oxide may be sufficiently stable to reach the bone marrow. Interindividual variations in benzene metabolism are related to CYP2E1 expression, possibly owing to polymorphism of the *CYP2E1* gene. CYP2E1 is found in both the liver and bone marrow. Another enzyme found to metabolize benzene is CYP1B1.²⁰

An important protective mechanism against oxidative stress is the detoxification of lipid peroxidation products by glutathione S-transferase-theta (GSTT1) and -mu (GSTM1). Phase II metabolizing enzymes such as GSTT1 show genetic polymorphisms that correlate with GSTT1 activity. Studies have demonstrated an increased risk for myelodysplastic syndromes in individuals with a *GSTT1* gene defect or absence.²⁰

Hydroxylated metabolites of benzene are activated to toxic and genotoxic species in the bone marrow through oxidation by myeloperoxidase (MPO). NAD(P)H:quinone oxidoreductase (NQO1) is an enzyme capable of reducing the oxidized quinone metabolites and thereby potentially reducing their toxicities. A polymorphism in NQO1, a C609T substitution, has been identified, and individuals homozygous for this change (T/T) have no detectable NQO1. A higher frequency of an inactivating polymorphism in NQO1 has been reported in a cohort of patients with myeloid leukemias, especially those with an abnormality of chromosome 5 or 7, a chromosomal aberration associated with benzene exposure. It has been postulated that homozygotes (who display a complete loss of enzyme activity), as well as heterozygotes (who are at risk for loss of the remaining wild-type allele in their hematopoietic stem cells), may be particularly vulnerable to leukemogenic changes induced by carcinogens such as benzene.^{15,19,20} Limited gender comparisons suggest that males metabolize benzene at a higher rate than females, who retain benzene longer, owing to their higher body-fat content.

There is little evidence, however, that women and offspring are more susceptible to clastogenic or leukemogenic actions of benzene.

It remains unknown whether benzene affects reproductive function in humans.²¹ A study of benzene-exposed female dental surgeons failed to show an adverse effect on fertility, whereas another study of aircraft maintenance workers exposed to solvents and fuel showed some adverse effects on sperm function, including a decline in sperm motility, but the finding could not be attributed solely to benzene exposure.²⁰

It has been demonstrated that pretreatment of rats with ethanol, a CYP2E1 inducer, enhances metabolism of benzene and potentiates its acute myelotoxicity. Pretreatment of male B6C3F1 mice with acetone, another CYP2E1 inducer, increases benzene oxidation about five times. Pretreatment with diethyldithiocarbamate, a CYP2E1 inhibitor, completely abolishes benzene oxidation.

Pretreatment of mice with inducers of metabolism such as 3-methylcholanthrene and β -naphthoflavone increased both benzene metabolism and benzene toxicity.

Toluene inhibits benzene metabolism.²² Workers exposed to a combination of benzene and toluene produced significantly lower urinary phenol (a biomarker for benzene exposure) than those exposed to either benzene or toluene alone; toluene has also been shown to lower the toxicity of benzene in animals. It should be noted that Aroclor 1254, a polychlorinated biphenyl (PCB) used as a coolant in electrical transformers, is also known to alter the toxicity and metabolism of benzene.¹¹ It is unclear what role phenobarbital plays; one author claims a negligible effect, whereas another states it alters the toxicity and metabolism of benzene.^{11,15}

Benzene readily enters the central nervous system (CNS) and may cause immediate effects including headache, nausea, dizziness, confusion, convulsions, and coma leading to death.^{21,23} It has even been used as a general anesthetic. CNS responses to airborne levels are generally as follows: 2.5 ppm, no effect regardless of duration; 50 to 150 ppm, headache and lassitude; 500 ppm, sleepiness after 3 to 4 hours; 3000 ppm, sleep within 30 minutes, then progressive stupor; 7000 ppm, stupor within 30 minutes. Oral ingestion of 9 to 12 g of benzene causes staggering gait, vomiting, delirium, tachycardia, hypotension, coma, and occasionally death.²³ Severe inhalation may lead to noncardiogenic pulmonary edema. Ventricular arrhythmias may result from increased sensitivity of the myocardium to catecholamines. Benzene can cause chemical burns to the skin with prolonged contact or massive topical exposure.²¹

Evidence of benzene poisoning may appear in a few weeks or only after many years of exposure, or it may not be discovered until the onset of infection from bone marrow suppression, long after exposure has ceased.

Benzene produces a continuum of effects on the bone marrow ranging from reversible abnormalities to AML. These effects appear to be dose dependent. Chronic exposure to benzene results in bone marrow depression and tissue damage, with effects ranging from decreases in selective blood elements (leukocytes, lymphocytes, or platelets) to aplastic anemia (decreases in all cell types). Pancytopenia, aplastic anemia, AML, and their variants

may occur.²¹ Findings are variable, especially in early examination of blood. The most common abnormality is a decrease in total white blood cell count, which may be accompanied by a relative lymphocytosis and a macrocytic, normochromic, or slightly hyperchromic anemia and thrombocytopenia. The bone marrow may reveal nonspecific changes initially. Depression of bone marrow function occurs after months or years of relatively low-level exposure. Myelotoxicity may initially manifest as stimulation of all three bone marrow elements, which is soon followed by progressive anemia and thrombocytopenia. As the disease progresses, the bone marrow may become aplastic or hyperplastic in a manner that does not always correlate with the peripheral blood picture.

In the early stages, bone marrow depression is reversible; continued exposure, however, has led to fatal aplastic anemia.²³ After benzene exposure, decreases in circulating blood cells may also be observed in the presence of a dysplastic marrow characterized by abnormal architecture, chromosomal damage in many cells, and inadequate hematopoiesis leading to MDS, a preleukemic state that usually proceeds to AML. MDS is now believed to be a result of benzene exposure. There is interest centering on the possibility that environmental benzene exposure in the general public (such as exposure to vehicle exhaust emissions) may be associated with a rise in the occurrence of non-Hodgkin's lymphoma (NHL).²⁰ Causality is also suspected for chronic myelogenous leukemia and chronic lymphocytic leukemia.²¹ Benzene was formerly suspected of causing multiple myeloma, but subsequent studies have failed to confirm an association. In fact, the weight of the evidence, at present, leans against an association between benzene and multiple myeloma. There have been unproven associations between benzene exposure and acute lymphoblastic leukemia, myelofibrosis, and lymphomas.

The diagnosis of benzene poisoning is based on a history of exposure and typical clinical findings. With chronic hematologic toxicity, erythrocyte, leukocyte, and thrombocyte counts may first increase and then decrease before the onset of aplastic anemia. Such a pattern may signal a history of benzene exposure.

Biomarkers of exposure to benzene have been developed and carefully evaluated. Concentrations of the parent compound in exhaled breath parallel blood concentrations. This is confounded by smoking, which also causes elevations of benzene in exhaled breath. Urine benzene is quite specific and correlates well with concentrations between 32 and 800 $\mu\text{g}/\text{m}^3$, but it is easily confounded by smoking. Moreover, measurements at these levels are at the limit of detection, rendering them unreliable.²⁴

Urinary excretion of a variety of benzene metabolites (i.e., phenol, catechol, hydroquinone, 1,2,4-trihydroxybenzene, S-phenylmercapturic acid, and *t,t*-muconic acid) have shown correlation with benzene exposure in occupational settings. Phenol, catechol, and hydroquinone analyses are neither sensitive nor specific because relatively high levels are found in nonexposed

individuals. Similarly, *t,t*-muconic acid is not specific because it is a metabolite of sorbic acid, a common food additive. Nevertheless, urinary phenols have been useful for respiratory exposure greater than 5 ppm (16 mg/m³). Testing for urinary phenol is required by OSHA in workers exposed to benzene in an emergency involving an unexpected significant release of benzene. Below this concentration, there is too much interference from food and medication and results are unreliable.

S-phenylmercapturic acid (SPMA), an end product of the conjugation of benzene oxide and glutathione (GSH), is a suitable urinary biomarker of low-level benzene exposure (0.01 ppm) because of its specificity and relatively long half-life (9 hours). It is very specific for benzene.

Adducts to hemoglobin and cysteine groups of proteins have been demonstrated in rodents, but not in humans. DNA damage manifested by chromosome abnormalities has been detected in benzene-exposed workers, although such measures have not yet found widespread acceptance as biomarkers of effect.

Blood benzene is useful for determining exposure to concentrations exceeding 0.25 ppm but is also confounded by smoking. The specimen must be collected at or immediately after exposure because the half-life of benzene in the blood has been reported to be as brief as 30 to 60 minutes.²⁴

Potential etiologies for aplastic anemia include idiopathic, inborn (Fanconi's anemia), dose-related reactions (e.g., antineoplastic agents, benzene, chloramphenicol, inorganics, irradiation); idiosyncratic reactions (e.g., acetazolamide, arsenicals, barbiturates, chloramphenicol, gold, insecticides, phenothiazines, phenylbutazone, pyrimethamine, solvents, sulfa drugs, thiouracils); viral infections (e.g., hepatitis); pregnancy; and rheumatoid arthritis. Many medications can cause aplastic anemia.

For a summary of clinical management, refer to Box 94-1.

A spot urine phenol measurement of all exposed, including the victim, rescuers, and health care personnel, may serve as a useful indicator of high-level exposure to benzene. It is not immediately clinically useful because it may take days for the result to be reported, and it does not alter immediate therapy. Nevertheless, measurement should be made to ensure appropriate follow-up of those exposed. Acute high-level exposure to benzene may lead to hematotoxicity at a later date; thus, it is important to identify exposed individuals so that their blood indices can be followed to ensure appropriate diagnosis and treatment. This is mandated for occupational exposures by OSHA. OSHA (29CFR1910.1028) requires that after an emergency (unexpected) exposure to benzene, a urine phenol should be collected at the end of the work shift. The specimen's specific gravity must be corrected to 1.024 for proper adjustment of the phenol level. Levels of 75 mg/L or higher require complete blood counts with differentials every month for 3 months. A spot urine level higher than 20 mg/L suggests excessive occupational exposure, although the test is nonspecific and can be confounded by the presence of other aromatic com-

BOX 94-1**TREATMENT PROTOCOL FOR ACUTE EXPOSURE TO AROMATIC HYDROCARBONS**

1. Avoid unprotected contact with liquid and vapor via appropriate skin and respiratory protection.
2. Decontaminate victim by removal from exposure, removal and disposal of contaminated clothing, and copious irrigation of contaminated eyes and skin.
3. Monitor O₂ and intravenous line.
4. Do not induce emesis; gastric lavage if recent (within 30 minutes) ingestion.
5. Protect airway from aspiration.
6. Provide supportive care to maintain airway, oxygenation, ventilation, and circulation.
7. Treat coma, seizures, arrhythmias, and other complications if they occur.
8. Avoid sympathomimetics (e.g., epinephrine), if possible, to prevent potentially fatal tachyarrhythmias. Tachyarrhythmias may require treatment with β blockers (esmolol, metoprolol, or propranolol).
9. Perform chest roentgenogram, liver profile, urinalysis, serum electrolytes, blood urea nitrogen, creatinine, electrocardiogram, and complete blood counts with differential as necessary.
10. Do specific lab analyses as required, e.g., OSHA requires a urine phenol analysis for benzene exposure to determine the need to monitor for delayed hematotoxicity.
11. Monitor for 12–24 hours if exposure is substantial.

OSHA, Occupational Safety and Health Administration.

pounds both in the workplace and in the diet of those exposed. Over-the-counter cough and sore throat lozenges can cause an elevated urine phenol. Benzene can also be measured in expired air for up to 2 days after exposure.²¹

A baseline complete blood count with differential should be obtained along with the urine phenol. Other laboratory tests, including liver function studies, electrolytes, chest x-ray, and blood gases, may be ordered based on clinical findings.

There is no antidote.

Benzene overexposure requires prolonged (months to years) follow-up of hematologic parameters beyond the acute phase to monitor for changes in blood cell counts and differentials that may require hematology consultation and treatment (e.g., transfusion).

OSHA (29CFR1910.1028) requires that baseline and annual testing be made available to workers occupationally exposed to benzene. Workers are offered medical exams consisting of a medical and occupational history and complete blood count with differential. Abnormal findings trigger medical evaluations, which may lead to removal from exposure and evaluation by a hematologist or other appropriate specialist.

Urine S-phenylmercapturic acid measurement at the end of the work shift is a sensitive and specific marker of exposure to low levels of benzene and can be used to detect overexposure. The American Conference of Governmental Industrial Hygienists (ACGIH) has established a biologic exposure index (BEI) of 25 μ g/g creatinine.

Recovery from acute benzene exposure depends on severity of symptoms. Symptoms may persist for 2 to 3 weeks. Chronic effects of benzene intoxication may arise and persist long after an acute exposure occurs. Benzene is a leukemogen; leukemia can occur before or after aplastic anemia. Individual response to either acute or chronic benzene exposure is variable.

STYRENE

Styrene, also known as cinnamene, phenylethylene, and vinyl benzene, is a high-production-volume chemical, with more than 10 billion pounds produced annually in the United States.²⁵ Styrene is a colorless to slightly yellow, oily liquid that spontaneously polymerizes unless inhibited. It is liquid at room temperature and highly flammable.^{26,27} At low concentrations, it has a sweet odor; at concentrations above 100 ppm, it's odor is objectionable. Styrene has a low vapor pressure and is soluble in organic solvents, but only slightly soluble in water.²⁷

Although styrene was discovered in 1831, it did not become commercially important until 1942, when it was used in the synthesis of unsaturated polyesters and reinforced plastics. Currently, styrene is widely used to make plastics and resins for surface coatings. It is also used as a chemical intermediate. Styrene-containing polymers are used to make tires, boat hulls, shower stalls, bath tubs, dental restorative plastics, and many other plastic products. Styrene can be synthesized but is also found naturally in storax, a gum derived from styracaceous trees. Primary exposures to styrene occur during its manufacture and polymerization, particularly in situations in which open polymerization processes are used, for example, in boat building or shower-stall manufacturing. Styrene is present in tobacco smoke and has been detected in ambient urban air samples.

Styrene is naturally present in foods such as strawberries, beef, and spices, and is naturally produced in the processing of foods such as wine and cheese. Styrene is permitted as a direct food additive in small quantities under the Food and Drug Act, and as an indirect food additive that migrates from packaging materials into food. It undergoes rapid biodegradation; styrene levels in surface water and groundwater are generally very low (<1 µg/L) or nondetectable.

Cancer bioassays and epidemiology studies have failed to identify the nervous system as a target, and they have failed to identify a cancer risk associated with styrene.²⁸

Several epidemiologic studies on workers have shown that styrene affects color vision in a dose-dependent manner. These effects on color perception are in the blue-yellow axis, in contrast to congenital color-blindness, which is in the red-green axis. Alterations appear to be reversible when exposure conditions are improved. The Lanthony D15-d panel has proved the most efficient in detecting acquired deficiencies in color vision.²⁹

The mechanism of styrene's effects on the nervous system is not known. It is likely that the effects of high-level, acute exposure are due to styrene itself because they appear shortly after exposure and before significant

metabolism. However, it is unclear whether the parent compound or metabolites are neurotoxic at lower exposure levels. Because of its potential reactivity, styrene oxide is an obvious candidate metabolite for concern; its potential reactivity has implications for genotoxicity and carcinogenesis for styrene because it is mutagenic *in vitro* and carcinogenic in animal studies. However, neither animal studies nor human epidemiology studies have validated these concerns.

Styrene is absorbed after oral, inhalation, or dermal exposure. The primary route of human exposure is through the lungs. Average retention of styrene in the respiratory tract after inhalation of 4.6 to 46 ppm is 71% for humans. Once absorbed, styrene is widely distributed in the body.

Styrene requires metabolic activation to induce effects other than acute toxicity.³⁰ Metabolism of styrene includes, as an initial step, oxidation of styrene by cytochrome P-450 enzymes to form styrene oxide or styrene-7,8-epoxide, which may be responsible for some of the toxic effects observed after styrene exposure. The major metabolic and detoxication pathway involving styrene oxide results in the formation of styrene glycol, followed by mandelic acid and phenylglycolic acid, which are often used as biologic exposure indices.

Styrene oxide is further metabolized by epoxide hydrolase and GSH S-transferase activities. There are species differences, with humans showing little conversion to styrene oxide through CYP450, but enhanced conversion of styrene oxide by epoxide hydrolase, which suggests the human body burden of styrene oxide after either styrene or styrene oxide exposure is lower than in rats or mice.

Due to its relatively high lipid solubility, styrene may be retained in human fat for up to 5 weeks after exposure. The half-life of styrene in fat is 2.2 to 4 days for men exposed to 50 ppm styrene for 1 hour (30 minutes rest plus 30 minutes exercise).²⁷ The half-life of styrene in human blood is believed to be biphasic. There is a rapid elimination phase with a half-life of 0.57 to 0.68 hour and a second slow phase with a half-life of 13 hours.

The elimination of mandelic acid in urine is biphasic. The first-phase half-life is 2 to 4 hours, and the second-phase half-life is 25 to 30 hours. The elimination half-life of phenylglyoxylic acid in urine is 11 hours.

Styrene has been found in breast milk in U.S. cities. It has been suggested that styrene would be expected to be found in breast milk at higher concentrations than in blood or urine because of its lipophilicity.

Styrene has been subjected to extensive toxicologic investigation. Subchronic and chronic experimental studies with styrene have not clearly identified neurotoxic effects in animals beyond those effects that can be attributed to CNS depression.

Animal studies indicate that styrene may alter brain neurochemistry, although the pattern of effects is not well understood. The only long-lasting reproducible effect observed in animal studies is ototoxicity, which has not been clearly demonstrated in humans.

Ototoxicity has been found at styrene concentrations at and above 800 ppm for prolonged periods. These

functional changes in laboratory animals have been correlated with morphologic changes, including deficits in outer hair cells in the basal and lower middle turns of the organ of Corti. Ototoxicity has not been observed at 50 or 200 ppm exposure levels. Studies in humans have generally been negative or failed to control for noise. However, a recent study funded by NIOSH found a dose-dependent effect of low-level styrene exposure on hearing thresholds, which acted independently of the effect of noise exposure. Levels of mandelic acid in urine correlated with hearing loss, lending credence to claims that low-level styrene exposure can contribute to elevated hearing thresholds independently.³¹

Several studies have reported impaired color vision among styrene workers.

Based on differences in metabolism between rodents and humans, no lung or nasal toxicity is expected in humans from styrene exposure.³²

Although not thoroughly tested, styrene does not appear to be an important reproductive toxicant. Similarly, studies so far do not indicate that developmental toxicity is likely to be a major concern. Teratologic studies have shown fetotoxicity, fetal weight reduction, and reduced survival in rats, but only at doses that also produced maternal toxicity. No malformations have been reported.

There is no evidence that styrene is a teratogen. Styrene is not a developmental toxicant at nonmaternally toxic exposures in experimental animals. There are still no convincing indications of styrene-induced malformations. There is some evidence, from reliable studies, for slight embryo-fetal toxicity (primarily developmental delays; possible increases in skeletal variations) at maternally toxic exposures. There is a combined weight of evidence that suggests the developing CNS may be adversely affected by the neurotoxic effects of styrene at high doses.³³

High-level styrene inhalation exposure of rabbits and oral administration to rats induce some changes in brain dopamine, which may affect the function of the hypothalamus and pituitary. Abnormalities of pituitary secretion in women exposed to styrene have also been suggested. These effects may be connected with putative effects on the menstrual cycle.

The current weight of evidence suggests that styrene is not likely to affect estrogenic or androgenic activity, and, thus, it would not appear to be a hormonally active agent.

Styrene irritates the mucosal membranes of the respiratory tract. It can cause sore throat, nasal irritation, and increased nasal secretion. Pulmonary edema may develop 24 to 72 hours after high-grade exposure.

It has been suggested that at 100 to 200 ppm, the irritant properties of styrene develop, and at concentrations between 150 and 200 ppm, impairment of reaction time and balance may occur. At 350 ppm, definite signs of impairment of reaction time and balance occur.

Styrene has irritating, drying, and defatting effects on the skin.

Occupational asthma due to exposure to styrene has been reported, and allergic contact dermatitis has also been reported.

At less than 10 ppm, styrene's odor is not detected. Between 50 and 100 ppm, styrene has a strong odor that is not objectionable. At 100 ppm, transient eye irritation may be observed, but tests of coordination and dexterity are unaffected. Reaction time is impaired at exposures of 350 ppm for 30 minutes, but perceptual speed and manual dexterity are unaffected. At 376 ppm for 25 minutes, performance on the Romberg test is impaired. At 800 ppm for a few hours, styrene is reported to cause listlessness, drowsiness, and impaired balance that lasts beyond the exposure period. Workplace exposures at more than 100 ppm styrene have resulted in the observation of similar acute effects. Subchronic and chronic experimental studies with styrene have not clearly identified neurotoxic effects in animals beyond those effects that can be attributed to CNS depression. Styrene vapor exposure at concentrations in excess of 50 ppm is irritating to the eyes and respiratory system.

Reports of clinically evident neurologic disease among styrene workers are uncommon. In general, the neurotoxicology literature for styrene consists of reports of subclinical effects among boat builders. The effects include changes in self-reported symptoms, psychomotor function, color vision, vestibular function, somatosensory evoked potentials, and nerve conduction velocity. Absence of clinical and neurobehavioral effects and nerve conduction changes following chronic workplace exposures have also been reported. Although fairly voluminous, the clinical literature does not allow conclusions about chronic neurotoxicity, particularly at levels recommended for workplace exposure, which are generally in the range of 20 to 50 ppm. Because the half-life of styrene in body fat is 2 to 4 days, many of the studies have failed to distinguish between acute toxicity due to peak exposures and chronic toxicity due to repeated low-level exposure. Also, workplace conditions are often not accounted for in sufficient detail. This is particularly important because boat building involves the use of many different materials, paints, solvents, and adhesives. Clean-up procedures to remove excess styrene from equipment and body surfaces may include neurotoxic solvents such as *n*-hexane and gasoline. Thus, the present database for styrene is inadequate to conclude that chronic low-level exposure to styrene provides a significant neurotoxic risk.

The metabolites of styrene, mandelic acid, phenylglyoxylic acid, hippuric acid, and styrene oxide can be analyzed in blood and urine as measures of exposure.

The differential diagnosis includes any acute condition that might affect the CNS, including cerebrovascular accident, trauma, alcohol, drug overdose, other chemicals, and so forth.

See Box 94-1 for appropriate management of acute exposure.

Patients with acute exposure to styrene should have baseline liver and renal function tests, urinalysis, complete blood count, and amylase and lipase levels performed. If significant respiratory tract irritation occurs, arterial blood gases should be monitored and a chest x-ray taken. Testing for metabolites of styrene, mandelic acid, phenylglyoxylic acid, and others may

be useful for documentation of exposure but, otherwise, have no clinical utility and will not affect clinical outcome.

There is no antidote; care is supportive. For elimination, refer to Box 94-1. Dialysis and hemoperfusion are not useful. Disposition is described in Box 94-1.

TOLUENE

Toluene, also referred to as toluol, methylbenzene, methacide, and phenylmethane,³⁴ is an alkylbenzene derived from crude oil and coal tar during petroleum refining. It is a common component of gasoline, adhesives, paints, inks, and solvents.¹

At room temperature, toluene is a volatile, flammable liquid with a sweet, pungent odor.³⁵ Its molecular weight is 92.15, and it has an odor threshold of 2.9 to 8 ppm.

Toluene has replaced benzene as the primary solvent in many commercial products such as oil paints and stains. It is readily available³ and is a favorite of solvent abusers, who intentionally inhale high concentrations to induce a “sniffer’s high.”^{15,36} The concentration of toluene inhaled by solvent abusers is 50 times the maximum permissible in industry.³⁷

Toluene is also used in the production of other chemicals. Gasoline, which contains 5% to 7% toluene by weight, is the largest source of atmospheric emissions and exposure to the general population.

Volatile substance abuse involves children throughout the world.³⁵ In North America, inhalant solvent (toluene) abuse is especially prevalent in economically disadvantaged, neglected, or abused adolescents. Most are Hispanic immigrants, or children of immigrants, from Central America and Mexico. Males outnumber females ten to one. Native Americans also have an especially high prevalence of inhalant abuse. Much North American inhalant abuse (“sniffing,” “huffing,” or “bagging”) involves paint or lacquer thinners that contain toluene as the principal constituent.

Owing to the CNS effects associated with toluene exposure, a number of researchers have attempted to measure subtle changes using neurobehavioral tests and measures of workers exposed to relatively low levels of toluene³⁴; however, the studies have shown conflicting results with no clear indication of neurobehavioral effects resulting from workplace exposures.

The toluene molecule is devoid of actual or potential electrophilic centers. In this respect, it is similar to benzene and the xylene (dimethylbenzene) isomers.³⁸

The desired effects of recreational toluene inhalation are euphoria and a sense of relaxation. Visual and auditory hallucinations may appear; they sometimes are frightening and provoke outbursts of antisocial behavior. Hallucinations usually abate after the initial months of abuse. Many chronic abusers inhale almost constantly from solvent-soaked rags or filled plastic bags and eventually in a mildly stuporous, tranquilized state. Sudden death may occur from vomiting, aspiration, suffocation by plastic bags, or cardiac arrhythmias. Inhalant abusers experience tolerance to the acute effects. Sudden with-

drawal produces a syndrome similar to ethanol withdrawal. Addiction is common.

Little is known about mechanisms by which toluene and similar solvents produce acute or residual CNS effects. The acute effects of high-level toluene exposure (excitement followed by CNS depression) suggest a neurotransmitter-mediated mechanism similar to that of the hydrocarbon general anesthetics and ethanol. It has also been suggested that toluene and other volatile hydrocarbons may act by enhancing γ -aminobutyric acid A (GABA_A) receptor function, attenuating *N*-methyl-D-aspartate (NMDA) receptor-stimulated calcium flux, or activating dopaminergic systems.

Multifocal and diffuse leukoencephalopathy from prolonged high-level exposure (inhalant abuse) most likely reflects a direct effect on myelin or on the oligodendrocyte. The biochemical and morphologic similarities to adrenoleukodystrophy raise the possibility of an induced disorder of peroxisome or fatty acid metabolism.

Chronic toluene abuse can cause transient distal renal tubular acidosis (RTA) via an incompletely understood mechanism. Prolonged (years) of inhalant abuse may cause renal dysfunction and a secondary severe electrolyte imbalance; the usual profile includes metabolic acidosis, hypokalemia, and hypophosphatemia. This syndrome is secondary to toluene-induced renal tubular acidosis, *not* to increased urinary levels of hippuric acid; it is suggested that the site of primary dysfunction is the distal renal tubule. Renal potassium loss may be severe and can result in symptomatic hypokalemia, which may be so profound as to cause diffuse flaccid paralysis.

It is suggested that maternal toluene exposure, like maternal alcoholism, causes embryonic cell death resulting in deficiencies in early migrating neuroepithelial and mesodermal components.

Toluene toxicokinetics has been thoroughly characterized in humans and laboratory animals. Toluene is well absorbed from the lungs and gastrointestinal tract; dermal absorption may also occur but is less efficient.

Toluene rapidly accumulates in and affects the brain, owing to the brain’s high rate of blood perfusion and high lipid content. The brainstem has the highest initial concentrations. Toluene is well metabolized, but a portion is exhaled unchanged. Circulating toluene is metabolized in hepatic microsomes, which contain CYP450s, particularly CYP2E1, that catalyze metabolism of toluene.

Toluene’s metabolic products are cresol (less than 1%) and the intermediate metabolite benzaldehyde. Benzaldehyde is then metabolized to benzoic acid, which is conjugated with glycine to form hippuric acid. In humans, up to 75% of inhaled toluene is metabolized to hippuric acid and excreted in the urine within 12 hours of exposure. The remainder of the toluene is excreted unchanged, with a small percentage excreted as a sulfate or glucuronide of cresol. The metabolism and excretion of toluene are rapid, occurring within 12 hours of exposure. Elimination from the CNS is rapid; however, subcutaneous lipid may constitute a temporary storage site, and its concentration may continue to increase for

1 hour after exposure. Plasma concentrations generally parallel the lipid-stored fraction. The concentration of blood toluene drops rapidly during the first 10 minutes after termination of exposure; after 3 hours, very low concentrations are detectable in blood and in alveolar air.³⁵ The half-life of toluene in adipose tissue of humans has ranged from 0.5 to 3 days.

Toluene readily crosses the placenta.³⁹

Recent genetic evidence suggests that some ethnic populations may be more at risk for the neurobehavioral effects of toluene than others because of metabolic differences.⁴⁰

Toluene is initially metabolized to benzyl alcohol by the microsomal mixed-function oxidase system. Subsequently, oxidation to benzaldehyde and then to benzoic acid is carried out by the alcohol and aldehyde dehydrogenase, respectively. All populations appear to have two forms of aldehyde dehydrogenase, one having a high K_m and one with a much lower K_m . However, some Japanese and possibly other populations of Asian origin and Native Americans have a defective gene for the low K_m enzyme. When toluene-exposed Japanese workers (both male and female) were evaluated for the defective gene, it was found that those possessing the defective gene had lower levels of urinary hippuric acid and *o*-cresol than those with the normal or heterozygous gene. This observation suggests these individuals may be at a higher risk for toluene-induced CNS decrements owing to a decreased rate of toluene metabolism, leading to increased blood levels of benzaldehyde.

As toluene is metabolized by CYP450s (generally CYP2E1) and alcohol dehydrogenase, the chemical can interact with other xenobiotics metabolized by these enzymes. Concurrent exposure to solvents metabolized by the same CYP450 isozymes can result in competitive metabolic inhibition. Benzene and toluene suppress one another's metabolism in humans. Toluene greatly reduces manifestations of peripheral neuropathy caused by *n*-hexane in rats. Simultaneous exposure to high levels of toluene and xylene resulted in mutual metabolic suppression. Prior exposure to P450 inducers can result in increased rates of toluene metabolism and elimination and more rapid recovery from toluene-induced CNS depression.

In humans, occupational exposure to toluene is so low that it could not lead to the induction of P-450. However, the induction may be seen in toluene sniffers who are exposed to high concentrations.⁴¹

Contradictory effects of ethanol consumption on toluene metabolism are described; experimental animals given ethanol have elevated toluene blood levels, as do healthy human volunteers, whereas workers who regularly consume ethanol are reported to have lower plasma toluene measures than controls, presumably owing to enzyme induction. Phenobarbital stimulates hepatic side-chain hydroxylase, accelerating the metabolism of toluene to hippuric acid and yielding lower blood and tissue levels of toluene.

Human toxicity from toluene exposure occurs primarily by the inhalational and dermal routes, although ingestion is another absorption route. Toluene

is mildly irritating to the mucous membranes, skin, and eyes. Short-term exposure to airborne toluene levels of less than 100 ppm has not been associated with discomfort. Humans exposed to concentrations of toluene of between 200 and 800 ppm may experience respiratory and ocular irritation. Prolonged contact between toluene and skin can produce irritation from solvent defatting of the skin, and direct splashing of the eyes may cause corneal injury. Dermal sensitization to toluene is extremely rare.

Ingestion of toluene may cause vomiting or diarrhea, and if pulmonary aspiration occurs, chemical pneumonitis may result. Systemic absorption may lead to CNS depression.

The CNS is the primary target organ of toluene and other alkylbenzenes. CNS neurotoxicity is the primary concern in toxic inhalational exposure.

Manifestations of exposure range from slight dizziness and headache to unconsciousness, respiratory depression, and death. Occupational inhalation exposure guidelines are established to prevent significant decrements in psychomotor functions.

Exposure to levels at 100 ppm for 4 hours causes eye irritation, headache, and lightheadedness but no consistent alterations in performance.³⁵ However, controlled studies with volunteers at 100 ppm showed decrements in vigilance, visual perception, motor performance, and ability to carry out functions. One extensive study claimed minor alterations in memory and dexterity following a 7-hour exposure at 150 ppm. Exposures at 200 ppm for 8 hours caused mild fatigue, confusion, lassitude, and lacrimation. At 600 ppm, euphoria and severe headache were prominent; at 800 ppm, all symptoms were more pronounced and were followed by 4 days of nervousness, fatigue, and insomnia.

Acute CNS effects are rapidly reversible upon cessation of exposure.

Prolonged high-level (1000–20,000 ppm) toluene exposure from inhalant abuse can cause symptomatic, disabling, multifocal leukoencephalopathy.

Toluene neurotoxicity has been clearly defined; it is most consistent in case descriptions of persons who daily spend their waking hours for years, nose-to-rag/bag, in a toluene-induced recumbent stupor. The daily dose from inhalation can exceed 350 mg of toluene; one individual "huffed" (orally inhaled) a gallon every 2 weeks of 99% pure toluene. Consumed at this rate, the shortest documented duration before onset of lasting symptoms is 1 year; most begin to show clinical manifestations after 2 to 4 years. Initial symptoms are behavioral changes (loss of initiative, depression, irritability), weight loss, impaired sense of smell, impaired concentration and memory, and mild unsteadiness of hand movements and gait. Subsequently, symptoms are slurred speech, head tremor, stiff-legged and staggering gait, poor vision, deafness, and dementia. Examination after 4 weeks of abstinence (avoiding the effects of acute intoxication) discloses sustained multidirectional nystagmus, titubation, ataxic tremor of all limbs, spasticity with hyperreflexia and Babinski's responses, broad-based and staggering stiff-legged gait, deafness, impaired vision and color dis-

crimination, memory loss, inattention, apathy, and abulia. Even the most severely impaired display significant improvement after 6 months of abstinence; persons with mild or moderate dysfunction often recover completely. Infrequent abuse may cause no neurologically detectable CNS dysfunction; moderate frequency and intensity may cause a partial syndrome of mild cognitive dysfunction and slight tremor. Years of daily inhalation in the highest-level pattern described earlier almost inevitably leads to CNS dysfunction, and there is a predictable dose–effect relationship at these high levels.

Magnetic resonance imaging (MRI) has revealed permanent changes in brain structure, which correspond to the degree of brain dysfunction. Inhalational solvent abuse in particular has led to permanent neurologic sequelae and CNS lesions that have been described on both computed tomography (CT) and MRI.

Because of the accumulation of toluene in the anatomic areas of the CNS, symptoms can last hours beyond an exposure. Such impairments may be cognitive or involve coordination, motor control, intention tremor, and gait disturbances.

Decreased vision has been described in individuals chronically inhaling toluene-containing solvents. Optic neuropathy is manifest as decreased visual acuity but normal pupillary reactions along with associated cerebellar signs. Improvement in vision has occurred after discontinuation of toluene exposure.

Subtle neurologic effects have been reported in some groups of occupationally exposed individuals.¹⁵

Exposure to about 100 ppm of toluene for years may result in subclinical effects, as evidenced by altered brainstem auditory evoked potentials and changes in visual evoked potentials.

Chronic exposure to low toluene concentrations is associated with fatigue, headache, dizziness, shortness of breath, cough, throat irritation, nausea, and other constitutional symptoms. Disturbance of vestibulo-ocular responses has been demonstrated in subjects exposed to concentrations of toluene ranging from 103 to 140 ppm for more than 2 hours while doing light work. Color vision has also been shown to be impaired by occupational exposure to toluene.

It is claimed that chronic occupational exposure to low levels is associated with psychiatric change and mild cognitive dysfunction. There have been conflicting studies on the effect of chronic low-level (88–150 ppm) exposure of workers to toluene. Prolonged, low-level occupational inhalation of pure toluene is rare; most workers are exposed to solvent mixtures. There is one report of an anosmic lens cleaner who had chronic, intermittent exposure to toluene and developed, over a period of 3 months, poor concentration and memory, somnolence, slurred speech, and unsteady gait. Examination disclosed normal mental function, mild dysarthria, and gait-limb ataxia. He recovered completely within 1 month of abstinence. Although the data on this report (exposure and objective clinical findings) are limited, it suggests that intermittent, moderate- to high-level industrial exposure to toluene produces an illness that is a microcosm of the inhalant abuse syndrome.

Chronic exposure can lead to myopathy; hypokalemia and renal tubular acidosis are also common. Clinical findings are a hyperchloremic metabolic acidosis, hypokalemia, and aciduria. There is typically an associated transient renal azotemia, as well as proteinuria. Rarely, proximal RTA or the Fanconi's syndrome may occur. The metabolic acidosis is believed to be multifactorial, involving RTA, accumulation of toluene metabolites, and tissue hypoxia.

Toluene can cause nephrotoxicity in two forms: acute renal failure after massive ingestions and distal renal tubular acidosis. Clinical reports state that excess proteinuria, abnormal liver function test results, interstitial nephritis, and glomerulonephritis have also been related to toluene. Nephrotoxic effects that have been documented in chronic toluene abusers include hematuria, proteinuria, and type 1 renal tubular acidosis.

Patients with metabolic acidosis after toluene inhalational abuse have also exhibited associated hypokalemic muscular weakness and paralysis with neuropsychiatric manifestations.

Renal tubular function usually recovers during abstinence. Extreme cases of solvent inhalant abuse may also display evidence of hepatic failure. Studies with human volunteers and experimental animals have failed to demonstrate renal or hepatic dysfunction at levels encountered in the workplace.

Toluene is not a serious immunopathogen or carcinogen; previous reports of malignancy among exposed workers are now presumed to reflect the effects of benzene (formerly a component of commercial-grade toluene).

Toluene is a teratogen in humans and experimental animals. Children with microcephaly, minor craniofacial and limb anomalies, CNS defects, attention disorders, developmental delay, learning disorders, and language deficits were born to mothers who abused toluene by inhalation during pregnancy. These phenotypic and behavioral features strikingly resemble those associated with fetal alcohol syndrome.

There is report of a case of recurrent non-Q-wave myocardial infarction and cardiomyopathy associated with toluene abuse.⁴²

Most hospital admissions for toluene abuse are for hepatic-renal failure or life-threatening cardiac arrhythmias.

Correct diagnosis is seldom difficult when presented with an intoxicated person. In the emergency room, solvent-smelling breath (persistent for hours) and a perioral rash (“huffer’s rash”) are often clues. Children who lack obvious neurologic deficits may develop hypokalemia and metabolic acidosis during early toluene abstinence. Occasionally, they are repeatedly admitted to renal medical units for treatment of distal renal tubular dysfunction of “obscure origin.” Toxicologic screens in most commercial laboratories employing gas chromatography can detect toluene in the blood; hippuric acid analysis of urine is also widely available.

Hippuric acid is used as a biologic marker for occupational exposure to toluene. Minor toluene metabolites are *o*-cresol, *p*-cresol, and phenol. The minor

metabolites are conjugated with either sulfate or glucuronic acid and are excreted in the urine.

However, hippuric acid monitoring is especially unreliable in persons with low-level exposures. Individual variations with respect to metabolism of toluene and the correlation of occupational exposure to toluene and urinary excretion of hippuric acid and cresol can occur, especially if there is coexposure to other solvents or ethanol. Ethnic variations in toluene metabolism also are seen. Owing to this variability of metabolism among individuals, the biologic monitoring of hippuric acid and other metabolite excretions is merely a qualitative indication of exposure and not a quantitative indication of toluene toxicity. The average amount of hippuric acid excreted in the urine by persons not exposed to toluene is 0.7 to 1.0 g/L of urine.

Toluene in venous blood has been reported as the most reliable and sensitive marker of exposure. Although blood toluene, like other biomarkers, is influenced by smoking, exercise, alcohol ingestion, and sex differences, its usefulness as a surrogate of exposure is predicated on the multiphasic time course of elimination and a linear relationship at low levels of exposure. The initial elimination from blood upon termination of exposure is rapid, on the order of minutes; at an exposure level of 34 ppm, the blood level 16 hours after exposure was only 2% of the maximum blood level reached. Blood levels immediately after exposure reflect time-weighted average (TWA) exposure during the preceding 8 to 10 hours.⁴⁰

Because of a slow release of toluene from adipose tissues (half-life is about 80 hours), blood toluene levels on Monday mornings before work or near the end of the workweek were observed to correlate with exposures during the preceding week. This slow decline in blood toluene has been demonstrated to result in detectable levels in workers who ceased exposure 2 weeks previously.

O-cresol has been used as a marker of toluene exposure in the workplace. It can be easily obtained by a noninvasive urine sampling procedure at the end of the work shift. One study reported that a value of 3 mg *o*-cresol per liter of urine correlates with an exposure level of 50 ppm, which also correlates with a value of 1000 µg/L toluene in blood.⁴³

Laboratory studies of intoxicated persons may reveal evidence of renal tubular failure or mild hepatic dysfunction. Most hospitalizations of adolescents are for renal insufficiency and hypokalemia. Laboratory evidence of neuroendocrine effects is described in factory workers, whereas hypothalamic dysfunction (hyperprolactinemia, decreased testosterone and growth hormone) is reported in a boy whose toluene abuse was accompanied by central sleep apnea, diabetes insipidus, and poikilothermia.

CNS electrophysiologic studies reveal a characteristic abnormality of the brainstem auditory evoked response (BAER), namely, sparing of early components (wave I) and decrement or loss of late components (waves III–V). Abnormal BAERs appear to be among the most sensitive measures of toluene neurotoxicity; they may appear at a time when the neurologic exam is still unremarkable. Visual evoked responses appear less

sensitive; they usually display diminished amplitudes throughout, with moderate delay in the late component. Electroencephalograms are frequently abnormal; even after 4 weeks of abstinence, they show mild diffuse slowing without paroxysmal, epileptiform activity. CT in severe cases almost always discloses mild to moderate cerebellar cortical and cerebral hemisphere atrophy. MRI in some advanced cases has provided solid evidence of white matter disease; this is evidenced by increased signal intensity on T2-weighted images in the periventricular, internal capsular, and brainstem pyramidal regions. MRI also reveals loss of differentiation between gray and white matter throughout the CNS and atrophy of cerebellum, cerebral hemispheres, and brainstem. These MRI findings are nonspecific; they may be seen in inflammatory demyelinating diseases, anoxic demyelination, and ischemic white matter disease. Neuroimaging studies show that CNS white matter changes due to toluene toxicity appear to be irreversible.

Neurologic lesions on MRI and CT scanning correlate with impairments on psychological tests in toluene abusers. MRI of the CNS in toluene vapor abusers has demonstrated multifocal CNS involvement and diffuse CNS demyelination. These findings correlated with a clinical presentation that included neurobehavioral, cerebellar, brainstem, and pyramidal tract abnormalities.

Neuropathologic changes that correlated with MRI and CT scanning in toluene abuse patients include diffuse cerebral demyelination, diffuse cerebellar demyelination, demyelination of subcortical white matter, degeneration and gliosis of ascending and descending long fiber tracts and nerves of the corpus callosum, and atrophy of the cerebrum, cerebellum, and corpus callosum. Necropsy showed myelin pallor in deep periventricular white matter, with axonal and neuronal loss combined with demyelination. Electroencephalogram abnormalities are reported in some cases.

Individuals exposed to long-term low concentrations of toluene, as compared with controls, showed abnormal visual evoked potentials.

Treatment of toluene exposure lies primarily in the correction of the resulting metabolic disorders. Most patients require parenteral hydration and attention to renal function. Recovery is usually rapid with the correction of the electrolyte disorders.⁴⁴

Hypokalemia, cardiac arrhythmia, and metabolic acidosis require skilled medical management. Chronic toluene inhalational abuse can result in a normal anion-gap metabolic acidosis with hypokalemia, hypophosphatemia, and hyperchloremia. This type of acidosis was first described in association with glue sniffing and is termed *type 1 renal tubular acidosis*. Renal tubular acidosis is a derangement in the capacity of distal renal tubules to maintain a hydrogen ion gradient and usually is reversible within a few days once exposure to toluene ceases, although reversal of this disorder may require several weeks. Treatment ranges from observation to administration of sodium bicarbonate and potassium, depending on the severity of the acidemia and electrolyte loss.

Decontamination is described in Box 94-1.

Other than abstinence, there is no specific treatment for the CNS effects.

In acute symptomatic exposures, toluene may be detectable in blood drawn with a gas-tight syringe, but usually only for a few hours. The metabolites hippuric acid and orthocresol are excreted in the urine and can be used to document exposure, but urine levels do not correlate with systemic effects.³⁶

Other useful laboratory studies include electrolytes, glucose, blood urea nitrogen, creatinine, liver transaminases, creatine phosphokinase, and urinalysis.

There is no antidote. There is no role for enhanced elimination.

Consider hospitalizing the symptomatic patient who has significant inhalation or ingestion exposure with symptoms of CNS depression or respiratory distress.⁴⁵ Observe hospitalized patients for signs of acute tubular necrosis, encephalopathy, and arrhythmia. In addition, patients who have inhaled large amounts of toluene should be observed for signs of pulmonary edema, and those who have ingested toluene should be watched for signs of aspiration pneumonitis.

XYLENE

Xylene (dimethylbenzene) is a commonly used aromatic solvent with three isomeric forms: *ortho*-, *meta*-, and *para*-xylene. Xylenes are one of the highest-volume chemicals produced and used by industry. A mixture of all three isomers is termed *xylol*.¹ It is a colorless, flammable, liquid hydrocarbon with a characteristic aromatic odor. It is commonly found in products such as varnish, ink, paint thinners, degreasers, and insecticides.⁴⁶ Xylenes like benzene and toluene are major components of gasoline and fuel oil. The primary uses of xylenes industrially are as solvents and synthetic intermediates.¹⁵ Commercial xylene is often contaminated with other organic compounds such as ethylbenzene, toluene, benzene, trimethylbenzene, phenol, thiophene, and pyridine. The volumes of these contaminants are very minor, making up less than a fraction of 1%.

The odor threshold of xylenes depends on the isomer. On average, the odor threshold appears to be about 1.0 ppm. *m*-Xylene has an airborne odor threshold of 3.7 ppm; *o*-xylene, 0.17 ppm; and *p*-xylene, 0.47 ppm.

Liquid xylene is irritating to the skin and eyes, causing local vasodilation by the liberation of histamine and 5-hydroxytryptamine. Direct xylene eye splash causes initial transient discomfort and hyperemia of the conjunctiva. The cornea may rapidly develop a visually significant central haze usually limited to the anterior portions of the stroma. A characteristic clinical feature reveals clear vacuoles resembling microcystic corneal epithelial edema but localized mostly in the anterior stroma. The stromal vacuoles are very characteristic and only mentioned in a few other entities such as *n*-butanol and nitronaphthalene exposure. In contrast, epithelial cystic changes differ from stromal vacuoles and are commonly seen in other keratopathies such as contact lens toxicity and increased intraocular pressure.

The CNS mechanism of toxicity is identical to that of toluene and other hydrocarbons.³⁶

The toxicokinetics (TK) and acute toxicity of toluene, xylenes, and other aromatic solvents are quite similar. Xylenes and the others are well absorbed from the lungs and gastrointestinal tract, distributed to tissues according to tissue blood flow and lipid content, exhaled to some extent, well metabolized by hepatic P-450s, and largely excreted as urinary metabolites.

Dermal xylene absorption is low compared with respiratory tract absorption.

Xylene is metabolized through the P-450 mixed-function microsomal enzyme system in the endoplasmic reticulum of the liver. The biotransformation of xylene through side-chain oxidation and aromatic oxidation results in metabolites of methylbenzyl alcohols, methylbenzaldehyde, and methylbenzoic acids (toluic acids). Methylbenzoic acids are conjugated with glycine to form methyl hippuric acids, the main urinary metabolites of xylene. A minor (1%–4%) metabolic pathway of xylene metabolism is aromatic ring hydroxylation, which forms xylenol.

The major route of clearance is through the kidneys, with metabolites of xylene being excreted by a slow phase and a rapid phase. In humans, about 36% of xylene is excreted by the end of the daily working period, and about 70% to 80% of metabolites are excreted within 24 hours of cessation of exposure. Removal from fat occurs slowly over a period of days.⁴⁷

The co-ingestion of ethanol will inhibit the metabolism of xylene through the pathway leading to methylhippuric acid, but not the path leading to 2,4-xylenol.

Coexposure to other solvents affects xylene metabolism. Exposure to both methyl ethyl ketone and xylene results in about a 50% increase in blood xylene concentrations. Also, urinary excretion of methyl hippuric acid decreases, indicating competition for enzyme metabolism. Coexposure to trichloroethylene, ethylbenzene, and toluene also inhibits xylene metabolism. Increased use of the minor aromatic ring hydroxylation pathway occurs when other solvents compete with CYP450 enzyme pathway metabolism.

Xylene is irritating to the eyes, skin, and mucous membranes. Exposure may cause dyspnea, anorexia, nausea, vomiting, and dermatitis. There are several ways in which xylene can be toxic, such as through inhalation, ingestion, or direct contact with the liquid. Ocular injuries such as irritation or conjunctivitis have been reported after exposure to vapors or accidental splashes. Additional ocular toxic changes may include vacuolar keratopathy, which has been reported in only a few cases with prolonged exposure to high vapor concentrations or to mixed solvents.

Owing to its high vapor pressure, most exposures to xylene and its isomers are by inhalation.

Acute CNS effects are identical to those of toluene and other volatile hydrocarbons. Workers rarely progress to the level of intoxication because the respiratory irritability and odor threshold limit of xylene are such that workers are unlikely to tolerate high exposures necessary to produce these effects.⁴⁹ Nevertheless, animal

studies lend support to the theory that mixed xylene isomers are neurotoxic after inhalation.

Increased theta waves over occipital regions are seen in electroencephalogram results in subjects exposed to xylene peaks of 200 ppm for 4 hours.

Xylenes appear to have very limited capacity to adversely affect organs other than the CNS. Mild, transient liver or kidney toxicity has occasionally been reported in humans exposed to high vapor concentrations of xylenes.

Xylene does not appear to be genotoxic or carcinogenic.

For day-long working conditions, most experimentally exposed subjects have selected 100 ppm as the highest tolerable concentration, with considerable eye irritation in some individuals exposed to 200 ppm in air. Nose and throat irritation from xylene has been reported at 200 ppm for 3 to 5 minutes and 100 ppm for 1 to 7.5 hours per day for 5 days. Chronic occupational exposure to unspecified or unknown concentrations of xylene vapors has been associated with difficulty breathing and impaired pulmonary function. Nose and throat irritation has been reported with increased prevalence by workers who are exposed chronically to xylene vapors at a geometric mean TWA concentration of 14 ppm.

Death was reported in an individual exposed to paint solvents containing primarily xylene at an estimated atmospheric concentration of 10,000 ppm. Autopsy demonstrated severe pulmonary congestion with hemorrhage and pulmonary edema.

Liver necrosis and steatosis have been reported after xylene exposure.

Xylene vapors have a sweet odor that, in conjunction with irritation of the airways and respiratory tract, will cause most individuals to avoid exposure to the compound at high concentrations. Those who may be tolerant of the odor or who remain in the area of airborne xylene may develop headaches, nausea, vomiting, fatigue, dizziness, irritability, insomnia, a drunken feeling, impaired memory, loss of coordination, and unsteady gait, in addition to upper airway and ocular irritation.

Like toluene, xylene can also sensitize the myocardium to the arrhythmogenic effects of catecholamines.

Assays of blood and alveolar air can detect xylene, and its metabolites can be detected in urine. Blood levels of xylene can be affected by coexposure to other solvents. Coexposure to toluene, trichloroethylene, ethylbenzene, methyl ethyl ketone, or alcohol is known to increase xylene blood concentrations by competing for metabolic enzymes. Aspirin decreases methylhippuric acid urinary excretion.

Methylhippuric acid is not normally present in the urine, and methylhippuric acid concentration has, therefore, been proposed as a marker for the biologic monitoring of workers exposed to xylene. In general, methylhippuric acid levels appear to correlate linearly and significantly with the TWA exposure if urine is collected at the end of the daily working period and, preferably, in the latter half of the workweek when urinary metabolites are likely to reach maximum levels.⁴⁷

The BEI for xylene is 1.5 g methylhippuric acid per gram of creatinine in urine collected at the end of the work shift.⁴⁸

See Box 94-1 for acute clinical management.

After an acute splash in the eye, immediate and thorough irrigation with Ringer's lactate solution or saline is recommended. Delayed irrigation, especially in the presence of normal ocular pH, does not seem to be indicated. Removal of particulate chemical matter from ocular surfaces and conjunctival fornices is crucial. If significant corneal edema is present, topical steroids may shorten the course. Xylene keratopathy should be considered in the differential diagnosis of epithelial and stromal vacuolar keratopathy.

In acute symptomatic exposures, xylene may be detectable in blood drawn with a gas-tight syringe, but usually only for a few hours. The metabolite methylhippuric acid is excreted in the urine and can be used to document exposure, but urine levels do not correlate with systemic effects.

There is no antidote. There is no role for enhanced elimination. Disposition is the same as for toluene.

ANTONIO DUEÑAS-LAITA, MD, PHD

At a Glance...

- Fluorocarbons and chlorofluorocarbons (best known by the trade name Freon) are widely employed as refrigerants, aerosol propellants, and solvents. Because of their negative impact on the ozone layer, they are being gradually replaced by other compounds, including hydrogenated chlorofluorocarbons.
- Generally viewed as less toxic than other solvents, fluorocarbons are nonetheless responsible for numerous deaths due to occupational exposures and after intentional abuse.
- Narcosis and cardiac arrhythmias may occur after intense exposures. The pathophysiology of arrhythmia induction in humans is not clear.
- Decomposition of chlorofluorocarbons may lead to production of chlorine, hydrogen fluoride, phosphine, and chloride gases.
- Chlorofluorocarbons may cause eye, nose, and skin irritation as well as potentially severe cryogenic injuries (frostbite).
- Chronic chlorofluorocarbon exposures may lead to neuropsychiatric sequelae.
- Boron hydrides (boranes) are potent irritants that may induce pulmonary edema and central nervous system narcosis.
- Treatment of both fluorocarbons and boranes consists of removal from exposure and good supportive care.
- Hydrazines are potent alkaline compounds, are explosive, and interfere, through multiple mechanisms, with γ -aminobutyric acid production. As such, they may result in seizures that are poorly responsive to usual anticonvulsant therapy. Pyridoxine (vitamin B₆) administration may be life saving.
- Numerous hydrocarbons and substituted hydrocarbons, as well as nitrites, are abused by inhalation. Volatile inhalant abuse may lead to narcosis, seizures, arrhythmias, and sudden death. Chronic abuse of some compounds may result in encephalopathy. Treatment is supportive.

FREON AND OTHER FLUOROCARBONS**Introduction and Relevant History**

Fluorocarbons are halogenated hydrocarbons. The best known is Freon, the commercial name given to the group most commonly used in industry some years ago. Fluorocarbons that contain chlorine are called chlorofluorocarbons (CFCs). CFCs have been used industrially since the 1930s and are generally known by commercial names such as Freon, Arcton, and Frigen. They were initially used by the armed forces in World War II and reached the civilian market in 1947. Because of their unique combination of nonflammability and general inertness, CFCs are used as refrigerants, aerosol propellants, foam-blowing agents, solvents, glass chillers, and polymer intermediates, as well as in fire extinguishers and anesthetics.

Their chemical stability, however, which makes them relatively safe and nontoxic, is also responsible for their potential damage to the environment. Since 1974, it has been believed that CFCs might indirectly affect the stratospheric ozone layer through their ability to transport halogens, particularly chlorine, to this level. By the mid-1980s, a consensus had emerged that atmospheric CFCs could contribute significantly to ozone depletion, and an annual thinning (a “hole”) in the ozone layer over the Antarctic had been reported. Some of the atmospheric chemistry that is believed to occur and some of the measurements performed on the ozone layer are reviewed, together with the environmental regulatory actions that have been taken. These are leading to a controlled rapid phase-out of a number of industrial chemicals, including CFCs.

Production of CFCs ceased in the United States as of December 31, 1995, because of their destructive effect on the ultraviolet radiation shield (ozone) of the atmosphere.¹⁻³ However, these compounds are still available for sale, and some areas have stockpiled supplies. Hydrogenated chlorofluorocarbons (HCFCs), which can be used instead of CFCs, are currently being manufactured with a cease production date of the year 2020, again because their effect on the ozone layer. At that time, hydrogenated fluorocarbons (HFCs) will take the place of HCFCs and CFCs.⁴

CFCs were initially regarded as less toxic in terms of narcosis and other common solvent health effects, and thus higher levels of exposure were permitted. This led to a higher incumbent risk for problems. Many fatal cases associated with the inhalation of CFCs have been reported.⁵⁻¹⁰ Most of these have occurred in work-related incidents or self-induced exposures. The autopsy reports of these cases reflect generic evidence of acute cardiorespiratory failure. It is believed that the toxic action of CFCs occurs through cardiac toxicity or by hypoxic asphyxiation due to CFC saturation of the room atmosphere.^{6,11}

CFCs are known irritants to the upper airway with ambient exposure. They may also cause cryogenic effects on tissue. Liquid CFCs with low boiling points or under pressure can cause freezing of the skin if they come into contact with the body for more than 3 to 5 seconds.¹²

It should be noted that Freon decomposes into chlorine, hydrogen fluoride, phosphine, and chloride gases, all of which are extremely toxic.¹³

Structure

Fluorocarbons are a group of synthetic halogen-substituted methane and ethane derivatives containing atoms of chlorine and fluorine. At least 36 commercially available fluorocarbons exist, of which 10 are produced

TABLE 95-1 Common Chlorofluorocarbons and Their Chemical Formulas

COMPOUND NUMBER	CHEMICAL FORMULA	CHEMICAL NAME
CFC 11	CCl ₃ F	Trichlorofluoromethane
CFC 12	CCl ₂ F ₂	Dichlorodifluoromethane
HCFC 22	CHClF ₂	Chlorodifluoromethane
CFC 13	CClF ₃	Chlorotrifluoromethane
CFC 112	Cl ₂ F—CCl ₂ F	1,1,2,2-Tetrachloro-1,2 difluoroethane
CFC 113	Cl ₂ F—CClF ₂	1,1,2-Trichloro-1,2,2 trifluoroethane
CFC 114	ClF ₂ —CClF ₂	1,2-Dichloro-1,1,2,2 tetrafluoroethane
CFC 115	ClF ₂ —CF ₃	1-Chloro-1,1,2,2,2 pentafluoroethane

New York, John Wiley & Sons, 1994, pp 1177–1220, and American Conference of Governmental Industrial Hygienists, Inc.: *Documentation of the Threshold Limit Values and Biological Exposure Indices*, 5th ed. Cincinnati, OH, ACGIH, 1986

and used in significant amounts. The main CFCs and their chemical structures appear in Table 95-1.

Pathophysiology

Extensive animal studies have found a relationship between CFC inhalation and cardiac arrhythmias, even without evidence of asphyxiation.^{10,14,15} Arrhythmias reported to occur in CFC exposure include ventricular arrhythmias, atrioventricular nodal block, and atrial fibrillation.^{16,17} Reinhardt and associates also reported increased sensitization to arrhythmias when epinephrine was given to dogs with exposure to FC₁₁.¹⁸ It has been postulated that CFCs decrease the ionic permeability of the cellular membranes, leading to transient and localized conduction blocks, altered refractory periods, and disturbance of the pacemaker ability of the heart.^{19,20} Another theory suggests that CFCs do not sensitize the myocardium to endogenous catecholamines but have a depressant effect on the sinus atrioventricular and ventricular conduction systems, allowing other ectopic foci to produce arrhythmias.²¹

Despite the fatal exposures and reports of arrhythmia, the documentation of arrhythmias caused by CFCs in human subjects is ambiguous. Egeland and colleagues²² found no significant difference in atrial or ventricular premature beats, heart rate, or PR intervals in a group of 16 aerospace workers with high and low exposures. Edling and coworkers²³ studied 89 refrigerator repairmen and concluded that CFCs do not induce arrhythmias in exposed workers. However, the frequency of arrhythmia was high in these men regardless of exposure. No clear connection was found by Antti-Poika and colleagues,⁸ but one subject had ectopy that may have been related to exposure. Although ectopy or other arrhythmias occurring with CFC exposure have not been associated with underlying heart disease, increased circulating concentrations of catecholamines may make patients prone to arrhythmia.⁵ Caffeine intake, physical

activity, and tobacco use have been suggested to have a proarrhythmic effect.²³

Pharmacokinetics

CFCs are absorbed rapidly by inhalation, whereas oral absorption is slower and more complicated. The distribution half-life is rapid in comparison with elimination because of the slow release from fat stores. Clark and colleagues²⁴ reported three fatalities due to Freon exposure, and these patients had the highest concentrations in brain tissue, reflecting the high solubility of hydrocarbons. An individual who suffered a fatal exposure secondary to FC₁₁₃ that had vaporized out of the sludge collection pit in glass lens manufacture also showed high levels in brain tissue.⁹ High concentrations in heart tissue of people suffering fatal exposures have also been found.^{6,7} Lung concentrations reported in all human cases are low, and this is probably a reflection of resuscitative efforts. Elimination half-life is 1.5 hours, probably as a result of its slow liberation from fat stores.

Clinical Manifestations

Transient low-concentration CFC exposures result in eye, nose, and throat irritation. Frostbite of the oral cavity has been described after deliberate inhalation of a propellant.²⁵ Pulmonary irritation, bronchial constriction, cough, dyspnea, and chest tightness may develop after inhalation. Pulmonary edema is an autopsy finding in fatal inhalation cases.^{6,26} Edema may be secondary to aspiration or decomposition products of CFCs, which include chlorine, hydrogen fluoride, phosphine, and chloride gases.

Neurologic sequelae of CFCs involve a spectrum of symptoms that include headache, lightheadedness, dizziness, and disorientation. Workers with chronic exposure to CFC 113 were found to have impaired psychomotor speed, impaired learning and memory, and emotional lability.²⁷ Cerebral edema has been found at autopsy.²⁶

Toxic exposures to CFCs have been associated with fatal ventricular arrhythmias, atrial fibrillation, and sudden death.^{11,14-17,24} However, no clear connection with low-concentration exposure and cardiac arrhythmias has been documented.^{8,22,23}

Freon exposure causing severe frostbite has been reported,¹² and a related case of compartment syndrome required amputation of the digits.²⁸ Direct accidental injections have also occurred, and these respond to conservative therapy with minimal tissue damage.^{29,30}

Other rare toxic effects include gastric perforation secondary to ingestion, elevation of transaminase levels, jaundice, contact dermatitis, and rhabdomyolysis.³¹⁻³⁵

Management

The first step in the management of CFC exposure is to remove the offending agent, avoiding exposure to other subjects. Attention to airway, breathing, and circulation with supplemental oxygen, symptomatic therapy, and a calming environment to avoid endogenous adrenergic

stimulation are important. Use of adrenergic drugs should be avoided to prevent myocardial stimulation. Use of countershock or phenytoin may be indicated for ventricular arrhythmias. Digestive decontamination techniques (gastric lavage, activated charcoal) are not normally used because the ingestion of CFCs is exceptional. There is no antidote, and extrarenal purification techniques do not work.³⁶

If frostbite occurs, the exposed area should be soaked in lukewarm water if possible within 20 to 30 minutes after exposure. Ice or heat should not be applied. A light coating of a bland ointment, such as petroleum jelly, should be applied and covered with a light bandage. Ocular injuries should be irrigated and assessed for injury.

BORON

Introduction and Relevant History

Boron hydrides are highly toxic chemical compounds composed of boron and hydrogen. Inhalation, ingestion, or percutaneous exposure to boranes can result primarily in pulmonary, gastrointestinal, or central nervous system (CNS) toxicity.

Boranes are used mainly in high-energy fuels such as rocket propellants but are also used in semiconductor manufacturing and welding and as fungicides and bactericides. They are also used as initiators of ethylene, styrene, vinyl, and acrylic polymerization and in the vulcanization of rubber. In recent years, they have also been employed in the automobile airbag industry.^{37,38}

Structure

Boron hydrides are produced by the reaction of lithium aluminum hydride with boron fluoride to make diborane, and pyrolysis of diborane produces the remaining boranes. The three most commonly encountered in industry are diborane (B_2H_6), a colorless gas with a sickly sweet, nauseating smell, like rotten eggs; pentaborane (B_5H_9), a colorless volatile liquid with a sweetish, garlic-like, unpleasant odor; and decaborane ($B_{10}H_{14}$), a white crystal with an intense bitter chocolate odor. These compounds oxidize easily, are strong reducing agents that are highly flammable, and may ignite or explode in the presence of oxygen.

Pathophysiology

Boranes are highly toxic by inhalation, skin absorption, or ingestion. They may produce both acute and chronic poisoning.

Diborane gas is primarily a pulmonary irritant at 0.1 ppm. Inhalation exposure results in hydrolysis to boric acid and hydrogen.³⁹ Acute exposure causes pulmonary edema and hemorrhage as well as temporary damage to the liver and kidneys. Autopsies reveal rhinitis, pneumonia, and structural lung damage.^{40,41}

Pentaborane and decaborane vapor affects the nervous system and causes signs of both hyperexcitability and narcosis.⁴² Pentaborane is considered to be the most toxic of the boron hydrides when inhaled, although it is also readily absorbed through intact skin. CNS norepinephrine depletion, intracranial hypertension, and cortical atrophy have been demonstrated after exposure to pentaborane and decaborane. These agents also cause gastrointestinal toxicity, with fatty necrosis of the liver and elevation of transaminase levels.

Direct myotoxic effects of the boron hydrides as well as myoclonus and seizures can result in rhabdomyolysis and myoglobinuria.

Clinical Manifestations

Acute diborane poisoning in humans results in a syndrome like that of metal fume fever, with symptoms of tightness, heaviness, and burning in the chest; cough; shortness of breath; pericardial pain; nausea; shivering; and drowsiness. Signs of intoxication may occur soon after exposure or after a latent period of up to 24 hours and may persist for 1 to 3 days or more. Long-term exposure to low concentrations results in pulmonary irritation, dizziness, headaches, weakness, and tremors.

Drowsiness and nausea may occur with slight pentaborane toxicity. In moderate exposures, headaches, dizziness, nervous excitation, and hiccups may occur. Muscle pain and spasms of the muscles of the face and extremities may be noted. In more severe exposures, after 48 hours, patients may suffer loss of mental concentration, incoordination, disorientation, cramps, convulsions, and coma. On certain occasions, there have been reports of intense acidosis.^{43,44}

Decaborane toxicity in humans produces symptoms of restlessness, aggressiveness, depressed breathing, incoordination, general weakness, spasmodic movements, and convulsions.

Sometimes, symptoms of acute toxic exposure may take several hours to develop and may persist for days. Chronic liver, kidney, and CNS impairments can result from significant exposures. Low-level exposures over time may cause CNS symptoms, including poor decision making and concentration, as well as apparent psychiatric symptoms of poor emotional control and personality change.

Management

People exposed to boron hydrides should be immediately removed from the exposure. After contaminated clothing has been removed, victims' skin should be thoroughly washed with water. There is no known antidote for borane poisoning. Treatment is symptomatic and supportive. If high-level inhalation has occurred, hospitalization for 48 to 72 hours is recommended to monitor cardiopulmonary function, acid-base balance, and neurologic status.

As regards preventive steps, it should be made clear that toxic levels of some boron hydrides are below the odor threshold for humans. Exposure to others with a scent, in higher concentration, may cause loss of ability to detect an odor. Therefore, great caution must be used when working around these substances. Personal protective equipment should be used to prevent inhalation, skin, or mucous membrane exposure.

HYDRAZINES

Introduction and Relevant History

Hydrazine (NH_2NH_2) is a colorless, oily, fuming liquid that is used in agricultural chemicals, the space industry, and medicine. It is also used in photographic developing and in the manufacturing of drugs, herbicides, dyes, textile treatments, explosives, and plastics.⁴⁵ Hydrazine is also a powerful explosive, used as a rocket fuel, and can self-ignite when adsorbed onto earth, cloth, wood, and asbestos. It emits toxic nitrogen compounds when heated to decomposition. Its vapors are heavier than air and have an ammonia or fishy odor.⁴⁶

Pathophysiology

Hydrazines are poisonous by ingestion and by intravenous and dermal routes. Their toxicity occurs in multiple organ systems, and they are known carcinogens. Hydrazine and its metabolite monoacylhydrazine are hepatotoxic, causing nuclear and nucleolar enlargement, mitochondrial swelling, and increased formation of antibodies and free radicals.^{47,48} Because acetylation is the pathway for metabolism, toxicity may be more common in people who are slow acetylators.

Hydrazine is also known to produce a functional pyridoxine deficiency through inhibition of synthesis or deactivation of coenzymes.⁴⁹ Pyridoxine may be useful for treatment.

Other toxicities caused by hydrazine include a direct CNS toxicity, a negative inotropic effect on the heart leading to cardiovascular depression and hypotension, and hemolysis leading to acute tubular necrosis or nephritis.

Clinical Manifestations

Hydrazines are local irritants causing ocular irritation, facial edema, salivation, and dermal irritation. Even low concentrations can cause bronchial mucous destruction and pulmonary edema. Other symptoms are nausea, vomiting, dizziness, and agitation.

Anemia due to hemolysis has been reported and can lead to renal dysfunction.⁵⁰ This blood loss can also worsen a patient's cardiovascular status and lead to progressive weakness and dyspnea.

Manifestations of the liver disease include hypoglycemia and hyperglycemia, depending on a patient's glycogen stores. In extreme situations, a fatal hepatorenal failure may result.⁵¹

Finally, among CNS manifestations, severe encephalopathy and seizures are the most significant disorders.^{52,53}

Management

Prompt removal of the irritant and basic life support measures are key. Dermal exposure should be treated immediately with soap and water. Ocular exposure requires copious irrigation with tepid water.

Respiratory exposure should be treated with humidified supplemental oxygen and monitoring for respiratory distress. Chest radiographs, arterial blood gas determinations, and intubation may be clinically indicated.

Oral exposures may be treated with gastric lavage and activated charcoal. Emesis must be induced with caution because delayed neurologic effects, such as seizure and coma, may occur. This is dependent on the chemical ingested, the volume, and the duration of exposure.

Pyridoxine may be antidotal in hydrazine ingestions. The recommended dose for patients with neurologic symptoms is 70 mg/kg over 30 minutes intravenously, repeated as necessary, with a maximum of 15 g/day. These amounts should be respected because of the risk for peripheral neuropathy associated with the use of pyridoxine. Seizures are treated also with routine medications, including diazepam, lorazepam, or phenytoin, and phenobarbital. Other routine laboratory studies include monitoring blood glucose, liver function tests, and hemoglobin measurement. If methemoglobinemia exists at a level greater than 30%, methylene blue should be used, 1 to 2 mg/kg slowly every 4 hours as needed. The remaining treatment is supportive: fluid therapy, glucose in the case of hypoglycemia, conventional treatment of hepatic insufficiency if need be, and other maintenance measures.

ACROLEIN

Introduction and Relevant History

Acrolein, a colorless or yellowish liquid with a disagreeable odor, is ubiquitous in the environment. It is a highly toxic, reactive, and irritating aldehyde that occurs as a product of organic pyrolysis, as a metabolite of a number of compounds, and as a residue in water when used for the control of aquatic organisms. It is an intermediate in the production of acrylic acid, DL-methionine, and numerous other agents. Its major direct use is as a biocide for the control of aquatic flora and fauna. It is used also in the manufacturing of pharmaceuticals, food supplements, perfumes, plastics, and textiles. It is also present in cigarette smoke.⁵⁴

It enters the environment through a variety of sources, including organic combustion such as automobile exhaust, cigarette smoke, and manufacturing and cooking emissions, as well as direct biocidal applications. Organic combustion from both fixed and mobile sources is the significant source of acrolein in the atmosphere;

it represents up to 8% of all aldehydes generated by vehicles and residential fireplaces and 13% of all atmospheric aldehydes. This reactive aldehyde also occurs in organisms as a metabolite of allyl alcohol, allylamine, spermine, spermidine, and the anticancer drug cyclophosphamide, and as a product of ultraviolet radiation of the skin lipid triolein. Furthermore, small amounts are found in foods; when animal or vegetable fats are overheated. However, large amounts may also be produced. Most human contact occurs during exposure to smoke from cigarettes, automobiles, industrial processes, and structural and vegetation fires. Besides cigarette smoke, occupational exposures are a common mode of human contact, particularly in industries that involve combustion of organic compounds. Firefighters, in particular, are exposed to extremely high levels during the extinguishing and overhaul phases of their work.

Pathophysiology

Most exposures to acrolein occur through inhalation. Acrolein is a severe pulmonary irritant and lacrimating agent. The strong irritant effect usually prevents serious exposures, but fatalities have been reported.⁵⁵ Studies suggest that pulmonary insult from acrolein is due to alterations of the plasma membrane–dependent transport system in the pulmonary artery endothelial cells as well as to the intracellular generation of oxidants.^{56,57}

Skin and corneal burns may result from direct contact with the liquid. Concentrations of 0.25 ppm may cause eye irritation.

Clinical Manifestations

Splash contact may cause irritation, erythema, edema, and actual burns. Difficulty breathing, chest congestion, delayed pulmonary edema, asthma, bronchiectasis, and permanent lung damage may result from acute exposures. Nausea and vomiting are common. Ingestion may produce severe irritation of the mouth and gastrointestinal tract. Hypertension and tachycardia may result from inhalation. Inhalation can also cause loss of consciousness and coma.^{58,59}

Management

Because the primary toxic effects of acrolein involve irritation of the mucous membranes, lungs, and skin, removal of the agent is paramount. Washing with soap and water and irrigation of the eyes with tepid water are appropriate. If pain and burning persist, repeat examination is necessary.

Pulmonary support should be given as needed, including oxygen, intubation, and mechanical ventilation. Arterial blood gas measurement and chest radiograph are used to assess and monitor respiratory status. Patients with high-volume exposure may require hospitalization to be observed for delayed sequelae such as pulmonary edema.

Ingestion should be treated with gastric lavage followed by activated charcoal and cathartics. Gastric

lavage should not be used in patients with neurologic deterioration without airway protection.

All other treatment is supportive and symptomatic. The use of steroids remains controversial. Antibiotic use should be aimed at treating specific infections and should not be used as a prophylactic measure.

VOLATILE INHALANT ABUSE

Introduction and Relevant History

Inhalants or volatile substances are a broad heterogeneous group of substances with differing structures and toxic effects. Their study as a toxicologic entity is determined by their abuse as inhalant drugs. All are volatile and liposoluble and have good pulmonary absorption, which avoids first pass metabolism in the liver; in addition, a small quantity produces a rapid effect on the CNS.

In general, these substances are cheap and legally obtainable. From an epidemiologic point of view, the rate of abuse of volatile substances varies greatly from country to country, although in the United States or Great Britain, for instance, this problem causes up to 100 deaths every year.⁶⁰ In those areas where the problem exists, 13- to 15-year-olds are mainly affected, yet there are cases involving 8- to 19-year-olds.^{61,62}

Structure

The chief substances are (1) aerosols, including fluorocarbons (Freon) and isobutane; (2) aliphatic hydrocarbons, including n-hexane, ethane, acetylene, butane (lighter fuel), and isopentane; (3) general anesthetics, including nitrous oxide, ether, chloroform, enflurane, halothane, and isoflurane; (4) aromatic hydrocarbons, including benzene, toluene, xylene, styrene, and naphthalene; (5) esters, including ethylacetate, and isopropyl acetate; (6) fuels, including gasoline and naphthalene; (7) halogenated hydrocarbons, including carbon tetrachloride, trichloroethane, perchloroethylene, methylene chloride, methylchloroform, and fluorocarbons; (8) ketones, including acetone, methyl-n-butyl-ketone, and methylethyl ketone; and (9) nitrites, including amyl nitrite (“poppers” among the gay community), isobutyl nitrite, and butyl nitrite.⁶³

Patients who abuse these substances normally obtain them as products containing them, such as acrylic paints, adhesives, propellants, aerosols, stain removers, degreasers, dry-cleaning agents, nail polish removers, gasoline, glues, paint thinners, room fresheners, lighter fluid, shoe polish, and correction fluids.

Pharmacokinetics

There are various ways of inhaling these products: (1) sniffing—breathing in directly from the container; (2) huffing—placing a rag soaked in solvent over the nose and mouth and inhaling; and (3) bagging—inhalation from a paper or plastic bag. The concentration of

inhaled substances increases from sniffing to huffing to bagging. After one or two inhalations, the effects begin in a few seconds and last several minutes. Periodic inhalations, the most common use pattern, maintain the effects over several hours.⁶⁴

Volatile inhalants are rapidly absorbed by the alveolus and rapidly distributed to the central nervous system and lipid-rich tissues. Some of them can also be absorbed through the skin. Plasma concentrations are associated with the blood–air partition coefficient of each inhalant. Many inhalants are, in addition, eliminated mainly through the lungs. Several undergo hepatic transformation with the appearance of metabolites, which can be detected in the urine.

Clinical Manifestations

After inhaling for a few minutes, the user starts to notice a feeling similar to drunkenness, together with, among other effects, impaired perception, euphoria, a loss of inhibitions, and a pleasant dizziness. It has been pointed out that nitrites can increase the intensity of and prolong orgasm, as well as relax the muscles, thereby facilitating anal penetration. Such effects last between 15 and 45 minutes.

Acute toxicity requiring emergency room admission fundamentally involves arrhythmias or other serious cardiovascular manifestations, including ventricular fibrillation, ventricular and supraventricular tachycardia, bradycardia, myocardial depression, and hypotension. On occasions, these problems cause the patient to die, as a result of which *sudden death syndrome* by inhalants has come into modern-day parlance. Apparently, certain acute cardiac manifestations are caused by sensitivity to catecholamines produced by volatile substances.⁶⁵

Acute disorders may also affect the CNS, producing incoordination, delirium, agitation, hallucinations, central depression (dizziness, blurred vision, headache, stupor, lethargy, ataxia, coma), respiratory depression, and seizures. On other occasions, patients present with digestive disorders, such as nausea, vomiting, abdominal pain, hematemesis, and necrosis of the liver (with trichloroethylene, among others). In exceptional cases, reports exist of laryngospasm, pulmonary aspiration with consequent chemical pneumonitis, methemoglobinemia (more commonly occurring with the ingestion rather than the inhaling of nitrites), and elevated carboxyhemoglobin (methylene chloride).

In addition to acute cases, there is evidence that chronic abuse of these substances may induce long-term neurologic toxicity in up to 65% of nonsporadic users. Neurologic alterations in heavy long-term abusers are probably due to the action of neurotoxins on neuronal membranes. Findings include spastic motor neuropathy, cognitive dysfunction, personality changes, problems with hearing and sense of smell, cerebellar dysfunction, Parkinson's disease, and optic neuropathy. Magnetic resonance imaging has revealed that toluene causes irreversible changes in brain white matter.⁶⁶ In certain instances of neurologic toxicity, there is peripheral

neuropathy; this is the case of glues or adhesives containing n-hexane or methyl-n-butyl-ketone.

With regard to the digestive system, chronic abuse may bring about lack of appetite and weight loss. Hepatotoxicity is associated with chronic exposure to carbon tetrachloride, toluene, and trichloroethylene. In the case of toluene, reports also exist of renal tubular acidosis, metabolic acidosis, hypokalemia, muscle weakness, and rhabdomyolysis; benzene can induce aplastic anemia.^{66,67}

In recent years, there has been speculation that inhaling solvents during pregnancy produces fetal solvent syndrome, similar although not identical to fetal alcohol syndrome. Toluene is the agent most commonly related with this disorder.^{68,69}

Diagnosis

A diagnosis of arrhythmia or any other acute complaint associated with the abuse of volatile substances is a simple one if the patient cites previous use; however, it is difficult if no such reference exists in the clinical history. The detection of substance remains around the mouth or the appearance of “glue sniffer's rash” can aid in the diagnosis.

Conventional toxicological analysis is seldom helpful, but one occasionally observes metabolic acidosis with hyperchloremia or anion gap, methemoglobinemia (nitrites), or elevated carboxyhemoglobin (methylene chloride). Certain special types of analysis may have an *posteriori* clinical and legal interest but are rarely available in the hospital: hippuric acid (toluene), methyl hippuric acid (xylene), trichloroethanol, and trichloroacetic acid in urine.⁷⁰

Management

Treatment should be strictly individual. General monitoring of the airway, respiratory support, electrocardiogram monitoring, pulse oximetry, and chest radiography (to watch for the appearance of aspiration pneumonitis) are applicable in many cases. There are no specific antidotes, with few exceptions (discussed later). In the case of contamination of the skin or mucosa, these should be washed with abundant water.

As regards arrhythmia management, adenosine has been proposed for supraventricular tachyarrhythmias and lidocaine for ventricular tachycardia, with counter-shock with or without defibrillation suggested if no response is achieved. In the case of bradycardia, initial treatment should be with atropine, and if this fails, an external or transvenous pacemaker should be used.

Care should be taken with sympathomimetic vaso-pressors because these could trigger arrhythmias as a result of sensitivity to catecholamines induced by solvents.

For cases of agitation or delirium and convulsions, intravenous benzodiazepines are recommended. If methemoglobinemia induced by nitrites is above 30%, methylene blue (1–2 mg/kg intravenously over 10 minutes) should be administered. Further management should be symptomatic.⁷¹

96 Halogens (Bromine, Iodine, and Chlorine Compounds)

ALBERTO PEREZ, MD ■ CHARLES MCKAY, MD

At a Glance...

- The halogens are potent oxidizers and irritants, frequently used as antiseptics.
- Chronic bromide intoxication presents predominantly as a neuropsychiatric degenerative disorder.
- Acute ingestion of bromates found as neutralizers in cold-wave hair permanent kits can result in vascular collapse, renal failure, and sensorineural hearing loss.
- Acute iodine exposures result in severe skin, mucous membrane, and gastrointestinal injury.
- Chronic iodide toxicity can present as sialorrhea, coryza, bronchorrhea, and salivary gland enlargement, as well as hypothyroidism.
- Iodophors (organic iodine compounds) have little free iodine and are less toxic than iodine or iodide salts.
- Mixing chlorine-containing bleach (sodium hypochlorite) with acids or ammonia results in the release of chlorine gas or chloramine gas, respectively.
- Chlorine inhalation can produce delayed-onset pulmonary edema; early clinical presentation is predictive of short-term sequelae.
- Symptomatic severe chlorine inhalation can result in reactive airways dysfunction syndrome.
- Halogenated disinfection by-products are generated during disinfection of water containing large amounts of organic wastes.
- In large quantities, halogenated disinfection by-products cause reproductive abnormalities and bladder or rectal cancer in animals.
- Bromide and iodide can interfere with the analytic detection of chloride by certain instruments, resulting in pseudohyperchloremia.

Fluorine, chlorine, bromine, and iodine are collectively known as the *halogen elements*, and their ionic (salt) forms are known as fluoride, chloride, bromide, and iodide. They are strongly electronegative agents with potent oxidizing ability. Except for bromine, these are essential nutritional elements. This chapter reviews bromine, iodine, chlorine and their related compounds. Fluoride compounds are discussed in Chapter 90, whereas effects of and response to radioactive iodine compounds is covered in Chapter 104.

BROMINE COMPOUNDS: BROMIDE, BROMATE, AND BROMINE

Introduction and Relevant History

Bromides were historically prescribed as sedative-hypnotics and anticonvulsants in the mid 1800s.¹ They remained the mainstay anticonvulsant therapy until the

advent of barbiturates in the 1920s. Their widespread use as anxiolytics led to the admonition to “take a bromide.” Organic bromides, also known as *bromureides*, have been less commonly used.

In addition to acute sedative and anticonvulsant effects, chronic bromide ingestion produces a number of neuropsychiatric changes. In retrospective studies, it was found that many patients who were hospitalized in psychiatric institutions in the mid-20th century in fact had bromide intoxication.² Bromide psychosis has been described after prolonged use of bromide-containing medication (pyridostigmine, dextromethorphan).³⁻⁵ Historically, Bromo-Seltzer and Miles Nervine were once associated with widespread cases of bromide intoxication.^{1,6}

Dietary bromide exposure occurs in all humans because bromides can be found in trace amounts in natural soils and waters (e.g., igneous rock contains 0.02 mmol/kg bromide; fresh water contains 0.05 to 10 mmol/L, and seawater contains 0.4 to 0.8 mmol/L). Vegetables may contain bromide residues as a result of soil fumigation with methyl dibromide and ethylene dibromide.

Bromide salts are currently found in photographic chemicals (e.g., activators and developers), fire extinguishers, and refrigerants, as well as several medications (Table 96-1). Pharmaceutical bromides can be divided into inorganic bromide salts (NaBr, KBr, NH₄Br, and

TABLE 96-1 Bromide-Containing Medications

MEDICATION	% BROMIDE
Acecarbromal	29
Ammonium bromide	80
Bromisovalum	36
Bromodiphenhydramine	24
Carbromal	34
Dextromethorphan hydrobromide	23
Pyridostigmine bromide	31
Brompheniramine maleate	25
Halothane hydrobromide	81
Homatropine methylbromide	29
Neostigmine bromide	38
Bromocriptine	12
Pancuronium bromide	37
Potassium bromide	67
Propranolol bromide	18
Quinine hydrobromide	17
Vecuronium bromide	25
Scopolamine hydrobromide	29

CaBr₂) and organic bromides (e.g., brompheniramine). Detectable serum bromide concentrations have been reported 3 weeks after prolonged anesthesia with halothane.⁷ Ingestion of dextromethorphan, a common over-the-counter cough suppressant, has been associated with significant bromide absorption.⁸ Unusual but significant exposures to bromide have resulted from consumption of large amounts of bromide-containing soft drinks and from exposure to cleansing compounds containing bromide and over-the-counter medications.⁹⁻¹¹

Pharmacology

Bromine has a weight of 79.9 daltons. Daily bromide intake of more than 1 g may result in sedation, corresponding to serum concentrations of greater than 5 mEq/L (40 mg/dL). The primary pharmacologic action of bromide is a central nervous system (CNS) membrane-stabilizing effect that results in sedation and an elevated seizure threshold–anticonvulsant effect. This effect may result from the disturbance of active and passive transport of chloride across neuronal membranes.

Pharmacokinetics

Bromides are well absorbed from the gastrointestinal (GI) tract. Their oral bioavailability is about 96%, and peak serum concentrations are reached within 2 hours. Bromide has a low volume of distribution (0.35–0.48 L/kg) and tends to concentrate in erythrocytes and neurons.^{12,13}

Serum bromide concentrations are expressed in several units, including mEq/L, mg/L, mg/dL, and mmol/L. The interpretation of recorded values is therefore subject to considerable confusion. Because of bromide's close relationship with chloride, its serum concentrations are best expressed in the equivalent mEq/L or mmol/L. Unit relationships are as follows:

$$0.1 \text{ mg/dL} = 1 \text{ mg/L} = 0.0125 \text{ mEq/L} = 0.0125 \text{ mmol/L}$$

Bromide is readily filtered by the glomeruli. Once in the tubular lumen, bromide competes with chloride for reabsorption with tubules having a higher affinity for bromide ion; therefore, chloride is preferentially excreted under typical circumstances. As a result, prolonged administration of bromide results in significant total-body loss of chloride. An intimate relationship exists between in situ chloride and bromide concentrations; the body maintains the molar sum of chloride and bromide ion at about 110 mmol/L.¹² The elimination half-life of bromide is 7 to 12 days; this half-life is increased with a salt-deficient diet.^{1,11,12} Average renal bromide clearance is about 26 mL/kg per day. Bromide readily diffuses across the placenta and accumulates in fetal tissues. It is also secreted into breast milk.

Toxicology

Acute bromide intoxication is uncommon. Bromide salts are extremely irritating to the GI tract, generally

resulting in spontaneous emesis. Although animal studies have reported LD₅₀ in the range of 2 to 5 g/kg, the reported human lethal dose is as low as 14 mg/kg. Nonetheless, experimental administration of up to 9 mg/kg/day of bromide for 12 weeks was reported to cause difficulty with concentration and sleepiness only. Bromide intoxication usually results from long-term overmedication, resulting in *bromism*.

Bromism is a clinical syndrome that consists of GI, dermatologic, and CNS manifestations (Box 96-1). GI manifestations include nausea, vomiting, a fetid odor on the breath, anorexia, and weight loss.² Dermatologic manifestations are found in as many as 30% of those with bromism²; *bromoderma* is the name given to the associated skin lesions. The most common lesion is an acneiform eruption on the face. Another frequent finding is an eruption resembling ecthyma, appearing on the lower extremities (nodose bromoderma). Other skin lesions include pemphigus-like, bromide-filled vesicles on the lower extremity, erythema multiforme, pyoderma gangrenosum, and bromoderma tuberosum (tumor-like lesions).

The neurobehavioral signs and symptoms of bromism are prominent. Behavioral disturbances include the appearance of a bromide dementia characterized by delirium, agitation, auditory and visual hallucinations, depression, and schizophrenic and manic-depressive psychosis. Hallucinoses may occur with an otherwise clear consciousness. Neurologic manifestations of bromism include dysarthria, hyporeflexia, and coma. An increased cerebrospinal fluid protein level occurs in 2% to 40% of patients.¹⁴ Low-grade fever may be found in as many as 25% of cases.² Neurologic signs of bromism are slow to resolve and lag behind the decrease in serum bromide concentration because of the slow diffusion of bromide out of the CNS.¹³ Among those who present with obtundation or coma, retrograde amnesia may develop. Ocular findings may also be striking in bromide intoxication and may consist of mydriasis, color disturbances, blurred vision, and micropsia or macropsia.

BOX 96-1

CLINICAL MANIFESTATIONS OF BROMISM

Behavioral	Neurologic	Laboratory
Delirium	Dysarthria	Pseudohyperchloremia
Hallucinations	Hyporeflexia	Low or negative anion gap
Agitation	Encephalopathy	
Amnesia	Fever	
Depression	Papilledema	
Mania	Ataxia	
	Tremor	
Gastrointestinal	Dermatologic	Ocular
Nausea, vomiting	Facial acneiform eruption	Mydriasis
Abdominal pain	Nodose bromoderma	Color disturbances
Halitosis	Bromide-filled vesicles	Blurred vision
Anorexia		Micropsia
Weight loss		Ocular bobbing

These latter two syndromes are perceptual distortions in which objects appear smaller or larger, respectively, than they actually are. Ocular bobbing (opsoclonus) has been described in a patient with bromide encephalopathy.¹⁵ Papilledema is occasionally found on fundoscopic evaluation.

Bromide ingestions of 9 mg/kg/day have been associated with modest increases in serum thyroxine and triiodothyronine concentrations.¹⁶

Because of its ready diffusion across the placenta, bromide accumulates in the fetus and can produce neonatal bromism. Clinical features of neonatal bromism are CNS depression, hypotonia, and weak suck and cry.^{17,18} CNS manifestations of bromism are thought to be more prominent in neonates because their larger brains (15% of body weight versus 2% of body weight in an adult) are the storage site of a large bromide pool.¹⁸ Bromide also appears to be teratogenic.¹⁷

Diagnosis

The diagnosis of bromide toxicity is clinical. Direct laboratory measurement of serum bromide concentrations supports the diagnosis but is not readily available. Serum bromide concentrations can be measured by a gold chloride colorimetric procedure, ion-exchange chromatography, and coupled plasma mass spectrometry.^{8,19,20} Normal “background” bromide serum concentrations in adults are 0.03 to 0.06 mEq/L. Although serum bromide concentrations do not consistently correlate with severity of intoxication, levels greater than 12.5 mEq/L are associated with important clinical toxicity. Serious toxicity occurs when serum concentrations exceed 25 mEq/L. Serum concentrations of greater than 37.5 mEq/L may be lethal. Elderly and debilitated patients, especially those on salt-restricted diets or with congestive heart failure, hypertension, or chronic renal failure, manifest toxicity at lower levels.

Although total-body chloride is decreased with chronic bromide use, measured serum chloride concentrations may be elevated after bromide intake (pseudohyperchloremia).²¹ Serum chloride concentrations as high as 282 mEq/L have been reported with bromide intoxication.²² Despite the artifactual chloride elevation, the degree of elevation cannot be used to estimate serum bromide concentration. The pseudohyperchloremia of bromide intoxication can result in a low, even negative, anion gap, which can be diagnostic.²³ With high bromide concentrations, negative anion gaps as low as -60 mEq/L can occur. The physician should be cognizant of potential significant analytic interference by other halogens.

Management

There is no role for GI decontamination in chronic intoxications. In the rare case of acute bromide ingestion, emesis will probably have occurred. Aggressive GI decontamination (ipecac, gastric lavage) is not warranted. We would not expect significant amounts of bromide ion to be adsorbed to activated charcoal.

Organic bromides may be well adsorbed to charcoal; thus, the administration of charcoal after organic bromide ingestion is reasonable.

Neutral diuresis with intravenous sodium chloride will accelerate renal excretion. Urine output should be maintained at 3 to 6 mL/kg/hr. Saline diuresis reduces bromide half-life to 2 to 3 days. The use of mannitol or furosemide can further reduce bromide half-life and is helpful in avoiding fluid overload. Hemodialysis is effective in removing bromide (elimination half-life of 2 hours), but the clinician must be aware of postdialysis redistribution rebound. The end point of treatment is symptomatic improvement and, if accessible, a bromide determination less than 6 mEq/L. Correction of pseudo-hyperchloremia, if present, could serve as a screen for bromide clearance, although true hyperchloremia as a result of overaggressive saline infusion may interfere with interpretation.

BROMATES

Introduction and Relevant History

Bromate salts (KBrO_3 , NaBrO_3) are highly water-soluble oxidizing agents. These agents are used widely to bleach flour and produce explosives. Potassium bromate is almost completely converted to potassium bromide during the bread-baking process. Bromates are also found in the “neutralizers” that are part of cold-wave hair permanent kits, which contain either 2% potassium bromate or 10% sodium bromate.²⁴ A wave of bromate-containing hair permanent kit suicidal ingestions in the 1960s and 1970s that culminated in renal failure led to a clinical syndrome known as *hairdresser's anuria*.²⁵⁻²⁷

Pharmacology and Pharmacokinetics

Bromates are colorless, odorless, tasteless compounds that are readily absorbed from the GI tract. Once absorbed, a small amount of bromate ion may be reduced to bromide, and modestly elevated serum bromide concentrations result. Serum bromate concentrations are not readily measurable, and thus toxic serum bromate concentrations are unknown. Bromates are excreted unchanged in urine.

The lethal dose of potassium bromate has not been established in humans, but the LD_{50} in animal experiments range from 160 to 500 mg/kg. Life-threatening toxicity has occurred in children who ingested as little as 2 to 4 ounces of 2% potassium bromate solution.²⁵ Potassium bromate appears to be more toxic than sodium bromate.

Toxicology

Symptoms of bromate intoxication are diverse (Box 96-2). Manifestations appear within 2 hours of ingestion and begin with the GI effects of nausea, vomiting, diarrhea, and abdominal pain. These are thought to result from the formation of irritating hydrobromic acid

BOX 96-2

CLINICAL MANIFESTATIONS OF BROMATE INTOXICATION

Gastrointestinal	Renal	Auditory
Nausea Vomiting, diarrhea Abdominal pain	Acute renal failure Uremia	Sensorineural hearing loss
Central Nervous System	Cardiovascular	
Encephalopathy Seizures	Hypotension	

in the gut. Cardiovascular instability with hypotension may be an early manifestation with severe exposures.

Nephrotoxicity and ototoxicity are the hallmarks of bromate intoxication. Acute renal failure (ARF) varies from mild and transient to severe anuric form. ARF usually appears 1 to 3 days after ingestion. Renal failure occurs in 90% to 100% of patients with significant bromate intoxication and historically was the most common cause of death. In children, bromate-induced ARF typically resolves within 1 to 3 weeks of onset. In adult case series, however, many victims eventually develop chronic renal failure or persistent renal tubular acidosis.^{14,24,27} Pathologic findings in the kidneys consist of acute tubular necrosis with relative glomerular sparing. Tubular histopathology consists of karyorrhexis, karyolysis, and lymphocytic interstitial infiltrates. Later changes consist of scarring, interstitial fibrosis, and glomerular sclerosis.²⁴

Bromate ototoxicity can result in permanent sensorineural hearing loss with intact vestibular function. The mechanism of this effect is unclear; it may be related to damage of the stria vascularis with degenerative changes in the outer hair cells of the cochlea.²⁴ Deafness has been reported in as many as 85% of adults with significant bromate poisoning but is less frequent in children. Tinnitus and decreased hearing may appear as early as 4 to 6 hours after ingestion.²⁸

Other toxicities of bromate poisoning include encephalopathy, myocarditis, and hepatitis.²⁴ Encephalopathy is typically manifested as agitation, delirium, seizures, and coma. A peripheral neuropathy with burning in the feet has also been described in adults. The neuropathy usually manifests 1 to 2 months after the ingestion and is self-limited, with typical duration of 1 month.²⁴ Anemia may also be seen, resulting from microangiopathy, a clinical picture resembling hemolytic-uremic syndrome.²⁶

Management

General management principles apply to unstable patients who present after bromate intoxication. Fluid, acid-base, and electrolyte status should be carefully assessed, with particular attention to hyperkalemia. An electrocardiogram should be obtained in all cases of bromate ingestion. Acute renal failure, if present, should

be treated with judicious fluid restriction, fluid and electrolyte monitoring, and, if indicated, hemodialysis or peritoneal dialysis.

Because ototoxicity and nephrotoxicity are of rapid onset, prompt GI decontamination after recent ingestion is required. Gastric lavage with a 2% to 5% solution of sodium bicarbonate reduces bromate absorption and prevents the formation of irritant hydrobromic acid. The administration of activated charcoal is of unproven efficacy.

Bromate ion can be reduced to less toxic bromide by intravenous administration of sodium thiosulfate. Early therapy may be beneficial in reducing ototoxicity and nephrotoxicity. One to 5 g of sodium thiosulfate can be administered to adults (150 to 200 mg/kg to children) over 30 to 60 minutes. Administration of thiosulfate is associated with immediate elevations in serum bromide concentration, which confirm the conversion of bromate to the less toxic bromide.²⁸

Early hemodialysis or peritoneal dialysis may remove bromate and prevent clinical toxicity. Therefore, these modalities should be strongly considered for patients who present within a few hours of a significant bromate ingestion.²⁸

BROMINE

Bromine is a potent oxidizing agent. It is a highly hydrophilic reddish-brown gas that is heavier than air.²⁹ Elemental bromine is widely used in industry; its largest use is as an additive to gasoline.³⁰ Significant occupational exposure is controlled by an Occupational Safety and Health Administration (OSHA) permissible exposure limit for a time-weighted average 8-hour work day (PEL-TWA) of 0.1 ppm.

Bromine is very irritating to mucous membranes and produces pain and irritation of the upper airways and the eyes. Lacrimation, tearing, coughing, respiratory distress, and headaches all develop after inhalation exposures. High concentrations of bromine can cause inflammatory lesions of the upper airway as well as photophobia and blepharospasm.²⁹ Other clinical manifestations are dizziness, headache, and nosebleeds. Animal studies have shown that 3-hour exposures to bromine at 3 ppm can result in pulmonary edema.³⁰ Bromine gas at a concentration of 10 ppm is a severe irritant that cannot be tolerated. Death may occur secondary to bromine pneumonitis, which resembles adult respiratory distress syndrome. Necropsy revealed massive hemorrhagic alveolitis in one report. Direct skin exposure to liquid bromine can result in formation of vesicles and pustules, which develop into deep, painful ulcers with a brown discoloration of skin.³¹ The manifestations of bromine exposure parallel those of chlorine exposure.

Exposure to elemental bromine is uncommon but has been reported after occupational or environmental disasters. In one of the most important such exposures, a chemical plant in Geneva, Switzerland released bromine gas in November 1984, and about 25,000 inhabitants

TABLE 96-2 Clinical Manifestations Reported After Bromine Gas Exposure in 59 Patients

SYMPTOMS	NUMBER OF PATIENTS (%)
Eye irritation	53 (90)
Upper airway irritation	40 (68)
Cough	28 (47)
Expectoration	20 (34)
Headache	27 (46)
Photophobia	7 (12)
Weakness	7 (12)
Nausea	6 (10)
Dizziness	6 (10)
Abdominal pain	4 (7)
Itching	2 (3)
Sweating	2 (3)
Vomiting	2 (3)

From Morabia A, Sellegger C, Landry JC, et al: Accidental bromine exposure in an urban population: An acute epidemiological assessment. *Int J Epidemiol* 1988;17:148–152.

were exposed to high concentrations of bromine. Clinical manifestations were extensive²⁹ (Table 96-2). Many of these symptoms persisted 1 month later, particularly eye and upper airway irritation, headache, and cough. Smaller mass exposures have occurred from swimming pools, where bromine compounds are used as sanitizers.³²

Treatment of bromine exposure consists of ventilatory support and copious irrigation of eyes and skin with water or isotonic saline.²⁹ Corticosteroids have been administered in cases of severe respiratory distress without clear efficacy.²⁹ Prophylactic antibiotics are not recommended for bromine pneumonitis because they may promote the selection of resistant organisms.

IODINE

Introduction and Relevant History

Shortly after its identification in 1812, iodine's antiseptic and antimicrobial properties were recognized. Its essential role in thyroid hormone metabolism was also recognized early, with dietary supplementation begun in goitrous regions as early as 1920. An adult daily requirement of 150 μg is recommended. The threshold limit value for occupational iodine exposure is 0.1 ppm.

Uses of iodine include the manufacture of organic chemicals, pharmaceuticals such as contrast media for radiographic procedures, antiseptics and germicides, dyes and inks, and catalysts for photography, engraving, and lithography.

Medicinally, elemental iodine is used almost exclusively as a topical antiseptic or water-purifying agent. Iodine topical solution contains about 2 g of iodine and 2 g of sodium iodide per 100 mL. A tincture of iodine has the same composition, but in a 50% alcohol base. In aqueous solutions, iodine is present as seven different species: elemental iodine (I_2), hypoiodic acid (HOI), iodine

cation ($[\text{H}_2\text{OI}]^+$), triiodide ion (I_3^-), iodide ion (I^-), hypoiodite ion (OI^-), and iodate ion (IO_3^-).³³

Pharmacology

Elemental iodine, hypoiodic acid, and iodine cation are potent germicides, whereas triiodide and hypoiodite ions are relatively weak antiseptics. Topically applied iodide ion has no antimicrobial activity. Although the exact mechanism of its antimicrobial effect remains unclear, iodine compounds may work by (1) reacting with amine groups, (2) oxidizing the sulfhydryl group of cysteine, (3) disrupting protein synthesis, (4) reacting with the phenolic group of tyrosine, or (5) reacting with fatty acid double bonds, thereby disrupting the cell wall lipid bilayer.

Pharmacokinetics

Iodine is not absorbed through intact skin. Systemic absorption in the intestine of iodine requires reduction to iodide. Once absorbed, interconversion occurs between iodine and iodide. Both are renally excreted, with systemic accumulation seen in patients with renal impairment.

Toxicology

Topical use of 2% solution has minimal toxicity, although it may stain the skin and produce dermal injury (iodine burns). Iodine solutions of greater than 7% are corrosive to skin and mucous membranes. Sensitization may occur in susceptible individuals.³³ Tincture of iodine is more irritating than aqueous solution. Occlusive dressing increases the risk for dermal injury after iodine application. Ocular exposure results in intense pain and blepharospasm; staining of the corneal epithelium after prolonged occupational exposure has been reported. Severe inhalation exposure can lead to pneumonitis and pulmonary edema.

Iodine ingestion may result in perforation with peritonitis, metabolic acidosis, sepsis, and death. Two to 4 g of iodine is potentially fatal. Significant iodine ingestion also produces a clinical syndrome that includes tachycardia, parotitis, bronchitis, and insomnia.³⁰

Diagnosis

The diagnosis is essentially based on the history of exposure and consistent clinical findings. Any starch-containing food complexes with iodine and blue emesis that is considered pathognomonic for iodine ingestion may be seen. Iodine compounds can produce false-positive test results for blood when orthotoluidine (Hematest) or guaiac reagents are used. When used as a topical antiseptic, iodine may also produce pseudohyperglycemia.³⁴ As with bromide, pseudohyperchloremia could be noted with exceptional iodide exposures.

Management

The unstable patient with potential GI perforation requires aggressive supportive care, endoscopic evalua-

tion, and surgical consultation. As with any corrosive ingestion, ipecac, orogastric lavage, and activated charcoal (AC) are contraindicated. Immediate administration of dietary complex sugars (flour, starch) or milk may be effective by reducing iodine to the less toxic iodide; however, the specter of potential GI corrosion mitigates against their use in a symptomatic individual. The oral administration of sodium thiosulfate (100 mL of a 1% solution) can rapidly reduce iodine to iodide and may be of benefit if administered early. Thiosulfate can also be used to remove iodine stains from skin and clothing.³³

IODIDES

Introduction and Relevant History

Iodides have also been used as antimicrobial agents. Tertiary syphilis was among the dozens of diseases that were treated with potassium iodide at the turn of the century.³⁵ The successful quasi-eradication of endemic goiter by the addition of iodide (100 µg/g) to table salt underlines the importance of iodide as an essential nutrient. Other important dietary sources include dairy products and seafood.

Clinical conditions treated with iodide salts are hyperthyroidism and sporotrichosis. Iodides are also encountered in iodoquinol, amiodarone, and in certain expectorants. Potassium iodide salts are also provided as protection after unintentional exposure to I¹³¹ (see Chapter 104).

Pharmacokinetics

Iodide is readily absorbed from the GI tract and transported into the thyroid. Blood concentrations of iodide are typically low (0.2–0.4 µg/dL), whereas the thyroid typically contains about 10 mg iodide. Iodide is renally excreted, with a usual clearance of 40 mL/min.

Toxicology

Iodism, a syndrome resulting from chronic iodide intoxication, consists of oral, respiratory, salivary, pulmonary, dermatologic, and GI effects (Box 96-3). Metallic taste, burning in the mouth, gum and teeth soreness, and sialorrhoea make up the oral manifestations. Iodide toxicity can also simulate sinusitis or a head cold including fever.³⁶ Severe bronchorrhoea can result in pulmonary edema. Other signs of iodism include iodide mumps³⁷ and iododerma—similar to bromism.

Iodide can significantly affect thyroid metabolism with both hypothyroidism and hyperthyroidism resulting from excess iodide. Iodide's potent inhibition of thyroid hormone synthesis³⁵ (the Wolff-Chaikoff effect) and hormone release is the basis of its use in the treatment of hyperthyroid states and why excess iodide intake during pregnancy can result in neonatal hypothyroidism (cretinism). Prolonged use of iodide salts produces thyroid gland hyperplasia, goiter, thyroid adenoma, or severe hypothyroidism or thyrotoxicosis.³⁸

BOX 96-3

CLINICAL MANIFESTATIONS OF IODISM

Oral	Salivary	Dermatologic
Metallic taste	Excess salivation	Acneiform eruption
Gingivitis	Salivary gland enlargement	Vesicles
Pharyngitis		Pustules
Laryngitis		
Nasal	Pulmonary	Gastrointestinal
Nasal congestion	Productive cough	Bloody diarrhea
Sneezing	Pulmonary edema	Anorexia
"Sinus" headache		
Thyroid	Ocular	
Thyroid enlargement	Eye irritation	
Hypothyroidism	Periorbital edema	
Cretinism		
Adenoma		
Myxedema		

Immune reactions include anaphylactoid reactions (particularly to iodinated contrast agents), serum sickness-like syndrome; attributed cases of thrombotic thrombocytopenic purpura and fatal periarteritis nodosa have been reported.³⁶

Diagnosis

The diagnosis is essentially based on the history of exposure and clinical findings. As with bromide, elevated iodide concentrations may result in pseudohyperchloremia, rendering the anion gap calculation unreliable. The silver halide precipitation method of serum chloride measurement is not influenced by iodide elevation.³⁹ If clinically indicated, thyroid function tests should be ordered in cases of chronic exposure or follow-up to a large acute ingestion.

Management

The mainstay therapy is excretion enhancement through saline diuresis. Hemodialysis can increase excretion fourfold to fivefold but is rarely required in the presence of normal renal function.⁴⁰ Certain manifestations of iodism, particularly salivary gland inflammation and iododerma, may respond to corticosteroid therapy.^{41,42}

IODOPHORS

Iodophors are substances that have elemental iodine attached to a high-molecular-weight moiety. As a general rule, iodophors enhance the bactericidal activity of iodine. Iodophors are found in solutions, ointments, and surgical scrubs. The most common iodophor, povidone-iodine (Betadine), is an iodine molecule linked to

polyvinylpyrrolidone. Betadine is used most commonly as a 10% solution (which contains only 0.001% free iodine). Because iodine is tightly bound to the carrier, iodophors have very low rates of iodine release. These substances are therefore nonirritating after ingestion and generally have low toxicity. However, because they do contain substantial amounts of iodine, iodophors can result in significant iodine absorption in certain situations, particularly (1) when the integrity of the skin is compromised; (2) in infants, who have greater skin permeability; (3) after mucosal application (e.g., vaginal instillation); and (4) after excessive topical application.³⁹ Because of iodine diffusion into breast milk, vaginal or perirectal application of povidone-iodine and maternal treatment have been associated with elevated serum iodide levels in a breast-fed infant.^{43,44} Neonates readily absorb iodine from topical povidone-iodine solutions, and their total plasma iodine levels remain elevated for 3 days after a single application. Goiter and hypothyroidism, dermatitis, liver function abnormalities, and neutropenia have also been described after prolonged exposure to povidone-iodine and other iodophors. Serum iodide concentrations can increase 100-fold in those who have iodophors applied to open wounds, burns, or decubitus ulcers, and iodide-related fatalities are reported.⁴⁵ In an unusual report, Kurt and colleagues described a 9-week-old infant who received 150 mL of povidone-iodine through a nasogastric tube and died of severe corrosive injury to the GI tract with a blood iodine level of 14,600 $\mu\text{g}/\text{dL}$.⁴⁶ Systemic absorption of iodophors has also been associated with the development of a metabolic acidosis. The cause of the acidosis has not been identified, although its etiology may be related to either the acidity of the povidone-iodine solution ($\text{pH} < 3$), bicarbonate complexation to iodine, or renal tubular acidosis. Both normal and elevated lactate levels have been described after iodine absorption from iodophors.³⁹ Other metabolic abnormalities associated with iodine absorption from iodophors include hypernatremia, hyperchloremia, renal insufficiency, and renal tubular acidosis.

Treatment of iodine intoxication resulting from iodophor exposure consists of basic interventions used to treat iodide toxicity. However, because iodophors have very low toxicity unless ingested in massive amounts, no specific intervention is recommended after ingestion. Activated charcoal has a potential role because iodophors are organic compounds; charcoal should be considered after ingestion of more than 6 to 8 ounces of Betadine (or other iodophor). Because of the potential disturbances in thyroid function, thyroid-stimulating hormone should be monitored weekly for up to 4 weeks after very large ingestions.

CHLORINE

Introduction and Relevant History

Chlorine (atomic weight of 35.45 daltons) is a gas at standard temperature and pressure. It has a vapor

pressure of 4800 mm Hg at 20° C and a relative density to air of 2.5. It is commonly used in industrial processes as a reagent in plastics manufacturing and as a bleaching agent in the paper industry.⁴⁷ Chlorine-producing compounds are also used as disinfectants and water-purifying agents.

Although it was recognized in the 17th century that heating ammonium chloride and nitric acid together created an irritating gas, chlorine was first described and used as a bleaching agent in the 1770s. In 1774, chlorine was generated by oxygenation of hydrochloric acid, and it is currently produced by electrolysis of brine. Although chlorine was the first chemical warfare agent in World War I, only 1843 of the 70,552 reported Americans victims of gassing were reportedly exposed to chlorine.⁴⁸ Although initial clinical data linked these exposures with chronic pulmonary sequelae, lack of uniformity in evaluation and comorbidities prohibit any substantiated conclusions.

Chlorine is the most compressible element; it is shipped as a pressurized liquid. One pound of liquid chlorine generates about 5 cubic feet of gas when released. A typical rail tank car, containing more than 50 tons of liquid chlorine, would therefore be capable of releasing more than 500,000 cubic feet of gas.⁴⁹ It is this potential for massive release that results in such concern about transportation and storage accidents involving chlorine.

Chlorine is heavier than air (vapor density, 2.5) and is recognizable in concentrated releases as a yellow-green cloud. The noxious odor does not serve as a reliable warning. The odor threshold of chlorine is less than 3 ppm, whereas the OSHA threshold limit value–time-weighted average (TLV-TWA) for an 8-hour work day is 0.5 ppm. Extreme irritative symptoms can occur at levels as low as 1 ppm over 4 to 8 hours,⁵⁰ and levels of 30 ppm can lead to severe respiratory symptoms within minutes. Levels of 1000 ppm cause immediate death.⁵¹

From an epidemiologic perspective, the summary of poisonings in the United States reported to the American Association of Poison Control Centers (AAPCC) for 2003 documents 727 exposures to chlorine generated by the mixture of acid with bleach and 6090 other exposures to chlorine in the fume/gases/vapors section of the annual report. It is likely that other exposures are contained within the 57,790 exposures to hypochlorite-containing bleaches and disinfectants documented within the household cleaning substances category.⁵² Clinical experience certainly suggests that the most common source of chlorine exposure resulting in emergent symptoms is the admixture of household cleaning agents. The combination of bleach (sodium hypochlorite) and acids or ammonia results in the formation of chlorine or chloramine gases, respectively.⁵³ Another common source of residential chlorine poisoning is from swimming pool disinfectant processes.⁵⁴⁻⁵⁶ This is a particularly common exposure source for children. Hemodialysis patients may be exposed to chloramine toxicity if chloramines are inadequately removed after maintenance of hemodialysis machines.⁵⁷ Industrial and transportation incidents account for infrequent but large-scale releases of chlorine gas.^{58,59}

FIGURE 96-1 Irritant products from reaction of chlorine with water.

Structure and Structure–Activity Relationships

Chlorine itself is only moderately soluble in water, but when it comes in contact with water, hydrochloric acid and hypochlorous acid are generated (Fig. 96-1). Hypochlorous acid is thought to degenerate readily at physiologic pH to hydrochloric acid and oxygen free radicals with resultant coagulation necrosis and oxidative tissue damage. Hypochlorous acid is far more irritating than hydrochloric acid.⁶⁰ Chloramine gas, when exposed to moist surfaces, also releases hypochlorous acid.⁶¹

Pharmacology

Chlorine and chlorine-producing compounds primarily cause symptoms when inhaled in a closed space or in high concentrations. Contact of chlorine gas with moist surfaces such as the mucous membranes of the eyes, mouth, and respiratory tract produces both upper and lower airway symptoms. Upper airway irritation tends to be prominent and serves as a noxious warning preventing continued voluntary exposure; therefore, lower tract symptoms are less frequent. Nonetheless, severe lower airway damage can occur, particularly in settings of highly concentrated exposure or when victims are trapped. Persistent airways dysfunction and bronchiolitis obliterans have been described after acute exposure, although the true incidence of these chronic effects and their relation to smoking and preexisting atopy are uncertain.^{59,62-64} Although repeated symptomatic chlorine exposures can also lead to persistent airways dysfunction, chronic exposure to controlled levels without acute symptomatic “gassing” episodes is unlikely to cause chronic pulmonary dysfunction.^{65,66} Severe exposures may cause noncardiogenic pulmonary edema.

Diagnosis

Chlorine gas toxicity is primarily a clinical diagnosis suggested by the circumstances of exposure and clinical picture. Laboratory evaluation is nonspecific, often revealing leukocytosis, metabolic acidosis, and hypoxemia or respiratory alkalosis in those who are most symptomatic. Chest radiographs may demonstrate focal areas of consolidation, central pulmonary congestion, or diffuse increased interstitial markings.⁶⁷ Neumomediastinum has also been reported. All these abnormalities generally correlate with more severe clinically apparent disease. Laboratory studies other than pulse oximetry should have little if any role in the initial assessment and disposition of exposed individuals.

Triage can be performed on a clinical basis. The following triage guidelines were generated from available clinical data:

1. Mildly affected individuals improve with removal from exposure. Symptomatic treatment with humidified oxygen or bronchodilators may be beneficial. Asymptomatic individuals will not worsen.
2. Moderately affected individuals, if asymptomatic after a period of several hours after treatment, will not acutely worsen. Those with underlying pulmonary or atopic conditions may have persistence of reactive airways for weeks to months after the acute exposure. Rarely, chemical or infectious pneumonitis may develop over a few days after exposure.
3. Severely affected individuals demonstrate symptoms early and stabilize or suffer worsening of their condition; they require aggressive treatment and immediate hospitalization.

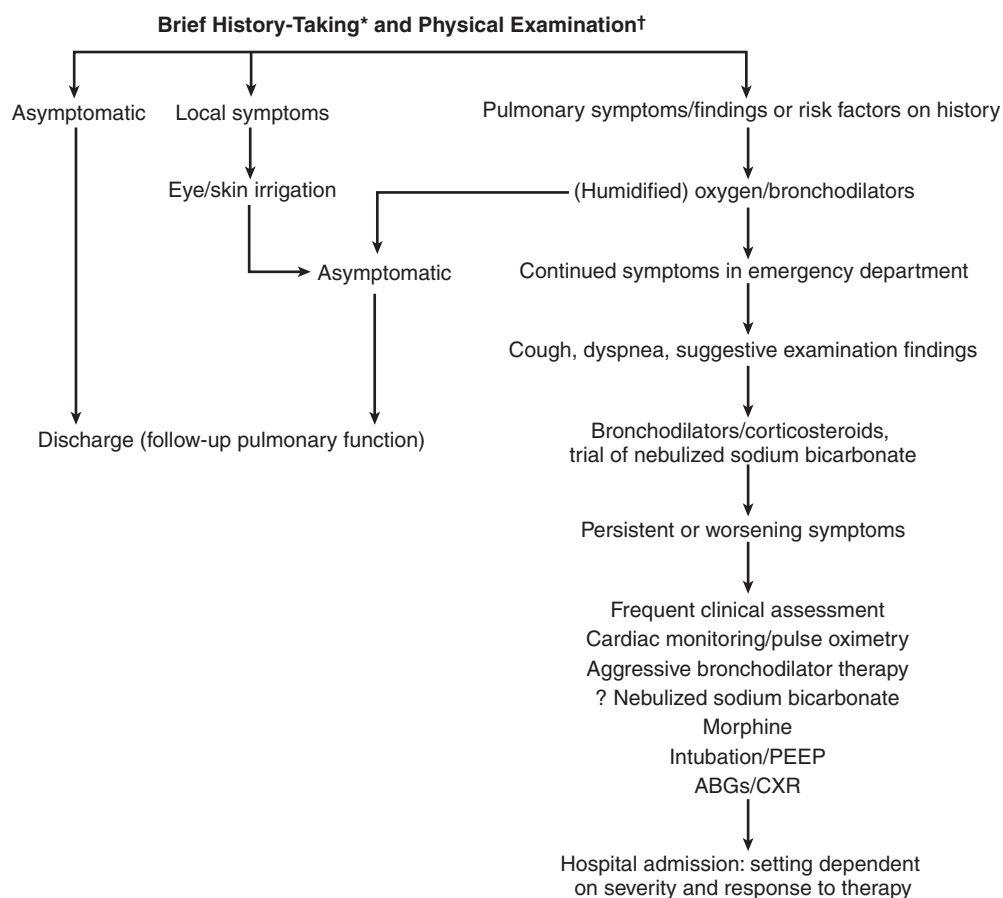

A triage algorithm is provided in Figure 96-2.

Toxicology

The clinical spectrum following acute chlorine exposure can include mucous membrane irritation with chemical conjunctivitis, corneal burns, orofacial burns, acute tracheobronchitis, chemical pneumonitis, pulmonary edema, and hypoxemia with metabolic acidosis. Initial symptoms after exposure to chlorine fumes include cough and eye, nose, and throat irritation. Chest heaviness/burning, dyspnea, wheezing, and hemoptysis or syncope can occur with more severe exposures. Nonspecific nausea and vomiting, headache, dizziness, and chills may also be reported.

The physical findings are often unremarkable, although initial tachypnea, conjunctival injection, tearing, and wheezing may be found. Tachycardia and both mildly elevated and depressed temperature may be noted.

Various pulmonary function abnormalities have been reported in the hours after an acute exposure, including both restrictive and obstructive deficits. These changes represent the variable effects of differing concentrations of chlorine and its by-products on the airways and parenchyma in patients with or without underlying lung diseases. In one study that evaluated 18 patients after exposure to a chlorine tank leak, all subjects had evidence of moderate pulmonary obstruction, which improved over 2 weeks.⁶² None developed pulmonary edema, although all were described as showing a “worsening clinical picture during the first 2 days of hospitalization, with signs of recovery noted thereafter.” Despite this assessment, only one patient in that case series was treated with bronchodilators or steroids. The authors described the presenting symptom of dyspnea as identifying individuals with a worse clinical course (slower recovery) than those with a primary complaint of paroxysmal dry cough. The former group was more likely to smoke (100% versus 25%) and to have a pre-exposure history of wheezing (50% versus 8%). This may serve as a useful triage tool in a multiple-patient encounter; however, prospective validation is lacking.

*Brief history-taking: Focus on concurrent trauma, burns, symptoms referable to mucous membrane, pulmonary signs (cough vs. dyspnea), nonspecific chest pain, nausea/vomiting, and mental status changes, as well as history of atopy, asthma, cardiopulmonary disease, or smoking.

†Physical examination: Evaluate acute chlorine exposure. PEEP, positive end-expiratory pressure; ABGs, arterial blood pressure.

FIGURE 96-2 Triage guidelines following acute chlorine exposure. ABGs, arterial blood gases (analysis); CXR, chest radiography; PEEP, positive end-expiratory pressure.

In one review of regional poison control center exposures, Mrvos and colleagues assessed symptoms in 216 individuals who were exposed to chlorine or chloramine gas from mixing household cleaners.⁵³ Symptoms were mild and did not require specific therapy. Most had early resolution of symptoms; only 16 had symptoms that persisted for more than 6 hours. One patient, who had underlying chronic pulmonary disease and a concurrent acute respiratory infection, was hospitalized. None developed pulmonary edema. This favorable experience can be contrasted with reports of acute pulmonary edema in two children immediately after brief exposures to vapors from containers of swimming pool chlorinator pellets.⁵⁵

Management

After victims are removed from the source of exposure, involved skin or symptomatic eyes should be copiously irrigated with water. Attention should focus on a patient's airway and any respiratory complaints.

Aggressive treatment includes high-flow humidified oxygen, inhaled bronchodilators, and intravenous corticosteroids. Arrhythmias are not a prominent complication of chlorine fume inhalation; once supplemental oxygen has been provided, subcutaneous epinephrine, if it is the only β -adrenergic agent available, should not be withheld for fear of provoking arrhythmias. Patients with respiratory failure secondary to pulmonary edema or the rare individual with upper airway obstruction from chlorine-induced burns may require intubation with early administration of positive end-expiratory pressure.⁶⁸ Although opiates have not been used at times because of the risks for altered mental status, respiratory depression, and cough inhibition, judicious use of parenteral opiates with close observation may be beneficial.⁶⁹

Some investigators have advocated nebulized sodium bicarbonate for patients with persistent cough or those with evidence of severe pulmonary injury. This therapy attempts to chemically neutralize the acid products of chlorine hydration. In one animal study, 10 sheep

treated with this modality after 4 minutes of exposure to 500 ppm chlorine had statistically higher PO₂ and lower PCO₂ values than animals treated with nebulized normal saline, although there was no difference in the mortality rate of 30% at 24 hours.⁷⁰ It has been recommended and used in unselected patient cohorts with anecdotal reports of improvement, but its value is unproven; no reports have described clinical worsening with this therapy.^{71,72} Although nebulized bicarbonate has been condemned because of concern about thermal injury from the heat of neutralization, this risk is theoretically minimized by the large surface area of the lungs as well as the small volumes of bicarbonate administered. Given the proposed mechanism, this therapy would seem most useful early in a patient with significant lower airway penetration of chlorine. It has been used in a dose of 3 mL of 8.4% sodium bicarbonate and 2 mL normal saline nebulized with oxygen or air. The nebulization can be repeated if beneficial; however, there is no rationale for its continued use long after the exposure.

Corticosteroids have been used to treat pulmonary edema and bronchospastic symptoms. As with many proposed uses of these anti-inflammatory agents, their efficacy in the treatment of chlorine toxicity has never been subjected to a randomized trial. Early inhaled budesonide (within 30 minutes of lung injury) was shown to be beneficial in a pig model.⁷³ One report of two sisters exposed to the same chlorine release suggested that the more rapid improvement in pulmonary parameters of one patient could be attributed to the combination of hospital admission, rest, and treatment with oxygen and corticosteroids compared with the sibling who received only brief oxygen therapy.⁷⁴ To date, this anecdotal report forms the basis for any recommended use of corticosteroids after chlorine exposure. Another potential treatment modality focuses on reducing the oxidative destruction that potentially follows chlorine-induced generation of oxygen radicals. Animal models of smoke inhalation, hydrochloric acid aspiration, and pulmonary macrophage allergic

response suggest that ibuprofen can reduce pulmonary injury when administered shortly after exposure to these agents.^{75,76} Inhibition of thromboxane A₂ synthesis has been postulated to be the mechanism for these effects. No clinical reports have described the utility of this agent after chlorine inhalation.

Antibiotics, although historically used after chlorine-induced pulmonary injury, should be reserved for documented episodes of infection, which for the most part manifest days after exposure. The initial tachypnea, sputum production, pulmonary findings, and consolidation on chest radiographs are attributable to chemical tracheobronchopneumonitis or pulmonary edema. Prophylactic antibiotics are unlikely to alter the clinical course and may also predispose to infection with antibiotic-resistant or other opportunistic organisms.

Case Series

Important clinical findings from six relatively large case series of acute chlorine exposure are summarized in Table 96-3. In the poison center review mentioned earlier, Mrvos and coworkers⁵³ found a high prevalence of cough with little dyspnea, as well as rapid resolution of symptoms, after home exposures to mixed cleaning agents.

Fleta and associates⁷⁷ reported on 76 children (newborn to 14 years old) who were exposed to a leak of 300 L of chlorine gas from a pressurized canister used to purify municipal drinking water in Spain. Seventy of the 76 children were discharged from the hospital within 2 hours; the longest period of observation was 12 hours. No one developed pulmonary edema. Most symptoms resolved on removal from the source; those with "signs of irritation of the lower respiratory tract" were treated with oxygen and intramuscular corticosteroids.

Moulick and colleagues⁶⁴ described 82 adults (21–60 years old) who were within 20 yards of a chlorine storage tank leak in Bombay, India. An ambient chlorine concentration of 66 ppm was measured in the area

2 hours after the exposure. Sixty-two patients were hospitalized for 2 or more days. Two patients developed pulmonary edema within 6 to 8 hours; 5 had hypoxemia requiring ventilatory support. “Late” pneumonia developed in two patients. All 56 who underwent bronchoscopy had tracheobronchial mucosal congestion; 20 patients had hemorrhagic spots. Erosions or ulcerations were identified in 7 patients; the presence of these correlated with more severe symptoms. All patients were treated with oxygen, aminophylline, hydrocortisone, and ampicillin. Four of 16 patients who were observed for a year or more had persistent cough for 4 to 6 weeks; no residual symptoms or chest radiographic or pulmonary function abnormalities were found at the end of the follow-up.

Hedges and Morrissey⁵⁸ summarized findings in 64 patients evaluated after a leak of about 4 tons of liquid chlorine from storage tanks in Philadelphia. These patients represented about 60% of the people evaluated at one medical center; after triage, the others were found to be asymptomatic and were sent home from the waiting area. All six patients admitted to the hospital with “marked tracheobronchitis” complained of dyspnea, whereas this complaint was present in only 10% of those able to be discharged. There were no deaths or cases of pulmonary edema. Symptomatic patients were treated with humidified oxygen, a combination of bronchodilators, and antitussives. Triage and treatment recommendations for management of multiple-casualty chlorine exposures were made by these authors.

Bosse⁷¹ reviewed 86 cases (24 adults) seen at 49 medical facilities in Kentucky with poison center recommendation of nebulized sodium bicarbonate treatment for symptomatic chlorine inhalation. Sixty-nine patients were discharged from the emergency department after one to two nebulized sodium bicarbonate treatments. Seven patients were treated with bronchodilators, and one received steroids. Seventeen patients were admitted to the hospital for 1 to 3 days. All improved; none developed pulmonary edema or required ventilatory support. Some received sodium bicarbonate; four were treated with inhaled bronchodilators, and one each received inhaled steroids and intravenous aminophylline.

Weill and colleagues⁷⁸ summarized initial symptoms and results of pulmonary function follow-up in those exposed to release of up to 30 tons of liquid chlorine after a freight train derailment in Louisiana. Ambient chlorine levels in some areas 7 hours after the derailment were in excess of 400 ppm, and levels at the fringe of contamination 3 hours after the event were 10 ppm.⁷⁹ Hundreds of animals in the area died; more than 100 people developed symptoms requiring treatment. The symptoms in the 17 admitted patients, of 75 who were treated at one hospital, are noted in the table. One infant died shortly after severe exposure. Therapy at that time (1961) relied mainly on oxygen, postural drainage, atropine, penicillin, chymotrypsin, Alevaire (a nonionic surfactant, sodium bicarbonate, and glycerin), and some narcotics and expectorants.

It is important to understand the circumstances of exposure when interpreting the relative prominence of

findings such as those listed in Table 96-3. Symptoms demonstrated by any one individual depend heavily on the circumstances of exposure and individual predisposing characteristics such as smoking history and atopy.

Chronic Chlorine Exposure

Other areas of potential concern about chlorine toxicity include chronic effects from low-level ambient workplace exposure and the potential carcinogenic or teratogenic effects of oral exposure to chlorinated water supplies. As described earlier, reversible obstructive airways dysfunction in workers continually exposed to chlorine has been demonstrated,^{65,66} although the effect of concurrent cigarette smoking, atopy, and the contribution of acute exposures above TLV-TWA levels (“gassing”) made it difficult to sort out relative contributions. In one study, the effects of up to 2.3 ppm chlorine inhalation by rhesus monkeys for 6 hours daily for 1 year were evaluated. Conjunctival and focal tracheal irritative changes were seen only at the highest exposure levels, and not in all animals.⁸⁰ Most individuals do not suffer prolonged airway dysfunction after an acute exposure, although resolution of abnormal findings on pulmonary function tests can be prolonged, particularly in smokers and those with preexisting pulmonary function abnormalities.⁸¹⁻⁸³

Some halogenated compounds are known to be mutagenic. The use of chlorine, chloramine, and chlorine dioxide as disinfecting and bleaching agents in municipal water supplies and the food industry has therefore generated concern about the tradeoff between convenience, markedly improved sanitation, and the risk for increased cancer incidence. Concern has focused on the generation of disinfection by-products known as trihalomethanes. These include chloroform, bromoform, dibromochloromethane, and bromodichloromethane. The water concentration of these by-products is increased by the higher concentration of nitrogen waste products in surface water and heat.^{84,85} A small study demonstrated detectable chloroform in the blood of indoor competitive swimmers (mean, 0.89 ng/mL), which was not found in outdoor swimmers.⁸⁶ This was associated with a “significantly elevated” β_2 -microglobulin urine concentration, possibly suggesting renal damage. Patients on long-term hemodialysis are another group exposed to increased concentrations of chlorine by-products.⁸⁷ Community-based population studies have also suggested a statistical increase in the relative risk (ranging from 1.2 to 2.2) of a number of cancers in those populations dependent on chlorinated surface water when compared with ground-water users.^{88,89} The affected sites have included the bladder, kidneys, pancreas, stomach, and rectum; malignant melanoma has also been associated. These associations obviously do not equate with causality, particularly within the individual. Various confounding variables, including socioeconomic factors or the presence of other toxic compounds, could have a role.

Similar concerns have been raised about possible reproductive toxicity of disinfection by-products. Although severe acute chlorine exposures have resulted

in fetal wastage in cows and decreased egg production in chickens,⁷⁹ low-level oral exposure to sodium hypochlorite in the drinking water of hens did not alter egg production until the chloride concentration exceeded 40 ppm.⁹⁰ Chlorine treatment of both male and female rats with up to 5 mg/kg per day resulted in no detectable reproductive or fetal changes.⁹¹ It is only at exposures several thousand times those typically seen in humans that animal studies show reproductive abnormalities.⁹² Despite these reassurances, there have been calls to ban the use of chlorine. Caution must be exercised before abandoning the use of a substance with at most uncertain low-level toxicity in favor of other agents that have not been studied as extensively.⁹³ Nonetheless, given the ubiquitous nature of chlorination processes, these issues will continue to be studied.⁹⁴

MARTIN BELSON, MD

At a Glance...

- Management of ammonia and nitrogen oxide poisonings involves supportive care, decontamination, and disposition.
- Supportive care includes removal from the source and rapid assessment of airway, breathing, and circulation; establishment of oxygen, the cardiac monitor, and intravenous access; administrations of nebulized β_2 agonists; and, as indicated, administration of endotracheal intubation and positive end-expiratory pressure.
- Decontamination includes removal of all contaminated clothing and irrigation of skin and eyes with water, if symptomatic. If ammonia or nitrogen oxide is ingested, do not induce vomiting or give activated charcoal.
- Disposition includes 2-hour observation in the emergency department for mild exposures without airway compromise; inpatient observation for anything more than mild symptoms; and intensive care unit admission for airway compromise or severe burns.

AMMONIA**Introduction and Relevant History**

Ammonia (NH_3) is a highly irritating, water-soluble, colorless gas with a distinctive pungent odor. When ammonia gas (anhydrous) is dissolved in water, the resulting material is ammonium hydroxide (NH_4OH), or “aqueous” ammonia. Anhydrous ammonia is easily compressed and forms a clear, colorless liquid under pressure, which makes it ideal for storage and shipping in pressurized containers, such as tank cars and trucks.

Ammonia is widely used as a refrigerant, a fertilizer, and a household and commercial cleaning agent. Ammonia is also used as a solvent in the manufacture of textiles and leather, in pulp and paper processing, and in petroleum refining. Other applications include the synthesis of plastics, pesticides, cyanide, explosives, and rocket fuels.

Aqueous ammonia with concentrations of 5% to 10% is used as a household cleaner or bleaching agent. Industrial-strength aqueous ammonia at concentrations greater than 25% to 30% is considered an alkaline corrosive. Anhydrous ammonia may burn but does not ignite readily; however, a pressurized container of the gas may explode in heat or fire.

Epidemiology

The widespread use of ammonia greatly increases the possibility of accidental or intentional release and human exposure to toxic concentrations. In fact, ammonia is

one of the most commonly spilled chemicals in the United States.¹ Human exposure to ammonia may occur after an industrial accident, such as the rupture of a tank, or after a transportation accident, which may result in large-scale environmental exposures to ammonia gas. Ammonia is one of the top five substances released in transit involving acute public health consequences.² However, most ammonia releases occur at fixed facilities (e.g., food manufacturing industry) rather than during transportation.³

In the household, exposure may occur if an ammonia-containing cleaner is mixed with a chlorine-containing bleach, leading to the release of chloramine fumes.^{4,5} According to the American Association of Poison Control Centers Toxic Exposure Surveillance System, 2993 exposures to chloramine occurred in 2002, resulting in one death.⁶

In a 5% to 10% concentration, ammonia generally is considered an irritant and rarely is reported to cause burns when inhaled.⁷ However, three patients who attempted suicide by ingesting household ammonia reportedly had esophageal burns. One of these patients had severe corrosive injury of the upper airway and esophagus with aspiration pneumonia and died. The death was attributed to adult respiratory distress syndrome and renal failure.⁸

Anhydrous ammonia accounts for a significant percentage of chemical burns in the occupational setting. In one review, 34% of the chemical burns admitted to University of Iowa hospitals were the result of ammonia exposure.⁹

Structure and Structure–Activity Relationships

Ammonia reacts with strong oxidizers, acids, and various heavy metals. It is corrosive to copper and galvanized surfaces. When ammonia is mixed inappropriately with sodium hypochlorite (NaOCl) bleach in an attempt to potentiate the chemicals’ individual cleaning powers, chloramine gas, an irritant with properties similar to those of chlorine, is formed (see text box).⁴

(a) Sodium hypochlorite (bleach) plus ammonia form monochloramine and dichloramine. (b) Chloramine gas may decompose in water to form free ammonia and hypochlorous acid. (c) hypochlorous acid may combine with moisture to yield nascent oxygen, a potent oxidizing agent and mucous membrane irritant.

Pathophysiology

The extent of injury after exposure to ammonia depends on a number of factors. According to the National Institute of Occupational Safety and Health (NIOSH), the irritating effects of exposure to ammonia are more dependent on concentration than length of exposure^{10,11} (Table 97-1). Although ammonia's odor threshold is low enough to provide adequate warning of its presence, the odor causes olfactory fatigue, making ammonia's presence difficult to detect when exposure is prolonged.

Anhydrous ammonia is highly water-soluble and rapidly produces an irritant and alkaline, corrosive effect on contact with mucosal membranes such as the eyes and upper respiratory tract. Ammonia and water combine to form ammonium hydroxide that dissociates to ammonium (NH_4^+) and hydroxyl (OH^-) ions. These ions cause a severe alkaline burn characterized by liquefaction necrosis.^{12,13} The reaction is exothermic and produces thermal as well as chemical injury.^{13,14} The deepest damage to the skin appears to occur in areas with the highest moisture content, such as the axilla and groin. Edema of all involved tissues is common, and laryngeal edema can be life threatening.^{14,15}

In the airways, desquamation of the epithelial layer of the upper tracheobronchial tree (tracheobronchitis) with membrane formation is the usual pathology.¹² There tends to be relatively little effect on the lower airways because ammonia's high solubility prevents it from reaching the distal airways. With very high concentrations of the vapors, damage to the pulmonary endothelial and epithelial cells leads to increased permeability and exudation of fluid into the alveoli, producing the characteristic clinical findings of acute lung injury (ALI).^{16,17} Experimental inhalation of nebulized high-dose ammonia causes ALI manifested by

a fall in oxygen saturation and a rise in airway pressure within 2 minutes of initiation.¹⁸

Ammonium hydroxide penetrates the eye far more rapidly than other alkalis. Researchers have demonstrated that ammonium hydroxide can significantly increase anterior chamber pH within 15 seconds.¹⁹

Toxicology

CLINICAL MANIFESTATIONS

The clinical manifestations of ammonia poisoning depend on many factors, including the ammonia's physical state, the concentration and amount of ammonia, the depth of inhalation, the duration of exposure, and the route of exposure. Inhalation of ammonia gas results in rapid onset of irritation to the eyes, nose, throat, and upper respiratory tract. Prolonged exposures, or exposures to large amounts of ammonia, may result in irritation of the lower respiratory tract. Ingestion of aqueous ammonia results in immediate burning of the mouth and throat and could cause esophageal and gastric damage. Skin or eye contact with either ammonia gas or aqueous ammonia may cause serious alkaline, corrosive burns. Clinical manifestations of ammonia poisoning typically result from an acute exposure, but ammonia poisoning also can cause chronic, long-term adverse effects.

Acute Clinical Manifestations

After inhalation of ammonia fumes, immediate signs and symptoms include a burning sensation in the nose, throat, and eyes, followed by lacrimation, blurred vision, rhinorrhea, and possibly eyelid and lip edema. Headache and coughing also are typical early findings. Upper airway edema rapidly may cause airway obstruction, preceded by hoarseness and stridor. Lower airway involvement may cause chest tightness, dyspnea, bronchospasm with wheezing, and hypoxia. ALI, presenting with rales and rhonchi if the ammonia concentration was great enough to have penetrated the lower airways, eventually may develop. Copious amounts of tracheal secretions, hemoptysis, and fever are not uncommon. Pneumonia with consolidation may be evident on radiographs.^{14,20,21}

Inhalation injury may follow a biphasic course. After the initial pneumonitis or ALI, a patient may experience relative improvement for 48 to 72 hours. Subsequently, there is the gradual onset of airway obstruction, and respiratory failure may develop.

Physical examination of the chest during the first 24 hours after exposure is the best predictor of subsequent hospital course.²⁰ In a report of 14 patients accidentally exposed to a high concentration of ammonia, all patients who exhibited respiratory symptoms and had a normal chest examination at the time of admission recovered quickly, without specific therapy. Patients who exhibited respiratory symptoms and significant findings on chest examination (i.e., rales, wheezing) had a more protracted and relatively more complicated hospital course. Also, among patients with a mild to moderate clinical illness, radiographic findings were rather

TABLE 97-1 Exposure Limits and Clinical Effects of Ammonia at Different Concentrations

CONCENTRATION (ppm)	EFFECTS
5	Odor threshold, tolerance may develop to the odor
25	NIOSH-REL
35	NIOSH-STEL
50	OSHA-PEL
<50	Eye and upper respiratory irritant
300	NIOSH-IDLH
1000	Direct caustic effects on the respiratory tract
2500	Death has been reported after 30 minutes of exposure
30,000	Lowest concentration leading to death after 5 minutes of exposure in human references ^{14,22}

IDLH, immediate danger to life or health; NIOSH, National Institute for Occupational Safety and Health; OSHA, Occupational Safety and Health Administration; PEL, permissible exposure limit; REL, recommended exposure limit; STEL, short-term exposure limit.

unremarkable. The report's authors concluded that the radiographic findings appear to offer little assistance in assessing the immediate status of respiratory tract involvement, or in predicting the future clinical course of patients suffering acute ammonia inhalation.²⁰

After ingestion of liquid ammonia, common signs and symptoms include severe pain in the mouth, chest, and abdomen, accompanied by vomiting and possibly followed by shock. Severe local edema of the lips and mouth is present; burns of the soft palate also may occur. Twenty-four to 72 hours later, esophageal and gastric perforation with mediastinitis may occur. Victims with perforation have severe abdominal pain and rigidity and may have associated respiratory complications, including ALI.^{22,23} Alkaline corrosive ingestions are discussed further in Chapter 98. Ingestion of ammonia does not normally result in systemic poisoning.

Dermal exposure to ammonia liquid or gas initially may result in a burning sensation, followed rapidly by blister or vesicle formation. Injuries may vary from mild erythema and edema after a low concentration exposure to severe edema and deep penetrating burns after a more concentrated exposure.²² Skin exposure to ammonia liquid that has a temperature of -33°C produces frostbite-type injuries, with first- to third-degree burns.^{14,22}

Chronic Clinical Manifestations

Repeated exposure to ammonia gas may cause chronic irritation of the conjunctiva and upper respiratory tract.²¹ The potential effect of chronic exposure to ammonia on pulmonary function remains controversial because some authors have failed to find an effect²⁴ whereas others have shown an association.^{25,26} The results of one large case-control study suggested that exposure to a high cumulative ammonia level (based on estimates only) produces a combined restrictive and obstructive ventilatory defect.²⁶

Adverse Effects

Although complete pulmonary recovery is the usual outcome, acute ammonia inhalation injury has been associated with chronic pulmonary conditions such as bronchiectasis, reactive airways dysfunction syndrome (RADS), and chronic obstructive pulmonary disorder.²⁷⁻³⁰ The association between exposure to high concentrations of ammonia and bronchiectasis is probably best documented, varying from 2 months to 2 years after the acute episode.^{27,28} The patients usually had severe clinical disease immediately after the exposure, with bacterial superinfection documented or suspected in most cases.

One patient without a preexisting history of sinusitis or allergies exhibited chronic, relapsing sinusitis after being exposed acutely to gaseous ammonia.³¹

Permanent ocular damage may occur as a result of tissue destruction and elevations in intraocular pressure. Ammonium hydroxide is especially destructive to the eye because it penetrates far more rapidly than do other alkalis. Cataract formation and corneal opacification are common complications of severe ammonia exposure, particularly if the patient is not treated promptly.¹²

Late complications from ulcerative esophagitis include stricture formation.^{22,23}

DIAGNOSIS

Laboratory Testing

Laboratory results generally are nonspecific and are not helpful after an ammonia exposure. It is important to obtain serial arterial blood gas values, both to monitor the progress of respiratory failure and because these patients may develop a metabolic acidosis. The serum ammonia level does not correlate with the degree of injury.²²

Differential Diagnosis

Exposure to other acid- or base-forming irritant gases may result in a clinical picture similar to that of exposure to ammonia. Other highly water-soluble agents include the chloramines, hydrogen chloride (HCl), acrolein, formaldehyde, and sulfur dioxide/sulfuric acid ($\text{SO}_2/\text{H}_2\text{SO}_4$); intermediate water-soluble agents include chlorine (Cl_2). Exposure to oxidant gases, such as oxides of nitrogen, and riot-control agents or lacrimators (e.g., capsaicin, chloroacetone) also should be considered.

MANAGEMENT

Supportive Measures

Prehospital management must be started early and aggressively in patients suspected of having been exposed to ammonia. First and foremost, it is necessary to evacuate patients from the exposure site. An initial survey of the patient's airway, breathing, and circulation will identify immediately any life-threatening injuries.

For any patient with respiratory symptoms, respiratory support with 100% oxygen through a non-rebreathing face mask is indicated in the prehospital setting, although early intubation may be necessary. Early intubation should be considered whenever a patient develops stridor, second- or third-degree burns to the neck or throat, or central nervous system depression.

In the hospital, aggressive respiratory support should be continued or initiated as indicated. Positive end-expiratory pressure ventilation may be necessary to maintain an adequate PO_2 .^{14,20} Inhaled β_2 agonists are indicated for bronchospasm. In one study, nebulized 3.75% sodium bicarbonate was shown to improve oxygenation after chlorine exposure.³² Nebulized 5% sodium bicarbonate was shown to be safe and potentially beneficial in a large retrospective study,³³ but has not been studied after ammonia exposure. In one case series, 22 patients exposed to chloramine gas were treated with a nebulized solution of 3.75% sodium bicarbonate with no significant statistical or clinical difference in outcome.⁵ At this time, routine use of nebulized sodium bicarbonate as a neutralizing agent is not recommended after exposure to ammonia.

Fluids should be restricted early, unless the patient clearly is dehydrated or hypotensive, because excessive hydration may contribute to further airway edema. Central venous and pulmonary capillary wedge pressure monitoring may be required in seriously burned patients.

Decontamination

If the exposure involves aqueous ammonia, removal of contaminated clothing is imperative. Emergency medical service personnel should wash exposed skin with copious amounts of water and irrigate the eyes continuously, if the patient is symptomatic, until definitive medical care is reached. Contact lenses should be removed before flushing the eyes to prevent the concentration of ammonia beneath the lenses.

If aqueous ammonia is ingested, vomiting should not be induced, and charcoal should not be given because it does not adsorb ammonia and may obscure the view for endoscopy.

In the hospital, it is important to determine whether decontamination of any remaining ammonia from the patient's eyes or skin is warranted to prevent further absorption and to protect the health care staff. Irrigation of the eyes should continue until the patient is more comfortable and until a conjunctivae sac pH below 8.5 is achieved.¹⁴ Irrigation of affected skin should continue for at least 15 to 20 minutes.

After the initial skin washing, irrigation with water should be continued at regular intervals for 24 hours. The use of greasy ointments is discouraged for at least 24 hours because they may promote increased penetration of anhydrous ammonia.¹² Nonviable skin should be debrided early, and wounds should be dressed with topical antibiotics. Alkaline corrosive injury to the skin is discussed further in Chapter 98.

Laboratory Monitoring

Serial arterial blood gas measurements and radiographs and continuous pulse oximetry may be indicated depending on the severity of illness.

Other Medical and Diagnostic Interventions

There is no specific antidote for poisoning from ammonia exposure. Use of systemic corticosteroids for inhalation injury is controversial, although many case reports include their use. In experimental studies, methylprednisolone was not shown to protect the lung from the acute physiologic consequences of inhalation injury,³⁴ and budesonide inhalation had no effect on ammonia-induced lung injury.¹⁸ Prophylactic systemic antibiotics are not recommended. If mediastinitis develops, antibiotics are recommended.^{14,20,22}

After the eyes have been adequately irrigated, slit-lamp evaluation with fluorescein stain should be performed to evaluate for corneal burns. Immediate consultation with an ophthalmologist is essential for an abnormal slit-lamp examination. Use of ophthalmic antibiotics for corneal damage is recommended. A mydriatic agent (e.g., Atropine) and cycloplegic agent (e.g., Cyclogyl) can decrease the patient's discomfort and generally are recommended.¹² Ophthalmic corticosteroids frequently are recommended for use shortly after alkaline injury, but no controlled trials are available to support this recommendation. Alkaline corrosive injury to the eye is discussed further in Chapters 15 and 98.

If an aqueous ammonia solution of 10% or greater has been ingested, or there are symptoms of corrosive injury

(e.g., drooling), flexible endoscopy is warranted to evaluate for serious esophageal or gastric injury. A chest film should be obtained to look for mediastinal air, which suggests esophageal perforation. The use of corticosteroids has been proven ineffective in alkaline corrosive ingestions and may be harmful to patients with serious infection.³⁵

Bronchoscopy can be both a diagnostic and therapeutic aid by assisting with the removal of sloughed tissues.

Disposition

Patients with mild exposures, who have no evidence of airway compromise, may be discharged from the emergency department after 2 hours of observation, with instructions to seek medical attention if late symptoms present.³⁵ Any patient who has developed anything more than minor symptoms should be admitted for inpatient observation. Any patient with airway compromise or severe burns should be admitted to an intensive care unit. Because of the potential for chronic respiratory effects, hospitalized patients require outpatient follow-up.

NITROGEN OXIDES

Introduction and Relevant History

Nitrogen oxides are a series of oxidized nitrogenous compounds that are irritant gases with relatively low water solubility (Table 97-2). These compounds occur together in dynamic equilibrium. For example, below 21° C, NO₂ exists as a liquid in the form of N₂O₄; however, higher temperatures favor the formation of NO₂.³⁶

Toxic gas inhalation involving nitrogen oxides has been reported in both single cases and mass exposures for the past 200 years. The earliest recorded case of toxic inhalation of these fumes involved a French merchant who died after breathing concentrated nitric acid fumes in 1804.³⁷ Nitrogen oxides were not recognized as the cause of silo filler's disease until 1956,³⁸ although the clinical entity was recognized as early as 1914.³⁹

NO₂, in addition to hydrogen cyanide, is produced in the pyrolysis of nitrocellulose, a component of radiographic film. During the Cleveland Clinic disaster of 1929, NO₂ and cyanide poisoning caused 125 casualties.^{37,40}

Missile silos, where nitrogen tetroxide is used as a fuel oxidizer, have been the site of accidental exposures, including three Apollo-mission astronauts.^{41,42}

TABLE 97-2 Nitrogen Oxides

NO	Nitric oxide (mononitrogen monoxide)
NO ₂	Nitrogen dioxide
N ₂ O	Nitrous oxide
N ₂ O ₂	Nitrogen peroxide
N ₂ O ₃	Nitrogen trioxide (dinitrogen trioxide)
N ₂ O ₄	Nitrogen tetroxide (dinitrogen tetroxide)
N ₂ O ₅	Nitrogen pentoxide (dinitrogen pentoxide)

During one outbreak, there were reports of 116 cases of nitrogen dioxide–induced respiratory illness in high school students attending hockey games at a Minnesota arena. Of those surveyed, 69% of students who were on or near the ice developed acute symptoms. Authorities blamed a defective engine in the ice-resurfacing machine.⁴³

Epidemiology

Nitrogen oxides are formed naturally, primarily as a result of bacterial metabolism of nitrogenous compounds. Combustion of fossil fuels (e.g., motor vehicle exhaust) is the chief human-made source of nitrogen oxides.

Common nonoccupational exposures to nitrogen oxides include kerosene heaters, gas appliances,⁴⁴ cigarette smoke, ice-skating rinks,^{43,45} and ambient air pollution. Common occupational exposures include electric arc welding, manufacture of explosives, dyes and lacquers,³⁷ nitric acid production, firefighting,⁴⁶ and agriculture. NO₂ is produced during the decomposition of grain that has high nitrite content (i.e., corn) stored in silos. Inhalation of NO₂ generated from this source is responsible for silo filler's disease.^{41,47-49} The decomposition process begins shortly after putting crops into a silo and continues for at least 10 days. Dangerous amounts of gas may remain in the silo for a month if the silo is not opened.⁴⁸ One case report involved a man who was exposed to NO₂ 6 weeks after silage was stored.⁴⁹

Because NO is useful as a vasodilator to treat such conditions as pulmonary hypertension and acute lung injury, health care workers in intensive care could be exposed to both NO and NO₂.^{50,51}

Structure and Structure–Activity Relationships

Nitrogen oxides are a series of oxidized nitrogenous compounds that react violently with combustible and reducing materials (e.g., NH₃, carbon disulfide) (see Table 97-2). NO₂ is a reddish-brown gas or yellowish-brown liquid that reacts with water to produce nitric acid and nitric oxide. NO is a colorless gas that reacts with water to form nitric acid and rapidly is converted in air to NO₂.

Pathophysiology

Because nitrogen oxides are less soluble (hydrolyze more slowly) than most irritant gases, they penetrate the lower respiratory tract (the principal site of toxicity) more readily. Within the lungs, slow accumulation of nitrogen oxides and hydration to nitric acid (HNO₃) in the alveoli result in delayed onset of chemical pneumonitis. Pulmonary edema occurs when one inhales high concentrations of the gases.^{41,52} Both increased airway resistance and decreased diffusion capacity occur. Inhalation of as little as 0.3 ppm of NO₂ has been shown to potentiate induced bronchospasm in asthmatic individuals.⁵³ The acute increase in airway resistance that occurs after nitrogen dioxide exposure, even at low

TABLE 97-3 Exposure Limits and Clinical Effects of Nitrogen Oxides at Different Concentrations

CONCENTRATION (ppm)	NITROGEN OXIDE	EFFECTS
1	NO ₂	NIOSH-REL (15-minute STEL)
1–1.6	NO ₂	Lowest level associated with measurable impairment of pulmonary function
0.04–5	NO ₂	Odor detectable (acrid or bleach)
5	NO ₂	OSHA-PEL (ceiling limit)
1–13	NO ₂	Mucous membrane irritation

doses, appears to be mediated by histamine release.³⁷ According to NIOSH, the toxic effects associated with exposure to NO₂ are primarily determined by peak, and not average, concentrations of exposure^{54,55} (Table 97-3).

The toxicity of the oxides of nitrogen may result from the initiation of lipid peroxidation and oxidation of cellular proteins, which leads to the generation of free radicals.⁵⁶ These free radicals damage the pulmonary epithelial cells, most notably type I alveolar and ciliated cells, principally at the juncture of the terminal airways and the gas exchange tissues.^{56,57} Antioxidants, such as ascorbic acid, that act as a free radical scavenger help protect human endothelial cells exposed to NO₂. This implies an important role for free radicals in the toxicology of these agents.^{56,58,59}

NO, whose affinity for hemoglobin is 1000 times greater than that of carbon monoxide, may be absorbed from the lung and bound to hemoglobin. As a result, hemoglobin is oxidized to nitrosylhemoglobin (NOHb) and subsequently to methhemoglobin.³⁶ Some absorbed NO₂ participates in other reactions, including nitrosation of amines to form nitrosamines, a reaction that may play a role in gastrointestinal cancers.

Toxicology

CLINICAL MANIFESTATIONS

The clinical presentation and progression of the disease depend on the concentration and duration of exposure, the patient's activity level, and perhaps the patient's predisposition to lung disease. Clinical presentation generally is divided into three clinical stages: acute, delayed, and subacute.³⁷ These stages may be observed in sequence or alone.

Acute Phase

Because of the poor water solubility of nitrogen oxides, upper respiratory irritation may not be evident after exposure to very low levels. With more concentrated exposures, upper respiratory symptoms such as burning eyes, sore throat, and cough may occur. Nonspecific signs and symptoms may include nausea, vomiting, headache, dizziness, a “choking sensation,” and weakness. Bronchospasm may be present with wheezing and dyspnea. Radiographic findings soon after exposure may be normal and do not rule out the subsequent development of ALI. Many of the effects are self-limited if exposure has been only mild and brief. Symptoms may persist for 1 to 2 weeks, and complete recovery usually follows.

Delayed Phase

A symptom-free interval of 3 to 24 hours typically follows the acute phase. This asymptomatic phase, in turn, is followed by the development of chemical pneumonitis or ALI, characterized by dyspnea, tachypnea, hemoptysis, bronchospasm, rales, and hypoxia. Hypotension (direct effect of nitrate- or nitrite-induced vasodilation) is not common. Methemoglobinemia may occur in this stage, and levels have been reported from 2% to 44%.³⁶

Radiographic findings generally begin with perihilar infiltrates and progress to ALI. In one study of 34 patients, 40% of the patients who developed ALI died.³⁷ Those who survived developed long-term complications, experienced a subacute phase, or recovered completely.

Subacute Phase

This phase, in which the patient develops bronchiolitis obliterans, usually appears 2 to 4 weeks after the delayed phase. It also may occur in the absence of a prior episode of ALI, about 10 to 30 days after the initial exposure. The patient becomes acutely ill with fever and chills, cough, dyspnea, rales, wheezing, and hypoxia. At this point, the chest radiographic findings again may resemble those characteristic of ALI or may show multiple discrete nodules (miliary pattern).³⁶ Pulmonary function testing reveals both obstructive and restrictive defects. This stage may prove fatal.^{37,42,48}

Chronic Clinical Manifestations

In animals, long-term exposure to nitrogen oxides has caused emphysema, immunosuppression,⁶⁰ and increased incidence of pulmonary adenomas.⁶¹ There have been reports of coal miners developing emphysema with long-term exposure to NO₂.⁶² There is little evidence to implicate NO₂ directly as a pulmonary carcinogen in humans, but it could modify and influence the carcinogenic process in the lung.⁶³ One report of the mortality experience in a large cohort, from 1977 to 1992, found an association between mean ambient NO₂ concentrations and lung cancer in women.⁶⁴

Because various indoor and outdoor sources release nitrogen oxides, the general public may experience persistent, low-level exposure to these compounds. Although epidemiologic studies have not identified an

independent effect of long-term exposure to ambient NO₂, researchers hypothesize that several chronic health problems may occur as a result of this low-grade exposure, including increased incidence and severity of respiratory tract infections, reduced lung function, and increased symptoms in patients with asthma and chronic obstructive pulmonary disease.^{65,66}

Adverse Effects

Persistent respiratory disease, including symptoms of chronic bronchitis and spirometric evidence of obstructive or restrictive disease, has been documented after acute exposure to nitrogen oxides.^{41,67} In one study of 23 cases, of the 5 cases that progressed beyond the acute phase, all had some persistent pulmonary dysfunction several years later.⁴¹ In another study, 6 cases of RADS were diagnosed among 234 patients exposed to dinitrogen tetroxide.⁶⁸

It is difficult to predict who will have long-term complications from a single acute exposure, and meaningful numbers from studies are essentially nonexistent. Generally, a patient whose illness does not progress beyond the acute phase will not have subsequent problems, and patients who have pulmonary edema or whose illness evolves to bronchiolitis obliterans seem to have a high probability of developing long-term complications.

With regard to nonrespiratory symptoms, in one report 6 of 24 victims of a missile-silo accident developed chronic headaches and other subjective neuropsychiatric complaints after the accident.⁶⁹

DIAGNOSIS

Laboratory Testing

Serial arterial blood gas measurements and radiographs, methemoglobin levels, and continuous pulse oximetry may be indicated, depending on the degree of the patients' illness. Patients with bronchiolitis obliterans may have a neutrophilic leukocytosis and an elevated sedimentation rate.

Differential Diagnosis

A latency period of several hours, followed by signs and symptoms consistent with ALI, is suggestive of this exposure. The differential diagnosis should include allergic lung disease due to molds (farmer's lung due to hypersensitivity reaction), asthma, pneumonia, miliary tuberculosis, viral influenza, carbon monoxide exposure, myocardial infarction, or ALI following exposure to other toxic products of combustion or respiratory irritants with low water solubility (e.g., phosgene).

MANAGEMENT

Supportive Measures

Treatment depends on a patient's phase of clinical illness and the symptomatic presentation. Oxygen and intubation with positive-pressure ventilation, as needed, are considered the mainstays of treatment.³⁷ Use of the minimum concentration of oxygen has been recommended to maintain arterial oxygenation because hyperoxia may exacerbate the oxidant injury induced by

NO₂.³⁶ Inhaled bronchodilators are recommended for bronchospasm.

Because these patients are prone to infection, frequent sputum cultures should be obtained and antibiotics started when indicated.

Decontamination

Wet clothing should be removed, and any exposed skin flushed with water. Exposed eyes should be irrigated with copious amounts of water or saline.

Other Medical and Diagnostic Interventions

There is no specific antidote for nitrogen oxide poisoning. Methemoglobinemia should be treated with oxygen and methylene blue (1–2 mg/kg intravenously). Corticosteroids have been shown in many case reports to be beneficial, in both the treatment and prevention of ALI and bronchiolitis obliterans.^{36,41,42,48,49,70} Many researchers report dramatic improvement in symptoms after use of corticosteroids and recurrence of the symptoms when the corticosteroids are abruptly stopped; the symptoms then respond to reinstatement of the corticosteroids.^{36,41,42,48} High-dose corticosteroids have been recommended for a 6- to 8-week course, and tapered gradually to prevent relapses.^{41,46}

Disposition

In all instances in which significant exposure may have occurred, affected patients should be observed for at least 24 to 48 hours after exposure, even if they are asymptomatic and exhibiting a normal chest radiograph. In-hospital observation for 6 hours is recommended for patients with potential or mild nitrogen oxide exposure. If a patient is asymptomatic after that time and has rapid access to medical care, he or she may be discharged for close follow-up.

PAUL M. WAX, MD ■ MARK YAREMA, MD

At a Glance...

- Alkalis and acids can injure either the esophagus or the stomach.
- The potential for tissue injury is dependent on the duration of contact and on the concentration, volume, and pH of the product.
- No one symptom or group of symptoms can reliably predict the degree of esophageal injury after a corrosive ingestion.
- Upper gastrointestinal endoscopy is the only diagnostic test available that reliably detects the degree of esophageal injury.
- Patients who are asymptomatic after a corrosive ingestion can be safely discharged without the need for endoscopy.
- Corticosteroid therapy remains highly controversial. Corticosteroids may be beneficial for endoscopy-diagnosed second-degree burns.
- The risk for esophageal stricture is greatest after circumferential second- and third-degree burns.
- There is a long latency period between corrosive ingestion and esophageal or gastric carcinoma.

INTRODUCTION AND RELEVANT HISTORY

Corrosives are a group of chemicals that have the capacity to cause tissue injury on contact with multiple organ systems, most commonly the gastrointestinal, respiratory, ophthalmologic, and dermatologic systems. Examples of agents capable of causing chemical burn injuries include alkalis (e.g., NaOH, KOH), acids (e.g., HCl, H₂SO₄), and certain antiseptics, such as phenol,

formaldehyde, iodine, and concentrated hydrogen peroxide. Hydrofluoric acid (HF), a relatively weak acid, is particularly known for its ability to cause necrotizing injury and life-threatening systemic toxicity as a result of the fluoride moiety chelating endogenous calcium (see Chapter 90). For the purpose of this chapter, the term *corrosive* (a term sometimes used interchangeably with *caustic*) refers to any of these agents capable of causing tissue injury on contact. The term *lye* refers to specific alkali, typically sodium hydroxide or potassium hydroxide.

Corrosives are widely available to the public, primarily as household cleaners (Table 98-1). More than 60,000 corrosive exposures were reported to poison centers in the United States in 2002.¹ The focus of this chapter is on alkalis and acids and their toxic effect on the previously mentioned systems, with special attention to the gastrointestinal tract.

Before 1950, strong lyes (concentration > 50%) made up most caustic ingestions in the United States. Not uncommonly, ingestions of strong lyes led to respiratory compromise, severe esophageal burns, perforation of the esophagus and stomach, mediastinitis, late stricture, and sometimes death.

Over the years, three legislative acts were passed by Congress to help reduce the occurrence of corrosive injuries in the United States, particularly in children. The first was the Federal Caustic Poison Act of 1927, which for the first time mandated that concentrated lye and acid-containing products clearly display a “poison” label.² The second was the Federal Hazardous Substances Act of 1960, which imposed mandatory standards for labeling of hazardous materials. Finally, in 1970, Congress enacted the Poison Prevention Pack-

TABLE 98-1 Sampling of Currently Manufactured Household Cleaning Products That Contain Caustic Chemicals

APPLICATION	PRODUCT	CHEMICAL	
Drain cleaner, liquid	Heavy Duty Liquid Drain Opener (Share)	H ₂ SO ₄ 93%	
	Drain Out Extra (Iron Out)	KOH 30%	
	Liquid-Plumr (Clorox)	NaOH 0.5%–2%, NaOCl 10%	
Drain cleaner, crystals	Maximum Strength Drain Opener (Enforcer)	KOH 5%–15%	
	Crystal Drain Opener (Rohyme)	NaOH 74%	
	Crystal, Drain Out (Iron Out)	NaOH 55%	
	Drano Pipe Cleaner (Johnson)	NaOH 54%	
Oven cleaner	Easy-Off Heavy Duty Oven Cleaner (Rickitt Benckiser)	NaOH < 5%	
	Rust remover	Rust Stain Remover (Whink)	HF 2.5%–3%
		Rust Stripper (Certified)	NaOH 50%–75%
Toilet bowl cleaner	Naval Jelly Rust Remover (Loctite)	Phosphoric Acid 25%–30%	
	Instant Power Toilet Bowl Cleaner (Scotch)	HCl 26%	
	Bowl and Porcelain Cleaner (Cleanline)	HCl < 10%	
Swimming pool cleaner	Muriatic Acid, Aqua Chem (Recreational Water)	HCl 31%	

aging Act.³ This legislation resulted in the mandatory packaging of corrosive agents in child-resistant containers if the concentration of the active agent was either greater than 10% or 2% by weight of free chemical.

Despite these legislative efforts, highly concentrated caustic products remain on the market, although they are typically less available as household products than in the past. Such products continue to be used in commercial industries, on farms, and as swimming pool cleansers. Household products that contain caustic chemicals include drain cleaners, toilet bowl cleaners, and general purpose anticorrosive cleaners. Although low lye (<10%) or no lye (enzymatic) drain cleaners have replaced some of the more highly concentrated caustic products, household liquid drain cleaners with high concentrations of alkali (30% KOH) or acid (93% H₂SO₄) may still be purchased in neighborhood hardware stores (e.g., Home Depot) in 2004 (see Table 98-1). Commercial industries and farms often use concentrated corrosives as chemical reagents and as cleansers.³ Dairy farms use pipeline cleaners that contain liquid NaOH and KOH in concentrations of 8% to 25%.

Ingestion of crystal lye may be particularly problematic and result in severe burns because of the opportunity for prolonged tissue contact. Fortunately, most crystal lye ingestions are limited by immediate oral pain. The ingestion of granular automatic dishwashing detergents has been associated with devastating injuries.⁴ Crystal drain cleaners have lye concentration as high as 74% NaOH and may cause proximal esophageal injury. Some liquid dishwashing detergents and laundry detergents have a pH greater than 12, but because the titratable base content is significantly lower, there is less risk for injury after ingestion.

Ingestion of liquid household bleach containing dilute (5.25%) sodium hypochlorite (NaOCl) rarely causes significant injury. Industrial-strength bleach may contain significantly higher concentrations of sodium hypochlorite, leading to esophageal necrosis. Toilet bowl cleaners contain hydrochloric acid as high as 26% HCl. General purpose anticorrosive cleaners, such as 31% muriatic acid (HCl), are sold in gallon containers for home use and as swimming pool cleaners.

Sodium hydroxide is also found as a constituent of hair perm relaxers. Excessive topical use of these relaxers may occasionally cause facial and oral burns, as well as esophageal burns and airway compromise, if ingested, although most exposures do not cause significant injuries.^{5,6} The alkali powder in airbags has caused ocular burns. Perfumes accidentally sprayed into the eyes can cause burns.⁷ Cement is alkaline and causes topical burns, typically on the knees.⁸

More than 70 different pills may cause damage when they come in contact with the esophageal mucosa for prolonged periods.⁹ Patients who take medications in the supine position or take pills without water are at higher risk. Pills most likely to adhere are doxycycline, tetracycline, potassium chloride, and aspirin. Ingestion of potassium chloride pills has caused perforation into the aorta, left atrium, and bronchial artery.⁹

STRUCTURE AND STRUCTURE–ACTIVITY RELATIONSHIPS

Pathophysiology

The type of agent, formulation of the product, concentration of solution, volume, viscosity, pH, duration of contact, and presence or absence of food in the stomach are all factors that influence the extent of injury from a caustic exposure. The titratable alkaline reserve of an alkali or acid may be particularly correlative with the likelihood of burn injury.¹⁰ Regarding alkalis, it has been suggested that the critical pH that causes esophageal ulceration is 12.5.¹¹ Corrosives may cause injury to any exposed tissue, including skin, mucous membranes, eyes, gastrointestinal tract, and lungs.

Alkalis

Alkalis, such as sodium hydroxide and potassium hydroxide, directly damage tissue by producing saponification of the fatty acids within cell membranes, resulting in the loss of membrane integrity. In addition, the reaction of hydroxide ions with collagen may cause protein disruption and considerable edema. The end result is liquefaction necrosis and a softening of the tissues. Unfortunately, the process of liquefaction necrosis allows for further penetrance of the alkali into the tissue and further injury.

The depth of the necrosis is dependent on the concentration of the lye.¹² Strong caustics cause their damage quickly. In one study, contact of the esophageal tissue with sodium hydroxide at 22.5% for only 10 seconds resulted in a full-thickness burn.¹² In another study, a solution of 30% sodium hydroxide in contact with tissue for 1 second resulted in a full-thickness burn.¹³

Acids

Acids, such as hydrochloric acid and sulfuric acid, dissociate on contact with water to release hydrogen ions. Contact of acids with tissue causes tissue destruction. Unlike alkalis, a coagulum or eschar may develop after acid contact, in some cases limiting the further spread of the acid and depth of necrosis. However, subsequent sloughing of the coagulum may still occur, extending the tissue injury sometimes in a delayed manner. Full-thickness burns resulting in perforation may result.¹⁴

Historically, acid-induced injury to the gastrointestinal tract was summarized in the phrase “lick the esophagus, bite the pyloric antrum.”¹⁵ However, reports indicate that acid ingestion may result in both esophageal and gastric injury.¹⁶ Gastric injury is more likely to occur in the pylorus and antrum. This may be because of the preferential flow of liquids rapidly from the esophagus along the lesser curvature of the stomach to the pylorus rather than into the fundus and body, where solids tend to collect. Duodenal injury may also occur, but this is appears to be less common than gastric injury, possibly

because of pylorospasm induced by the acid or the neutralization of the acid by duodenal contents.

In the past, it was thought that ingestion of strong acids was more likely to cause gastric necrosis and that ingestion of strong lyes was more likely to cause esophageal injury. In fact, it appears that acids cause a similar incidence of esophageal and gastric injury and may also cause laryngeal burns. Alkalis may cause gastric necrosis and perforation and small intestine injury, as well as esophageal injury.^{17,18} Perforation from either acids or alkalis may result in extensive necrosis of abdominal viscera.

Time Course and Natural History

Typically, the damage from corrosives occurs in four stages. Initially, necrosis occurs with invasion by bacteria and polymorphonuclear leukocytes. Subsequently, vascular thrombosis occurs, increasing the damage. Over the next 2 to 5 days, superficial layers of injured tissues begin to slough. After the caustic exposure, the tensile strength of the healing tissue may be quite low for up to 3 weeks. In some cases, this loss of tissue integrity greatly increases the chance of delayed perforation and is the main reason patients remain at risk for deterioration for up to 14 days or longer after exposure. The formation of granulation tissue, collagen deposition, and re-epithelization signals the tissue recovery process and generally occurs between 1 week and several months after the exposure. Unfortunately, the wound healing itself may herald a constrictive phase, ultimately causing esophageal stricture formation because of scar contraction—a process that may occur over a period of weeks to years.

Morphology

Caustic injuries are categorized as first-, second-, and third-degree burns, similar to thermal burns, based on their appearance at endoscopy (Table 98-2). The initial depth of injury found on esophagoscopy correlates with the risk for stricture formation. First-degree (grade 1) burns consist of edema and hyperemia. In these cases,

the depth of involvement would be similar to a sunburn. Blisters do not occur, and strictures would not result from these superficial burns. Ulcers, whitish membranes, exudates, friability, and hemorrhage characterize second-degree (grade 2) burns. These partial-thickness burns are further subdivided into grade 2a—non-circumferential—and grade 2b—circumferential—burn injuries. Although overall about 15% to 20% of grade 2 esophageal burns develop strictures, 75% of grade 2b burns develop strictures.¹⁹ Third-degree injuries involve the full thickness of the mucosa, often with necrosis. These injuries are most likely to perforate. Of those who survive the acute injury, 90% develop strictures.

Special Populations

PEDIATRIC PATIENTS

Corrosive injury to the esophagus remains a serious health problem in children. Nearly 80% of reported caustic ingestions occur in children. At least 85% of reported ingestions are unintentional.²⁰ More than 125,000 ingestions of household cleaning products in 2002 occurred in children younger than 6 years, second only to cosmetics and personal care products in frequency.¹ Storage of corrosives in inappropriate containers, such as sports drink bottles, soda cans and bottles, and jars, contributes to unintentional ingestion. Although contact with the oral mucosa usually causes severe pain and vomiting that theoretically limits further damage, a small ingestion may be sufficient to result in serious morbidity and mortality. Given the long-term complications of stricture and esophageal and gastric carcinoma, prevention of exposure to these toxic agents is of paramount importance.

PSYCHIATRIC PATIENTS

Although unintentional ingestion of small amounts of a caustic agent may still cause devastating injuries, intentional ingestion among adolescents and adults accounts for a higher percentage of significant injuries. Among suicidal patients who ingest caustic agents, more than half have a history of psychiatric illness.²¹ Many of these deliberate ingestions of caustic chemicals occur among individuals who are confined in psychiatric hospitals or prisons. This occurs because of the availability of a variety of cleansers in these facilities (and the lack of availability of pharmaceuticals and other toxic agents). Because some psychiatric patients have been known to attempt to mask their symptoms after caustic ingestion, a high suspicion of possibly corrosive injury should be considered in this population.

TOXICOLOGY

Clinical Manifestations

The acute and chronic (long-term) complications resulting from caustic ingestion may be devastating. Initially during the first few hours and days after the caustic exposure, the development of airway edema

TABLE 98-2 Classification of Corrosive Burns to the GI Tract

GRADE OF INJURY	FINDINGS
0	Normal examination
1	Erythema, hyperemia
2a	Superficial ulceration, erosions, whitish membranes
2b	As for grade 2a, plus deep discrete or circumferential ulcerations
3	Multiple deep ulcerations, areas of necrosis

From Zargar SA, Kochlar R, Nagi B, et al: Ingestion of corrosive acids. Spectrum of injury to upper gastrointestinal tract and natural history. *Gastroenterology* 1989;97:702.

leading to a compromised airway and esophageal or gastric perforation is the most emergent issue. Over the long term, the ingestion of caustics may lead to esophageal or gastric strictures requiring repetitive dilatory procedures and in some cases esophageal bypass and colonic interposition. Patients with significant acute injuries are at significantly increased risk for esophageal carcinoma, a most unfortunate long-term sequela.

Acute Presentation

Small ingestions of a concentrated caustic can be as problematic as larger ingestions. More than 40% of patients reporting to have “only taken a lick” have esophageal burns.²² Some of the most common complaints are oral pain (41%), abdominal pain (34%), vomiting (19%), and drooling (19%).²⁰ Other clinical features may include crying, dysphagia, odynophagia, hematemesis, wheezing, coughing, stridor, dysphonia, chest pain, and respiratory distress. Pain, crying, excessive salivation, and dysphagia tend to be associated with lesions of the buccal mucosa but do not accurately predict lesions elsewhere. Spontaneous vomiting is associated with a higher incidence of more severe esophageal injury. Visible burns to the face, lips, and oral cavity may be seen and appear as white or gray patches with an erythematous border.

Laryngeal edema often occurs over a matter of minutes to hours, requiring rapid intubation. Peritoneal signs suggest hollow viscus perforation or contiguous extension of the burn injury to adjoining visceral areas. Systemic toxicity, hypovolemic shock, and hemodynamic instability manifested as hypotension, tachycardia, fever, and acidosis may occur in these cases and are ominous findings. Emergency surgical intervention may be required in these cases.

Correlating clinical symptoms with the severity of esophageal burns can prove very difficult because different studies have presented conflicting data over the years.^{19,20,23} Although there is a tendency to use the results of the oropharyngeal examination to predict more distal injury, such a strategy is not reliable. Oral burns on admission predicted burns of the esophagus with a sensitivity of 52.9% and specificity of 51%.²⁴ Prolonged drooling and dysphagia (12–24 hr) were much more predictive of significant lesions, with 100% sensitivity and 90% specificity.²⁴ Vomiting and stridor also appear more predictive than oropharyngeal burns in predicting burn injury.

Although acid ingestions are much less common than alkali ingestions in the United States, significant acid ingestions may also cause extensive tissue injury and result in a higher mortality rate than alkali ingestions. Massive upper gastrointestinal bleeding and aspiration pneumonia may also occur.^{25,26} Systemic effects from acid ingestions include metabolic acidosis, disseminated intravascular coagulation, hyponatremia, and hypotension. The more fulminant course of some acid ingestions may be due to systemic absorption of the acid resulting in metabolic acidosis (which may also be the result of extensive tissue necrosis), hemolysis, and renal failure.

In Russia, concentrated acetic acid ingestions account for 64% of caustic ingestions.²⁷

Patients with pill-associated caustic injury may present with less acute symptoms. They may not clearly relate their current symptoms to the pill ingestion, although they often recall a transient feeling of “something stuck.” Most present with severe retrosternal pain. Dysphagia is not common. The pain lasts 3 days to a few weeks. Occasionally, more severe cases present with hematemesis, weight loss, or fever. Endoscopy generally reveals a sharply demarcated superficial ulcer. Deep ulcerations or even penetration may occur particularly with potassium tablets.

Long-Term Complications

Long-term consequences can be more damaging than the acute injury. The two major long-term concerns after alkali ingestion are the risk for stricture and esophageal carcinoma. Patients with significant esophageal burns, particularly those that are circumferential, develop esophageal stricture. Eighty percent of strictures first become apparent in 2 to 8 weeks. Symptoms include dysphagia and food impactions. Strictures that become symptomatic early are generally more severe.

The risk for stricture can be predicted based on the degree of burn visualized at endoscopy. First-degree burns do not progress to stricture. Second-degree burns may progress to stricture in at least 15% to 20% of cases. Third-degree burns carry the worst prognosis for stricture, with a risk for at least 90%.^{19,22}

The latent period between corrosive ingestion and the development of squamous cell esophageal carcinoma may be as long as 40 to 50 years. Hence, adults with significant childhood exposures need lifelong surveillance. Patients have at least a 1000- to 3000-fold increased risk for esophageal cancer after corrosive ingestion.²⁸ A recent long-term study showed that 1.8% of patients who ingested caustic soda developed esophageal cancer.²⁹ Nearly 3% of esophageal cancer patients have a history of caustic ingestion.²⁸

Sequelae of acid ingestion include esophageal stricture, pyloric and antral stenosis, duodenal atonicity, gastric metaplasia, and carcinoma. The risk for carcinoma after caustic acid ingestion is unknown.

DIAGNOSIS

Laboratory Testing

No specific laboratory tests are available that predict severity of poisoning after corrosive ingestion. General laboratory studies should include a complete blood count, serum electrolytes, blood type and screen, renal and liver function tests, and coagulation studies. An arterial blood gas measurement should be obtained if there is ongoing stridor or evidence of hemodynamic compromise. Arterial blood gas determination may be particularly useful after significant acid ingestions given the propensity for severe acid–base disturbances in these

cases. A recent study suggested that pH less than 7.22 was correlative with severe injury requiring surgical intervention.³⁶ A white blood cell count greater than 20,000/mL may be predictive of death after caustic ingestion when combined with other parameters such as age, ingestion of strong acid, presence of deep gastric ulcers, or gastric necrosis.³¹ In intentional overdoses, co-ingestants should be considered and a comprehensive urine drug screen obtained. However, the caustic chemical itself will not be detected on a urine drug screen.

Other Diagnostic Testing

In symptomatic patients, a chest x-ray and abdominal flat plate should be obtained to look for evidence of peritoneal and mediastinal air denoting perforation or pleural effusion, suggesting esophageal leak. It is important to note that the depth of esophageal burns cannot be predicted based on signs or symptoms. Noninvasive techniques, such as chest and abdominal x-rays, water-soluble contrast swallow, or computed tomography (CT) with contrast can suggest or detect perforation but do not provide sufficient information to gauge depth of burn injury.³²

The test of choice for proper staging of burn severity is upper gastrointestinal endoscopy. Not only can endoscopy define the extent of disease after acute ingestion, but also it can document healing after ingestion. Endoscopy results will divide patients into four groups: no esophageal/gastric injury, gastric injury, linear burns of the esophagus, and circumferential burns. Those with gastric injury are at risk for pyloric ulceration and later gastric outlet obstruction. Linear burns of the esophagus often heal well; circumferential burns are likely to lead to stricture.

Much attention has been devoted to finding a single clinical feature or group of signs and symptoms that can reliably predict esophageal injury, and therefore which patients should go on to endoscopy. Studies to date have produced conflicting results. What is clear is that patients who are asymptomatic on presentation and are able to drink liquids without any discomfort can be assumed to have no significant esophagogastric injury and may be managed conservatively without the need for endoscopy.³³ As stated previously, the absence of external visible signs of exposure cannot be equated with absence of esophageal lesions.^{23,34,35} In general, the greater the number of presenting signs and symptoms, the higher the like-lihood of significant esophageal burns.^{34,36} Unfortunately, there is no pathognomonic group of presenting signs and symptoms that can identify all patients with potentially serious gastrointestinal burns.^{33,34}

Based on the studies to date, the main indication for endoscopy is a symptomatic patient who exhibits vomiting, drooling, dysphagia, odynophagia, stridor, or dyspnea. Endoscopy may also be warranted in less symptomatic cases if the ingestion is intentional. Ideally, endoscopy should be performed within 12 to 24 hours after ingestion. Endoscopy performed before 12 hours

may not delineate the extent of injury, and wound softening makes endoscopy initiated after 24 hours more hazardous.

In some cases, early endoscopy may help guide the need for corticosteroid therapy, which, if indicated, should be initiated within the first 24 hours. The gastroenterologist may also choose to place a soft feeding tube or silk string in the esophagus when burns are present at the time of endoscopy. The string provides a guide for future dilation. In the past, endoscopy was often terminated at the most proximal burn area because of worry about iatrogenic perforation. Although this concern was applicable to rigid esophagogastroscopy techniques, flexible endoscopes can be carefully passed beyond the area of burn (unless there is a perforation), allowing for a more complete examination including evaluation of the stomach, if possible.

Any suspicion of abdominal involvement should be studied by repeated abdominal CT or ultrasound.³⁷ Follow-up contrast studies are useful to evaluate for the presence of esophageal or gastric strictures.

MANAGEMENT

Supportive Measures

Protection of the airway supersedes all other interventions. Because oropharyngeal and laryngeal edema may rapidly ensue, making airway control considerably problematic, early endotracheal intubation is indicated when there is concern regarding compromise of the airway, especially in cases with stridor. Fiberoptic airway evaluation to determine the extent of injury may prove useful. Surgical cricothyrotomy may be required when the airway cannot be secured by less invasive means. Blind nasotracheal intubation is contraindicated. Intravenous access should be established and fluid resuscitation initiated. With significant exposures, vigorous fluid resuscitation may be required. It is essential to employ early and continuous hemodynamic monitoring to evaluate for evidence of shock and volume depletion secondary to hollow viscus perforation. Analgesics should be provided as clinically indicated, with care taken not to oversedate the patient.

On arrival in the emergency department, the patient should be fully unclothed and examined for evidence of dermal and ocular caustic exposures. Ongoing dermal exposure from a caustic spill may continue to be injurious until the clothing is removed and copious irrigation has taken place. Contaminated clothing should be treated as hazardous waste and disposed using proper precautions.

Decontamination

Treatment often begins at the scene of the ingestion. Sips of water or milk can dislodge solid particles and dilute material residing in the stomach, but may cause an exothermic reaction. In alert patients who are not vomiting and can tolerate liquids, small volumes (1–2

cups) of water or milk may be considered within the first few minutes after ingestion. Because injuries occur almost immediately, later dilution is not warranted. Forcing fluids is never indicated because the precipitation of emesis may lead to further caustic exposure. Experimentally, it has been shown that significant heat is generated by contact of the acid or alkali with the moist esophageal surface.³⁸ More recent studies have not generated significant amounts of heat.³⁹ Whether heat increases the injury has never been quantified, but has led to concerns regarding initial dilution or gastric lavage. Regardless of where treatment is initiated, those who come in contact with the patient should take proper precautions to protect themselves from secondary caustic exposure.

Over the years, neutralization approaches to caustic ingestions such as treating alkali ingestion with dilute acetic acid (vinegar) or treating acid ingestion with sodium bicarbonate have been frowned on. Such therapy may produce gas-forming exothermic reactions, potentially stressing already compromised tissues.

Gastrointestinal decontamination procedures, such as activated charcoal administration and gastric lavage, are usually not indicated. Activated charcoal would obscure endoscopic visualization of the mucosa and increase the risk for vomiting. Careful nasogastric aspiration may be useful in the setting of significant acid ingestions, however, given the ominous natural history of many of these ingestions and the somewhat lower risk for esophageal perforation. A nasogastric tube may be placed under fluoroscopy and used to drain the contents of the stomach and lavage with cold fluids. Polyvinyl chloride (PVC) nasogastric tubes harden with time and should not be used for long-term treatment.⁴⁰ Ipecac is always contraindicated.

Other Therapy

The initiation of corticosteroid therapy has remained controversial. Therapy with corticosteroids has been advocated to potentially limit the inflammatory response and prevent stricture formation. Studies to date have produced conflicting results on the effectiveness of these agents, and their use has not been validated in prospective clinical trials.^{29,41-45} These trials have suffered from methodologic errors such as a lack of randomization, nonblinding of patients and investigators, small number of patients in study groups, different corticosteroids used, failure to perform endoscopy in all patients, or retrospective study design.

The natural history of corrosive injury can be of assistance in determining which patients, if any, may benefit. The nature of first-degree burns is such that they do not need to be treated with corticosteroids because stricture formation does not occur in these cases. Similarly, third-degree burns are unlikely to benefit from corticosteroid therapy because the extensive damage caused is not expected to respond to corticosteroid therapy.⁴⁶ Furthermore, third-degree burn injuries have a high incidence of perforation and fistula formation, and steroid therapy may potentially worsen these

injuries. Therefore, the controversy is in regard to their use in second-degree burns. A 20-year prospective clinical trial demonstrated no benefit with corticosteroids in the prevention of strictures after corrosive ingestion, including those patients with second-degree burns.⁴³ However, power limitations of the study limit these conclusions. Regardless, corticosteroids continue to be recommended by some individuals in the treatment of circumferential second-degree burn injuries of the esophagus.^{41,47}

If the decision is made to treat with steroids based on endoscopic results, the choice of corticosteroid is largely left to the individual physician. The studies to date have included methylprednisolone, prednisolone, and prednisone. The recommended dose of prednisolone is 2 mg/kg/day in children or 40 mg three times daily in adults for 14 to 21 days, followed by a taper. Careful analysis of the benefits and risks of this therapy must be undertaken because corticosteroids may mask symptoms of a deteriorating clinical condition, and increase the risk for other infectious conditions because of their immunosuppressive effects.

Antibiotics are only indicated if there is clinical or endoscopic evidence of perforation or infection or if corticosteroid therapy is used. Prophylactic antibiotics can mask evidence of impending perforation. The antibiotics chosen should have coverage against a broad spectrum of oral and enteral pathogens because gram-positive and gram-negative pathogens and anaerobes can all be potentially encountered. Initial parenteral therapy with piperacillin-tazobactam or a third-generation cephalosporin plus clindamycin followed by oral therapy with a fluoroquinolone and clindamycin is one such regimen. Ampicillin and clindamycin have also been used in these cases.

Surgical Treatment

Immediate surgical intervention is indicated for the presence of free air, peritonitis, increasing and severe chest and abdominal pain, and hemorrhagic shock unresponsive to blood component therapy. Exploratory surgery may also be warranted in patients with suspected full-thickness burns. Early consultation with a gastroenterologist or general surgeon is recommended in any critically ill patient after corrosive ingestion.⁴⁸

Esophageal stricture begins early and remains a lifelong problem. Treatment with repeated bougienage can be started as early as 3 weeks after ingestion. Although no randomized trials have studied the efficacy of repeated dilation, it is a widely used treatment and in some cases may eliminate the need for surgical intervention.^{49,50} As with any esophageal dilating procedure, repeated trauma to the esophagus creates areas of weakness, increasing the chance of perforation. Recent animal studies and human case reports have suggested that esophageal stents have greater success long term.^{51,52} Colonic interposition procedures may be performed in some patients requiring eventual esophageal replacement.^{46,53,54} The development of cancer in the residual esophageal stump despite replace-

ment has been reported.⁵⁵ Gastric outlet obstruction may also require endoscopic balloon dilation or surgical correction.⁵⁶

Disposition

Asymptomatic patients can be observed in the emergency department and subsequently discharged home if they are able to ingest fluids with no discomfort. Parents should be informed that development of signs and symptoms after discharge warrants further medical attention. All symptomatic patients require admission to the intensive care unit and should remain NPO pending gastrointestinal consultation. Psychiatric evaluation is warranted for patients with intentional ingestion.

At a Glance...

- Baby powder inhalation produces hypoxia by obstructing the airway and interfering with ciliary action. No systemic toxicity has been reported. Pulmonary manifestations range from cough to respiratory failure and apnea. Adult respiratory distress syndrome and long-term pulmonary impairment can occur.
- Management for baby powder inhalation includes establishing and maintaining the vital functions. Clear the airway, administer 100% oxygen, and give assisted ventilation and positive end-expiratory pressure if necessary. Obtain chest x-rays and monitor arterial blood gases if symptomatic. Corticosteroids may be useful. Admit to hospital in cases of hypoxemia or respiratory distress; the chest x-ray findings are sometimes delayed.
- After oral or dermal absorption of boric acid, the earliest symptoms are gastroenteritis with blue-green vomitus and diarrhea. Central nervous system stimulation may occur. An erythematous rash may develop within 6 hours after ingestion. Desquamation and exfoliation ("boiled lobster" appearance) can occur within 2 to 5 days after exposure. Blood levels of boric acid do not correlate well with toxicity.
- Management of boric acid toxicity consists of symptomatic and supportive care. Activated charcoal has limited utility. Hemodialysis may enhance elimination in severe cases.
- Onset of CNS stimulation (seizures) may begin within 5 minutes after camphor ingestion. It has a distinctive odor.
- Treat seizures with a benzodiazepine. Gastrointestinal decontamination is not advised, nor are extracorporeal measures. There is no specific antidote. Ingestions in children of more than 30 mg/kg or more than 3 g in an adult need medical evaluation and monitoring for at least 4 hours. Symptomatic patients should be placed in the intensive care unit.

BABY POWDER**Introduction and Relevant History**

There are many formulations of baby powder, but the major ingredient is usually talc.¹ Historically, talcum powder had originally been reported as an ingredient in paints used by cave dwellers and in glazed pottery made by the Chinese more than 1300 years ago. Today, talcum powder is a commercially mined mineral that is primarily composed of hydrated magnesium silicate.^{2,3} Talcum powder is used in the manufacture of a myriad of products, including animal feed, automobiles, cables, candles, ceramic tiles, chewing gum, cosmetics, wastewater treatment technology, fertilizers, paints, pharmaceuticals, plaster, putties, tires, and baby powder. Specific purity

guidelines have been set forth to eliminate asbestos contamination of cosmetic and pharmaceutical grade talc.^{3,4} Other common ingredients of baby powder may include calcium and zinc salts, petrolatum, and perfume. Cornstarch is a major ingredient in "talc free" baby powder.³ All these substances can, when inhaled, produce a similar aspiration pneumonitis.^{4,6} The routine use of nonmedicated powders in the skin care of infants can be hazardous and should be discouraged.^{5,6} Most exposure to baby powder generally occurs either through accidental inhalation by infants and children or through its routine use by women as a dusting powder in the perineal area.^{5,6} Workers are variably exposed to talc in the course of mining it.^{7,8} Oral ingestion of talc is not likely to be toxic; it is contained in some pills, and there is no evidence to suggest adverse effects from moderate intake.⁴

Epidemiology

Data on the toxic effects of talc inhalation originally came from a few case reports of unintentional massive exposures in infants and children.⁹⁻¹⁵ Many of the children in the older literature died as a result of the exposure. According to the Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System (TESS), there were 6291 powder exposures reported in 2002. Of these, 5719 (91%) cases were in children younger than 6 years, 259 (4.1%) were in patients between 6 and 19 years of age, and 301 (4.8%) were in patients older than 19 years. There were 403 (6.4%) exposures managed in a health care facility. Only 81 (13%) exposures resulted in moderate effects, and no major morbidity or mortality was reported.¹⁶ Most of the children who inhale baby powder recover well.^{2,16}

A number of studies have attempted to ascertain whether perineal exposure to talc in women increases the risk for ovarian cancer.⁸ Although the frequency and duration of use have also been examined, a clearcut relationship between perineal talc exposure and ovarian cancer has not been clearly established.¹⁷

Structure and Structure–Activity Relationships

The molecular formula of hydrous magnesium silicate is $\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2$. It has a molecular weight of 96.49.¹⁸

Pharmacology**PATHOPHYSIOLOGY**

The physical properties of talc account for its toxicity when inhaled. It is insoluble in water and not biodegrad-

able; it thus may obstruct the airways to variable degrees.¹⁴ The size of talc particles, which averages less than 5 μm ,¹⁹ would allow them to reach the alveoli; this has indeed been confirmed on pathologic specimens.¹⁰ Other pathologic findings after talc inhalation consist of inflammatory changes in the airway and interstitium, bronchiolitis with bronchiolar obstruction, atelectasis, emphysema, and fibrosis.^{10,11,14} These pathologic findings are in accord with the observation that the clinical picture may resemble severe bronchiolitis.¹³

PHARMACOKINETICS

Although widely used, baby powder has few, if any, indications. Its absorptive capacity is negligible compared with that of a diaper, its fragrance and friction-reducing effects are transient, and it is less effective than a cream or lotion, which cannot be inhaled. The kinetics of powders such as talcum has not been elucidated.

Toxicology

CLINICAL MANIFESTATIONS (ACUTE AND CHRONIC)

Acute aspiration of baby powder or talc can cause coughing, dyspnea, tachypnea, sneezing, vomiting, cyanosis, and pulmonary edema, which may be delayed up to several hours.² Respiratory acidosis, bronchitis, bronchiolitis, pulmonary edema, atelectasis, emphysema, and severe bronchiolar obstruction may develop.^{11,14} Cardiorespiratory arrest may occur after severe aspiration.¹³

Chronic inhalation of industrial talc dusts or body talc produces talcosis due to talc, silica, and asbestos (talc pneumoconiosis) and is characterized by productive cough, dyspnea, rales, diminished breath sounds, limited chest expansion, interstitial fibrosis, and granulomas.²⁰ The extent and severity of fibrosis correlates with the length of exposure and dust concentration. Pneumoconiosis associated with obstructive and restrictive lung disease after chronic intentional inhalation of talcum powder has been reported. Chest x-ray has revealed a diffuse reticulonodular interstitial infiltrate with conglomerate masses in both mid-lung zones.²¹ Chronic talc inhalation may increase the risk for bronchogenic carcinoma.²² Chronic abuse of talc-contaminated cocaine by insufflation has resulted in pulmonary talc granulomatosis, with chest x-ray showing diffuse bilateral infiltrates.²³

Intravenous injection of talc-containing tablets or capsules produces foreign-body vascular granulomas (microemboli) at the site of intramuscular or subcutaneous injection and widespread arterial wall granulomas.²⁰ Angiothrombotic pulmonary arterial hypertension and cor pulmonale may develop. Pulmonary effects include nonproductive cough, fever, dyspnea, and granulomatosis. Subtle x-ray changes may develop showing symmetric hilar and perihilar interstitial infiltrations, which are only minimally reversible.²⁴ Pulmonary infiltrates have been observed in intravenous drug abusers²⁵ and after therapeutic use for pleurodesis.²⁶

Diagnosis

LABORATORY TESTING

If the patient is symptomatic, obtain baseline complete blood count, electrolytes, and chest x-ray. Monitor arterial blood gases regularly in patients with severe respiratory findings. Chest x-ray may show symmetric hilar and perihilar infiltrates.

OTHER DIAGNOSTIC TESTING

Diagnosis may be established by transbronchial biopsy using scanning electron microscopy and energy-dispersive x-ray analysis to establish the presence of and identify the particles.^{14,15} Subtle pulmonary abnormalities such as decreased carbon monoxide diffusing capacity are an earlier indication of pulmonary damage rather than clinical or radiologic evidence.

DIFFERENTIAL DIAGNOSIS

The medical causes of aspiration pneumonia and pneumonitis are extensive and include all causes of respiratory distress, especially pulmonary embolism and cardiogenic pulmonary edema, as well as other aspiration syndromes (airway obstruction, lung abscess, exogenous liquid pneumonia, chronic interstitial fibrosis). Differentiation is largely dependent on clinical setting.

Toxin-mediated small airway disease has developed after exposure to nitrogen dioxide, sulfur dioxide, ammonia, chlorine, phosgene, chloropicrin, trichloroethylene, ozone, cadmium, methyl sulfate, hydrogen sulfide, hydrogen fluoride, zinc chloride, talcum powder, high-dose oxygen therapy, and free-base cocaine.²⁷

Management

SUPPORTIVE MEASURES

Begin immediately to prevent complications from acute inhalation exposure of large amounts in an asymptomatic patient. Establish and maintain the vital functions. Clear the airway, and administer 100% oxygen.

DECONTAMINATION

Decontamination procedures are not useful in treating talcum inhalation.

LABORATORY MONITORING

Monitor blood gases in symptomatic patients for the development of respiratory acidosis. When the PCO_2 rises above 50 mm Hg, mechanical ventilation with positive end-expiratory pressure (PEEP) should be instituted.¹²

ANTIDOTES

N-Acetylcysteine

There is a case report in which the administration of *N*-acetylcysteine and oxygen in a mist tent appeared to be helpful in improving respiratory distress.¹² Aspiration of mucus secretions after tracheal instillation of 5 mL of normal saline may be preferred to *N*-acetylcysteine therapy at this time.

Corticosteroids

Prednisone, 1 to 2 mg/kg/day for 3 to 5 days, adult maximum 60 mg/day, may be administered to prevent inflammation and exudation of mucus secretions.¹² For symptomatic patients, dexamethasone, 0.1 to 0.2 mg/kg/day, adult maximum 10 mg.^{9,28} Bronchodilators have been tried with only limited success and generally not used. Prophylactic antibiotics such as ampicillin may be indicated but are not generally recommended unless for cultured pathogens.^{12,13}

Consider bronchoalveolar lavage with normal saline to remove aspirated powder. This will have limited value because of talc insolubility and is potentially dangerous, but it may remove excessive mucus secretions refractory to *N*-acetylcysteine therapy.^{12,13} Bronchoalveolar lavage has been used for the differential diagnosis of talc-induced lung disease.^{29,30}

Other

Chest physiotherapy and postural drainage may be helpful.

ELIMINATION

Elimination is not applicable.

DISPOSITION

Admit the patient to the hospital in cases of hypoxemia or respiratory distress. The chest x-ray findings are sometimes delayed.³¹ Follow-up pulmonary function studies for long-term restrictive-obstructive sequelae are indicated in significant inhalations.

BORIC ACID

Introduction and Relevant History

The Babylonians allegedly used borax more than 4000 years ago as a flux for working gold, and there are data to suggest that the Egyptians used boron for mummifying, medicinal, and metallurgic purposes.³² Today, borate-mineral concentrates are used in fertilizer, fire retardants, laundry bleaches, and glass and related vitreous applications.³² The antiseptic effects of boric acid were first described by Lord Lister in 1875.³³ At one time, it was mixed with honey and glycerin and sold to treat topical mucosal sores in children.³⁴ Historically, significant toxicity and fatalities occurred after chronic exposure to boric acid preparations. In one series, 11 infants died when inadvertently fed a 2.5% boric acid solution over several days.³⁵ Because of its weak antiseptic properties and significant toxicity, it is no longer used in medicinal preparations.³⁴ A common cause of exposure today is related to unintentional ingestion of powdered boric acid used to kill cockroaches. Acute unintentional ingestions rarely result in significant toxicity, whereas chronic exposure results in more serious toxicity.³⁶⁻³⁹ Suicidal ingestions of large amounts (280 g in one case) may be fatal.³⁸

Epidemiology

There were a total of 2724 exposures to boric acid reported by TESS in 2002. Of those, 1317 (48.3%) patients were younger than 6 years, 315 (11.5%) were between the ages of 6 and 19 years, and 1071 (39.3%) were older than 19 years. There were 481 (18%) patients treated in a health care facility. Eighty-three (8.8%) of the patients were judged to have moderate outcomes; 5 patients suffered major morbidity, and 1 expired.⁴⁰

Structure and Structure–Activity Relationships

Boric acid is an odorless, colorless compound that can occur in crystalline, granular, or white powder form. Borates and borate-mineral concentrates such as borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10 \text{H}_2\text{O}$) are salts or esters of boric acid.

Pharmacology

PATHOPHYSIOLOGY

Autopsy findings in patients who have died as a result of boric acid poisoning have noted significant involvement of several organ systems, including the skin, gastrointestinal tract, kidneys, brain, and liver.^{36,38,41,42} In those individuals with skin eruptions, pathologic specimens were consistent with an exfoliative dermatitis. The gastrointestinal tract demonstrates inflammatory changes, with congestion, edema, and mucosal exfoliation, although boric acid is not caustic. Renal changes have ranged from gross pallor to cloudy swelling and renal tubular degeneration. The CNS effects reported have included congestion and edema of the brain.³⁶ The liver rarely has demonstrated clinical manifestations of boric acid toxicity.^{36,43,44} Pathologic findings consist of fatty change and congestion.

PHARMACOKINETICS

Absorption of boric acid occurs easily through abraded or excoriated skin,^{38,41,45} but absorption through intact skin is negligible.^{46,47} Oral ingestion results in rapid and complete absorption of boric acid from the gastrointestinal tract. Distribution occurs throughout body water and ranges from 0.17 to 0.50 L/kg. The highest concentrations occur in the brain, liver, and kidneys.^{43,48,49} Most ingested boric acid is excreted unchanged by the kidneys; more than 50% of the oral dose is eliminated within 24 hours, and more than 90% is excreted within 96 hours of ingestion.^{38,44} The half-life of boric acid has been reported to range from 5 to 21 hours.^{38,48}

Special Populations (Pediatrics, Geriatrics, Liver Failure, Renal Failure, Pregnancy)

A case series of oral boric acid intoxications in a newborn nursery was reported by Wong and colleagues that

indicated the ingested dose by those infants who died ranged between 4.5 and 15.0 g of boric acid.³⁵ Deaths occurred as a result of drinking formula accidentally prepared with a 2.5% boric acid solution. Infants who survived the poisoning but were symptomatic ingested amounts ranging from 2.0 to 4.5 g. In general, a dose of 2 to 3 g in newborns and infants and 5 g in children is regarded as lethal. A significant amount of boric acid must be ingested for toxicity to occur because the solutions available with boric acid usually range in concentration from 2.5% to 5%. Of greater concern is the ingestion of boric acid powder, crystals, or granules; 1 teaspoonful of 100% boric acid in these forms contains 2.9 to 4.4 g.⁵⁰ The literature regarding adults describes four deaths due to acute boric acid or sodium borate ingestion since 1921.⁵¹ Based on these data and other case series, it has been estimated that the adult human median lethal dose is likely to be greater than 30 g. Although case series reveal a wide range for toxicity,^{36,38} ingestion of 15 to 20 g of boric acid is generally cited as the lethal dose for adults.³⁹

Toxicology

CLINICAL MANIFESTATIONS (ACUTE AND CHRONIC)

Usually, symptoms develop within 4 to 6 hours. The initial manifestations may resemble gastroenteritis, with blue-green vomitus, diarrhea that may be bloody (hemorrhagic gastroenteritis), and colicky abdominal pain.^{36,38} Solutions up to 5% do not cause gastrointestinal irritation. CNS stimulation, headache, agitation, delirium, hypertonia, hyperreflexia, meningeal irritation, and increased intracranial pressure may occur; in severe cases, seizures and coma may ensue.^{36,38,51} Cardiovascular effects include hypotension and oliguria; anuria and renal failure may develop.^{39,51,52}

An erythematous rash develops as early as 6 hours after ingestion in most patients, starting on the face, the inguinal creases, axillary creases, buttocks, and scrotum and then spreading to cover the entire surface, including the palms, soles, and oral and anal mucosa. Desquamation and exfoliation (“boiled lobster” appearance) can occur within 2 to 5 days after exposure. Anemia, abnormal liver function tests, and rarely alopecia totalis have been reported.⁵¹

Chronic boric acid poisoning occurs usually in infants from repeated topical application to diaper dermatitis. This may also be associated with renal impairment, hypothermia, or hyperthermia.^{36,53}

Reversible upper respiratory tract irritation has been reported with exposure to boron oxide or boric acid dust concentrations of less than 10 mg/m³ and borax dust concentrations of 1.1 mg/m³ to 14.6 mg/m³ and 10 to 14 mg/m³.⁵⁴⁻⁵⁶ Symptoms commonly included nasal irritation, mucous membrane dryness, dry or productive cough, and nose bleeds. Shortness of breath, chest pain, and chest tightness were reported less frequently.⁵⁴⁻⁵⁶ A statistically significant increased risk for phlegm production and chronic bronchitis in nonsmokers was associated with exposure to 14.6 mg/m³ of borax dust.⁵⁵

Diagnosis

The diagnosis of boric acid poisoning requires careful history taking with the appropriate clinical picture.

LABORATORY TESTING

Although levels of boric acid do not correlate well with toxicity, levels in seriously poisoned patients with acute exposure are generally above 34 mg/dL.³⁸ Seizures in one child with chronic exposure were associated with a serum boric acid level of 9.44 mg/dL.³⁴ A fatal case of acute boric acid poisoning in an adult had a 52-hour level of 42 mg/dL.³⁹ Boric acid levels in Wong’s series of 11 fatal pediatric poisonings ranged from 40 to 160 mg/dL.³⁵ Because most hospital laboratories do not have the capability to quickly determine serum borate levels, this information cannot be relied on to make the diagnosis of borate toxicity. Two commercial laboratories that are able to quantitate serum borate levels are National Medical Services, Inc., 2300 Stratford Ave., P.O. Box 433A, Willow Grove, PA, 19090, telephone 215-657-4900, and West Coast Analytical Services, Inc., 9840 Alburdis Ave., Santa Fe Springs, CA 90670, telephone 310-948-2225. The U.S. Borax and Chemical Co. provides a 24-hour telephone number for medical emergencies related to borates: 800-228-5635.

OTHER DIAGNOSTIC TESTING

Urinary boron concentrations can indicate total-body burden of boron. The normal range of urinary boron has been reported as 0.004 to 0.66 mg/100 mL.⁵⁷

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the “boiled lobster” appearance is Kawasaki disease, scarlet fever, and staphylococcal scalded skin syndrome.⁵⁸

Management

SUPPORTIVE MEASURES

Treatment consists of symptomatic and supportive care and includes monitoring for the development of hypotension, fluid and electrolyte imbalance, seizures, renal failure, cardiac arrhythmias, and shock. Severe dehydration can occur and contribute to adverse renal and cardiovascular effects. Administer intravenous fluids to treat dehydration. Treatment of hypotension may include intravenous fluids, dopamine, or norepinephrine.

DECONTAMINATION

Syrup of ipecac is *not advised* for boric acid ingestion. Activated charcoal has limited ability to absorb boric acid. An in vitro study demonstrated that 30 g of charcoal was required to adsorb 38% of a 1-g boric acid dose.⁵⁹ The use of activated charcoal in potentially fatal ingestions of 5 g in a child and 20 g in an adult was considered impractical because 5 to 10 times the recommended doses of activated charcoal would be required to effectively adsorb the boric acid.

LABORATORY MONITORING

Monitor renal function tests, cardiovascular status, and fluid and electrolyte balance in symptomatic patients.

ANTIDOTES

No antidotes are available.

ELIMINATION

Hemodialysis, peritoneal dialysis, and exchange transfusion may enhance elimination. Exchange transfusion has been advocated and successful in cases of chronic exposure.^{60,61} Hemodialysis and peritoneal dialysis have been advocated to increase excretion.⁶² In comparison to renal elimination, the amount removed by peritoneal dialysis is small.⁶³

DISPOSITION

Unintentional ingestions usually result in minimal toxicity. A lick or a taste of a topical powder of less than 5% may be observed at home. A teaspoonful of a 99% powder in a child should be evaluated in an emergency department. When an approximation of the amount ingested can be made, Table 99-1 can be used to determine the appropriate management. This table has been modified from a large series involving 784 boric acid ingestions.³⁸

CAMPHOR

Introduction and Relevant History

Camphor was one of the therapeutic agents of the 19th-century pharmacopoeia used as an analgesic, expectorant, counterirritant, and abortifacient, as well as a stimulant.⁶⁴ Camphor is a naturally occurring essential oil (volatile oil). Historically, it has been claimed that camphor was mentioned by Marco Polo in the 13th century and Camoens in 1571, who called it the “balsam of disease.”⁶⁵ Camphor is highly prized by the Chinese, who used it for embalming purposes and to scent soap.⁶⁵ In the 1930s, Ladislav Meduna induced seizures with intramuscular injections of camphor to treat catatonia, a therapeutic predecessor to electroconvulsive therapy.⁶⁶ This continued use persisted into the 1940s.

TABLE 99-1 Triage of Boric Acid Ingestions

BODY WEIGHT	AMOUNT INGESTED	MANAGEMENT
<30 kg	<200 mg/kg >200 mg/kg	Observe at home. Emergency department for gastrointestinal decontamination and evaluation
>30 kg	<6 g ingested >6 g	Observe at home. Emergency department for gastrointestinal decontamination and evaluation

Most unintentional overdoses of camphor have occurred when it has been mistakenly administered for castor oil or cough syrup.⁶⁷ Often produced in similar packaging and stocked on adjacent shelves in pharmacies, the confusion of camphorated oil, a 20% mixture of camphor and cottonseed oil, for castor oil was predictable. In 1983, the U.S. Food and Drug Administration ruled that over-the-counter products cannot contain camphor in excess of 11%.⁶⁸ In 1994, the American Academy of Pediatrics recommended the removal of camphor from all medicinal products.⁶⁷ However, despite these efforts, camphor continues to be ubiquitous in over-the-counter preparations such as local anesthetics, antipruritics, rubefacients, antitussives, “chest cold” inhalants, and some herbal products despite a lack of therapeutic value and the availability of safer alternatives.

Epidemiology

According to the 2002 Annual Report of the American Association of Poison Control Centers TESS, there were a total of 8817 exposures to camphor reported. Of those, 6852 (77.7%) patients were younger than 6 years, 526 (5.9%) were between the ages of 6 and 19 years, and 1426 (16.2%) were older than 19 years. There were 922 (10.5%) cases treated in a health care facility. Seventy-seven patients were judged to have moderate outcomes, 9 suffered major morbidity, and 1 expired.⁶⁹

Structure and Structure–Activity Relationships

Camphor is a crystalline ketone, related to the terpenes, that was originally steam-distilled from the bark of the camphor tree *Cinnamomum camphora*. Today, it is synthetically produced from α -pinene ($C_{10}H_{10}$), a hydrocarbon extracted from turpentine oil.⁷⁰ Chemically, it is described as a bicyclomonoterpenoid or 1,7,7-trimethylbicyclo(2,1,1)-2-heptanone.^{71,72}

Pharmacology

The mechanism of toxicity of camphor is unclear. Topically, camphor is a rubefacient, producing local hyperemia and warmth. It is thought to generate its perceived therapeutic benefits through the “counterirritant analgesic effect” in which moderate visceral pain is masked by a milder skin irritation.⁷³ Camphor’s intense odor and sensation of warmth on application contributes to the feeling of relief from pain or congestion that may be greater than that actually physiologically present. Although the biochemical basis by which camphor leads to CNS excitation and seizures is not well understood, it is thought to act directly to stimulate nervous tissue. In 1954, Smith and Margolis reported a 19-month-old child who died 5 days after the ingestion of an estimated 1 teaspoon of camphorated oil.⁶⁴ They found “extensive degenerative changes” selectively involving the neurons of the cerebral cortex, basal ganglia, and hippocampus. The same investigators found

no neurologic pathologic lesions in mice when seizures were prevented by the concomitant administration of pentobarbital with camphor. These findings suggest that the neuronal damage found in camphor fatalities may result from seizures and anoxia rather than from a direct action of camphor on neurons.⁶⁴

PATHOPHYSIOLOGY

See Box 99-1 for the pharmacokinetics of camphor ingestion.

Special Populations

After oral ingestion, camphor has been associated with spontaneous abortion. It has therefore been classified by the Food and Drug Administration as a Pregnancy Category C drug.⁷⁴

Toxicology

CLINICAL MANIFESTATIONS (ACUTE AND CHRONIC)

Classically, seizures may occur suddenly and without warning within 5 minutes of an acute ingestion of camphor; these seizures may be followed by coma.⁷⁵ In Phelan's review of 748 patients, 42% had seizures after ingestion of 700 to 6000 mg of camphor.⁷⁶ Apnea and visual hallucinations, confusion, tremors, and myoclonic jerking may occur.⁷⁷ Other disturbances that may precede the seizures include anxiety, confusion, dizziness, and facial fasciculations. Death is due to respiratory arrest or secondary to status epilepticus.

BOX 99-1

PHARMACOKINETICS

Absorption

- Rapidly and readily absorbed through the skin and mucous membranes, including the gastrointestinal and respiratory tracts⁷¹

Distribution

- Camphor crosses the placenta.⁸⁶
- Large volume of distribution: 1.2–4 L/kg⁸⁷
- Camphor is highly lipid soluble, so significant toxic substances accumulate in fat tissue.
- Onset of action is 5–20 min with a peak effect within 90 min.⁸⁶

Metabolism

- Camphor is rapidly oxidized to campherols (2-hydroxycamphor and 3-hydroxycamphor) and then conjugated in the liver to the glucuronide form.⁸⁶

Excretion

- Campherol conjugated to glucuronic acid is eliminated mainly in the urine as an inactive compound.
- Pulmonary excretion of camphor and its metabolites causes an odor on the breath.⁸⁶

Elimination Half-Life

- A plasma elimination half-life of 93–167 min was reported in a volunteer given 200 mg of camphor.⁸⁷

Initial gastrointestinal symptoms usually include the feeling of warmth, thirst, nausea, spontaneous vomiting, epigastric burning, and abdominal pain. Aspiration of vomitus is a major complication. Urinary retention, anuria, and albuminuria (transient) have been described in some patients.

Chronic administration of camphor can cause an altered mental status with elevation of the liver enzymes, which may mimic Reye syndrome. The liver has showed fatty metamorphosis with no cell necrosis, inflammation, or biliary stasis.⁷⁷ Similar effects may occur in acute poisoning.

ADVERSE EFFECTS

Adverse effects associated with the topical use of any camphor-containing creams include dermal irritation when applied in excessive amounts or too vigorously.

Diagnosis

Because most instances of camphor intoxication occur after unintentional ingestion, patients usually promptly seek medical attention and willingly offer historical information relevant to the poisoning. Even in the absence of such historical information, however, the presence of camphor is readily apparent owing to its intense and characteristic odor, which may be detected on the breath, vomitus, clothes, and hair. This is further aided by the typical clinical picture of gastrointestinal distress, agitation, somnolence, and seizures. Hyperthermia and tachycardia usually accompany prolonged agitation and seizures. No laboratory derangements are specifically characteristic of camphor poisoning, although transient liver function abnormalities have been reported in some cases.^{78,79}

LABORATORY TESTING

Camphor plasma concentrations are not readily available and do not correlate with symptoms. However, patients who had camphor plasma concentrations of 1.5 µg/mL were asymptomatic, and those who developed seizures have been reported to have levels of 19.5 µg/mL.⁶⁷

OTHER DIAGNOSTIC TESTING

Complete blood count, electrolytes, liver function tests, and renal function tests should be monitored. Consider a chest radiograph to exclude aspiration. Obtain arterial blood gases if the patient is comatose or has respiratory symptoms. Abnormalities reported can include leukocytosis, albuminuria, and a transient rise in liver enzymes.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis is any cause of afebrile seizures. The odor on the patient's body or clothes may be an important clue.

Management

SUPPORTIVE MEASURES

Monitor for hypotension, dysrhythmias, and respiratory depression. Treat respiratory depression with endotracheal intubation and ventilatory assistance as necessary.

Intravenous access should be obtained; fluid and pressor support may become necessary. Seizure precautions should be established. Treat seizures with intravenous diazepam (adult: 5–10 mg, repeat every 10–15 minutes as needed; child: 0.2–0.5 mg/kg [maximum, 10 mg/dose], repeat every 15 minutes as needed) or intravenous lorazepam (adult: 2–4 mg [maximum, 8 mg/dose]; child: 0.05–0.1 mg/kg [maximum, 4 mg]). Consider phenobarbital if seizures recur after diazepam. The dose for intravenous phenobarbital in adults and children is 20 mg/kg at 50 to 100 mg/min.

DECONTAMINATION

Avoid the induction of emesis because of the potential for an early onset of seizures.⁸⁰ Activated charcoal has doubtful efficacy.⁸¹ Some clinicians have advised early emesis, gastric lavage, and activated charcoal, but these forms of gastrointestinal decontamination are unreasonable in view of the potential for early onset of symptoms and danger of aspiration. *Avoid* giving fats, oils, alcohol, or milk, which increase absorption and increase the risk for aspiration.⁸⁰

For dermal exposures, remove contaminated clothing and wash the exposed area extremely thoroughly with soap and water.

For inhalation exposures, move patient from the toxic environment to fresh air. Monitor for respiratory distress. If cough or difficulty in breathing develops, evaluate for hypoxia, respiratory tract irritation, bronchitis, or pneumonitis.

Provide symptomatic and supportive care as needed (100% humidified supplemental oxygen, endotracheal intubation, assisted ventilation, and inhaled β -adrenergic agonists).

LABORATORY MONITORING

See previous discussion. If prolonged seizures occur, monitor arterial blood gases, body temperature, renal function, creatinine kinase, and the urine for myoglobin.

ANTIDOTES

There are no specific antidotes for camphor toxicity, but *N*-acetylcysteine has been reported effective in preventing liver damage in chronic poisoning.⁸²

ELIMINATION

Extracorporeal measures of elimination are not routinely used for camphor poisoning owing to the large distribution of camphor. There are, however, isolated case reports in which both lipid hemodialysis⁷⁹ and resin hemoperfusion⁸³ have been used to lower the blood camphor concentration in severely poisoned patients. Lipid dialysis, however, is no longer recommended because of complications of the therapy, and resin hemoperfusion is no longer available in the United States.⁸⁴

DISPOSITION

Medical evaluation and monitoring for symptoms (CNS depression or seizures) with seizure precautions should be considered for *any* ingestion of camphor of more than 30 mg/kg in a child, more than 1 g in an adult, or

deliberate ingestion. If symptoms of intoxication are present, the patient should be admitted to an intensive care unit.^{74,85} Patients who are asymptomatic or who have only mild gastrointestinal symptoms and are asymptomatic for 4 hours after ingestion are at low risk for serious complications.^{74,86} Clinically significant camphor toxicity has not been reported below 30 mg/kg of camphor and is uncommon below 50 mg/kg of camphor in asymptomatic patients.⁷⁴ Patients who have developed either severe gastrointestinal or neurologic symptoms of poisoning should also be admitted regardless of the amount ingested. Patients should be observed in a monitored setting where immediate anticonvulsant therapy and respiratory support can be provided. Consider transportation by ambulance after any acute ingestion. Seizures may occur suddenly within minutes after ingestion while en route to the emergency department.⁸⁴

THOMAS R. CARACCIO, PHARMD, RPH ■ R. B. MCFEE, DO, MPH

At a Glance...

- Alcohols (hair spray, cologne) ingested by children can cause hypoglycemia and central nervous system (CNS) depression.
- Oxidizers and corrosives such as thioglycolic acid and sodium bromate (hair waving agents) can cause severe burns and erosions to the skin, gastrointestinal (GI) tract, or eyes depending on the route of exposure. Bromate ingestion produces GI symptoms within 30 minutes and can lead to profound, irreversible renal failure that can result in death.
- Acetonitrile (artificial nail remover), which is metabolized to cyanide, can cause respiratory failure, convulsions, and death.
- Nitroalkane or nitroethane (artificial nail removers) can cause methemoglobinemia and respiratory distress.
- Cosmetics, especially face and skin care products, cause approximately 10% of contact dermatitis cases. Reactions range from the irritant contact form of dermatitis to allergic contact dermatitis and contact urticaria.
- With the exception of acetonitrile (cyanide antidote kit), management of cosmetic toxicity primarily consists of symptomatic and supportive care.
- Decontamination of skin and ocular exposures should consist of copious irrigation guided by bidirectional pH paper until neutral pH is obtained and symptoms have resolved.

INTRODUCTION AND RELEVANT HISTORY

The term *cosmetics* refers to a broad range of products—synthetic and natural—used to enhance appearance or improve hygiene.¹⁻³ The ancient Egyptians and Romans used creams for beautification.¹ Queen Cleopatra was well known for her use of cosmetics and skin creams.¹ In the late 19th century, women used belladonna alkaloids to dilate their pupils to make their eyes appear more attractive.³ Virtually all cultures have utilized a variety of powders, creams, and other preparations to enhance beauty and adorn and decorate the human body. Such preparations range from colorful makeup including henna, to hair dyes, tattoos, body paints, feathers, and skin piercing. Some of these applications are permanent, others temporary to suit a particular function. The cosmetic industry is a multi-billion-dollar per year enterprise. As society increasingly becomes preoccupied with youthful appearance, the demand for new products including topical applications has grown significantly. Although historically cosmetic products were developed from plants and herbs, most of these substances in contemporary society are synthetic.^{1,3} Ingredients of synthetic cosmetics are contributing to the increasing incidence of skin reactions termed *cosmetic dermatitis*.^{1,4,5} (Table 100-1).

From a regulatory standpoint, according to the U.S. Food and Drug Administration (FDA) Federal Food, Drugs and Cosmetics Act (FDCA) of 1938, the term *cosmetic* is defined as “articles intended to be rubbed, sprinkled, sprayed, introduced into, or otherwise applied to the human body, or any part thereof, for cleansing, beautifying, promoting attractiveness, or altering the appearance without affecting the body’s structure or functions.”^{1-3,6,7} Critical to an agent being classified as a cosmetic is the understanding that the product will not be toxic when used according to labeled instructions.^{2,8} Cosmetics come not only under the auspices of the FDA; they must also follow requirements of the 1970 U.S. Poison Prevention Packaging Act, the Fair Packaging and Label Act of 1966, and the Color Additives Amendments to the FDCA of 1962.⁷ The FDA in 21 CFR 720.4 describes 13 categories of products designated “cosmetics” that contain a total of 66 product types^{7,9} (Table 100-2). These regulations notwithstanding, the manufacturer is responsible for assuring the safety of cosmetics. Of interest, premarket approval of cosmetics is not required. No product can be marketed if it contains “a poisonous or deleterious substance, which may render it injurious to health” (FDCA Section 601).⁷ Some cosmetics, namely, hair-coloring preparations, are permitted to include dyes that are not on the FDA safety list.² The product packaging must clearly state, “Caution: this preparation contains ingredients that may cause skin irritation in certain individuals, and a preliminary test according to accompanying directions should first be made. This product must *not* be used for dyeing eyelashes or eyebrows; to do so may cause blindness.” The

TABLE 100-1 Most Frequently Identified Ingredients Causing Cosmetic Dermatitis*

RANK	CATEGORY	NUMBER OF PREPARATIONS/FORMULATIONS
1	Fragrance Ingredients	161
2	Preservatives	149
3	p-Phenylenediamine (PPD)	41
4	Lanolin and derivatives	29
5	Glyceryl thioglycolate	25

TABLE 100-2 Cosmetic Product Categories*

CATEGORY	PRODUCT TYPE	CATEGORY	PRODUCT TYPE
Baby products	Shampoos Lotions Oils Powders Creams Other baby products	Makeup preparations (not for eyes)	Blushers (all types) Face powders Foundations Leg and body paints Lipsticks Makeup bases
Bath preparations	Bath oils, tablets, salts Bubble bath preparations Bath capsules Other bath preparations	Manicuring preparations	Rouges Makeup fixatives Other makeup preparations Basecoats and undercoats Cuticle softeners
Eye makeup preparations	Eyebrow pencil Eyeliner Eye shadow Eye lotion Eye makeup remover Mascara Other eye makeup preparations	Oral hygiene products	Nail creams and lotions Nail polishes and enamel Nail polish and enamel removers Other manicuring preparations Dentifrices (aerosol, liquid, paste, and powder)
Fragrance preparations	Perfumes, colognes, and toilet waters Powders (dusting and talcum, excluding aftershave talc) Sachets Other fragrance preparations	Personal cleanliness	Mouthwashes and breath fresheners (liquid and powder) Other oral hygiene products Bath soaps and detergents Douches Feminine hygiene deodorants Other personal cleanliness products
Hair preparations (noncoloring)	Hair conditioners Hair sprays (aerosol fixatives) Hair straighteners Permanent wave solutions Rinses (noncoloring) Shampoos (noncoloring) Tonics, dressings, and other hair grooming aids Wave sets Other hair preparations	Shaving preparations	Aftershave lotions Beard softeners Men's talcum Preshave lotions (all types) Shaving cream (aerosol, brushless, lather) Shaving soap (cakes, sticks, etc) Other shaving preparations
Hair coloring preparations	Hair dyes and colors (<i>all</i> types require a caution statement and patch test) Hair tints Hair rinses (coloring) Hair shampoos (coloring) Hair color sprays (aerosol) Hair lighteners with color Hair bleaches Other hair coloring preparations	Skin care preparations (creams, lotions, powders, and sprays)	Cleansing (cold creams, cleansing lotions, liquids, and pads) Depilatories Face and neck (excluding shaving preparations) Body and hand (excluding shaving preparations) Foot powders and sprays Moisturizing Nighttime preparations Paste masks (mud packs) Skin fresheners Other skin preparations
		Suntan preparations	Suntan gels, creams, and liquids Indoor tanning preparations Other suntan preparations

*Data from Code of Federal Regulations, Title 21, Vol. 7 (21 CFR 710), Food and Drug Administration, Center for Food Safety and Applied Nutrition. Washington, DC, U.S. Government Printing Office, Rev. April 1, 2002.

instructions accompanying these products must include directions to perform a patch test 24 hours prior to applying the preparation.

In terms of product safety, producers rely heavily on historical safety data, structure-activity studies, and validated *in vitro* testing to demonstrate the safety of their products.⁷

Several resources are available to provide in-depth toxicity information on chemicals utilized in the production of cosmetics. These include the *International Journal of Toxicology*, which reports evaluations by the Cosmetic Ingredient Review (CIR) Expert Panel of the Cosmetic, Toiletry and Fragrance Association (CTFA).

The chemical ingredient can be identified in the CTFA Cosmetic Ingredient Dictionary, which is available through the Cosmetic Toiletry and Fragrance Association, located in Washington, DC.² Cosmetic manufacturers also file cosmetic ingredient composition with the FDA. The FDA Cosmetic Information Center can be accessed via a toll-free number: 1 (800) 270-8869. Labeling, ingredients, dyes, and sun care product information are available as well as instructions for reporting adverse reactions.

Historically, most categories of cosmetics are considered to pose a very low risk of toxicity beyond dermal reactions.^{1,2,10,11} However, certain categories—notably, artificial nail removers and hair straightening products—

contain a variety of chemicals that pose a moderate to severe toxicity risk.^{1,3,12-19} Alcohol-containing products also pose a serious poisoning risk.¹⁸ Like most toxicants, primary routes of exposure are ingestion and topical exposures, which include the skin and the eyes.^{2,11,19,20} Caution must always be exercised to prevent children from becoming exposed to cosmetics. Many of these products pose a greater health risk in overdose or unintentional ingestion to children than to adults. This is especially true of alcohol-containing products such as colognes and perfumes.

EPIDEMIOLOGY

Cosmetics and personal care products resulted in 224,792 calls to poison centers in 2004 according to the American Association of Poison Control Centers Toxic Exposure Surveillance System (TESS).¹⁹ Of these calls, 38,081 involved adults; the majority—185,862—involved children and represented the leading category (13.4%) of toxicant affecting children 6 years of age and younger. Three deaths were associated with cosmetics, including that of a 72-year-old man who intentionally ingested a large amount of aftershave and a 39-year-old and a 54-year-old who both ingested mouthwash. Only ethanol-containing products were associated with fatalities. Overall, this category is associated with mostly mild to nontoxic exposures: 69,465 (96%) were considered mild to none in severity, and 14,334 were referred to a health-care facility (HCF). Contrast this with 279,955 analgesic category exposures, which were responsible for 658 deaths.

HAIR PRODUCTS

Hair care products include hair colors, hair lighteners, hair waving agents, hair straighteners, hair sprays, shampoos, and conditioners.¹⁻³ Most of these products, such as the shampoos, have low or virtually no risk of toxicity. The hair lighteners, straighteners, and waving agents that contain oxidizers and potential corrosives pose a greater risk to health especially when misused or ingested.²¹

Epidemiology

According to TESS¹⁹ in 2004 there were 2347 hair coloring-related exposures, for which the following numbers of patients were sent to an HCF: 355 with no toxicity, 585 with mild toxicity, 135 with toxicity of moderate severity, 2 with major severity, and there were no deaths. Hair relaxing agents with sodium hydroxide (NaOH) accounted for 768 exposures. Of those referred to an HCF, 151 were relatively nontoxic, 268 were mildly toxic, 96 were of moderate severity, 1 was major, and there were no deaths. Hair relaxing agents with other alkaline ingredients accounted for 847 cases. Again, there were no deaths, and most cases were of mild to moderate severity. For the nonalkaline hair relaxers, there were 66 cases. Permanent wave solutions accoun-

ted for 397 cases. Of these, 68 were nontoxic, 117 mild, 52 moderate, and 0 severe. There were no deaths. Hair spray accounted for 2165 calls, but there were only nine major exposures and the rest were predominantly nontoxic or mildly toxic. Of the 6175 hair shampoo calls, 64 were moderately severe cases and 2 major.

HAIR COLORS

Hair color products are categorized as either permanent or semipermanent. Permanent hair colors contain oxidizing agents and dye intermediates in a 1:1 concentration. The oxidizer interacts with a dye intermediate to cause color molecules to adhere to the hair shaft. The oxidizer is usually hydrogen peroxide (H_2O_2)—most commonly a 6% solution by volume although 12% solutions are available. H_2O_2 oxidizes while lightening the hair. Usually greater than 10% H_2O_2 is associated with toxicity although large ingestions of 6% H_2O_2 can cause gastritis. Commonly used dyes include *p*-phenylenediamine, resorcinol, and aminophenols. *Para*-phenylenediamine (PPD) and *para*-aminophenol undergo oxidation to reactive imine compounds. Resorcinol reacts with imines to produce the final colors.

Toxicology

Para-phenylenediamine can cause local irritation, or urticaria. PPD toxicity can include angioneurotic edema presenting from 2 to 24 hours postexposure. A 20-year-old adult who ingested 40 mL of 4% solution experienced angioneurotic edema, hemolysis, and renal failure. The patient survived after 13 days of hemodialysis. Rhabdomyolysis, renal failure, acute tubular necrosis, and disseminated intravascular coagulation (DIC) can occur.²² Aromatic nitro- and amino-compounds can become cyanogenic at toxic levels. These products also may contain soaps, water, isopropanol, ammonia, propylene glycol, and glycerin. These additional ingredients confer viscosity and enhance penetration. Hydrogen sulfide and ammonia are used to hasten the dyeing process. Ammonia can produce a pH of 9.5; scalp burns have resulted.

Other chemicals in hair dyes include toluene, diamine, ammonium hydroxide, sodium sulfite, and sodium hydroxide. Semipermanent hair colors contain propylene glycol, isopropanol, fatty acids, alkanolamines, and dyes. Permanent hair colors contain oxidizers; semipermanent hair colors do not. Some hair colors, such as “Grecian Formula” contain lead acetate.^{2,3} These progressive hair dyes contain less than 0.6% elemental lead with elemental sulfur in an alcohol vehicle. Lead forms insoluble oxides and the sulfides impart a darker color to gray hair when exposed to air. Lead hair dyes produce lead-coated hands with 150 to 700 mg per hand. While the potential for lead exposure exists, to date lead toxicity has not been reported as a result of this residue.¹⁷

Diagnosis

The diagnosis of oxidizing agents is usually made by history.

Laboratory tests may assist management in terms of monitoring electrolytes, blood alcohol concentration, and cardiac and respiratory function.

Management

If ingested, oxidizing agents are toxic. However, the ammonia or ethanolamine present in these products is highly emetogenic, making it unlikely that a quantity sufficient to cause toxicity would be ingested.²³ Nonetheless, if ingestion occurs, copious rinsing of the mouth is important. Symptomatic and supportive care are the mainstay of therapy.

Symptomatic patients and children with large ingestions should be referred to an HCF. Activated charcoal may mask erosions if endoscopic evaluation is necessary; its administration is discouraged. Some suggest drinking milk after rinsing the mouth with water as a method to alleviate GI irritation.² Syrup of ipecac (SOI) is not recommended. Beyond the fact many of these products are emetogenic, the potential for exacerbating gastric irritation and damage compared with the low potential for altering outcome militates against the use of SOI. Large-volume dilution may increase the likelihood of exothermic reactions. Since these products contain multiple ingredients, including alcohols, H_2O_2 , and other chemicals, management should be directed at likely toxicants. For example, individuals with low hepatic glycogen reserve and impaired gluconeogenesis due to an alcohol-depleting nicotinamide adenine dinucleotide (NAD) may be at greater risk for hypoglycemia when exposed to hair-coloring products containing alcohols. Children, malnourished patients, and chronically ill patients are especially susceptible. Ingestions of greater than 1 mL of 50% ethanol/kg can produce a blood alcohol concentration of 50 mg/dL or greater. Since these patients may develop symptoms consistent with hypotension or hypoglycemia, they should be referred to an HCF.²⁴ H_2O_2 decomposes and liberates oxygen. Large ingestions of H_2O_2 can be expected to cause mild-to-moderate gastritis.³ If a “Grecian Formula” product is ingested, it is prudent to obtain blood lead levels.^{2,17}

Ocular exposures require immediate and copious eye irrigation. If the product contains 6% H_2O_2 , injury usually is limited to burning and itching of the conjunctiva with no long-term sequelae if appropriate decontamination is initiated. Irrigation should continue for at least 15 to 20 minutes. If discomfort persists, continue irrigation and consider an ophthalmology consult. Higher H_2O_2 concentration exposures require immediate saline irrigation, ocular examination by a trained health care professional, and referral to an ophthalmologist. Skin exposure is unlikely to cause toxicity. However, some individuals may be hypersensitive to some of the ingredients or exhibit allergic reactions. A good outcome is expected with symptomatic and supportive care including washing the affected area completely with water and hypoallergenic soap. Antihistamines may be administered. No specific antidotes are available for hair-coloring products.

Disposition

With appropriate intervention, most patients survive the exposure to hair colors with good outcomes.

Prevention

Keeping these products out of the reach of young children is critical to reducing this pattern of pediatric

exposure and injury. Using the product only as directed will also reduce the risk from hair colors.

HAIR LIGHTENERS

Hair lighteners—often referred to as “hair bleaches”—are used to give hair a lighter color or as preparation for dye applications. In addition to the oxidizer H_2O_2 found in hair colors, other oxidizers are used, including ammonia and potassium or sodium persulfate. These agents intensify and speed the lightening process. Additional ingredients including metasilicates and detergents may be present to thicken, disperse, or stabilize the color.

Toxicology

Lightener solutions usually have a pH in the range of 9.5 to 11.5. Alkaline agents are corrosive irritants and, depending on the dose and duration of exposure, can cause GI irritation and ocular injury. Concentrated solutions of persulfates are irritating to the skin and mucous membranes. Ammonium persulfate can cause urticaria and anaphylactoid reactions. Owing to the powerful and offensive odors (and presumably taste) of many of these products, unintentional ingestion is unlikely. Intentional ingestion can produce clinically significant toxicity manifested by vomiting, hematemesis, and diarrhea.

Diagnosis

Most exposures are readily identified by history.

Laboratory testing should be tailored to the clinical situation and ingredients present in the preparation.

Management

Ingestion of products containing corrosive alkali agents should be managed in the same way as for any highly irritating corrosive chemical. Referral to an HCF, availability of endoscopic evaluation, and access to an intensive care unit usually are advised if the patient is symptomatic. Allergic or anaphylactoid reactions to hair-coloring agents should be managed per standard protocol, which includes close attention to cardiovascular/respiratory function. Oxygen and antihistamines (H_1 and H_2), fluid support, and bronchodilators if the clinical situation warrants, are administered. Ocular exposures require immediate and copious saline irrigation. While Morgan lenses may not be necessary, testing with pH paper to determine the effectiveness of decontamination, ocular examination by a trained health care professional, and referral to an ophthalmologist are warranted.

Disposition

Hair-coloring products are generally considered low toxicity exposures. Appropriate intervention and minimal toxicity offer good long-term outcomes.

Prevention

Keeping these products away from children and using the preparations as directed are critical to reducing the pediatric injury pattern.

HAIR WAVING AGENTS

The process of hair waving involves altering the molecular structure of hair during the stepwise process

of softening, followed by reshaping or curling, then finally hardening. Most hair waving solutions contain thioglycolate, which softens and straightens hair by breaking the sulfhydryl bonds. Other softeners in addition to thioglycolate and thioglycolic acid salts include sodium sulfite and ammonium sulfite. Hydrogen peroxide or sodium bromate in dilute acidic solution are used to halt the process as desired results are approached. Some permanent wave products contain 2% to 8% (weight/volume) mercuric chloride.³ Neutralizers in hair waving agents usually contain bromates. Sodium borate or perborate also is used (see Chapter 99).

Diagnosis

Most exposures are readily identified by history.

Laboratory testing should be tailored to the clinical situation and ingredients of the preparation. To obtain blood concentration of bromate in the serum, specify bromate exposure. However, serum bromate levels do not correlate with the severity of the intoxication. Intervention should not be delayed in lieu of laboratory results. Electrolytes, ethanol levels, complete blood count, methemoglobin, and renal function tests should be obtained.

Toxicology and Management

Thioglycolic acids are toxic corrosives. Ingestions can cause irritation of the mouth and throat accompanied by nausea, vomiting, and possibly diarrhea. Thioglycolate can cause immediate-type hypersensitivity reaction. In large amounts, it can cause hypoglycemia and cyanosis. Mercuric chloride as a toxicant can cause erosive oral and GI effects, which, if the exposure is significant, may cause hemorrhage and shock. A potentially lethal oral dose is 10 to 50 mg/kg.²⁰ The softening agents ammonium or sodium sulfite are alkaline with pH ranging from 7.0 to 8.5. They are GI irritants. Rinsing the mouth or exposed area is usually all that is necessary. Milk may provide symptomatic relief. Ocular exposure to any of these compounds requires immediate irrigation and possible referral to an ophthalmologist.

Bromates are very toxic. Contact between bromate-containing neutralizers and the skin or eyes can cause erythema, burning, and edema. Copious irrigation with soap and water usually is sufficient intervention. Very concentrated solutions (2%) at doses of 1 to 2 teaspoons (1.5 to 3 g) can produce serious toxicity in children between the ages of 1 to 3 years.³ The toxic dose in children is estimated to be 250 to 500 mg/kg.³ A 5-g ingestion can potentially lead to fatality with a 10-g ingestion representing a lethal dose in adults.^{2,12} Fortunately, few fatalities have been reported. No fatalities were reported in 2002 TESS. GI symptoms can occur within 30 minutes postingestion. Upon ingestion, significant gastroenteritis may result from the production of hydrobromic acid. Hypotension can ensue. The route of elimination for bromates is renal, and renal failure is the primary cause of death.^{12,13} Renal impairment may first present as anuria or oliguria within 24 hours. Bromate poisoning may present similarly to hemolytic uremic syndrome. Hemolysis and thrombocy-

topenias have been reported. Bromates may act as an oxidizing agent converting hemoglobin to methemoglobin, although this is infrequently reported. If methemoglobinemia occurs, do not use methylene blue because it may exacerbate bromate toxicity. Patients should respond to oxygen and symptomatic and supportive care. If toxicity is severe, exchange transfusion may be considered. Neurosensory hearing loss and tinnitus may occur within 24 hours. Irreversible otic and renal damage may occur. Central nervous system (CNS) depression and seizures may occur. Ocular exposure should be treated with copious water or saline irrigation. Ophthalmology referral is recommended owing to the significant alkalinity of bromates.

Sodium borate breaks down into borate and peroxide and is less toxic than bromates.^{3,20} However, a 3- to 6-g ingestion is potentially lethal to children with 15 to 30 g being similarly lethal to adults. Skin manifestation to borates can lead to desquamation and erythematous rash commonly found over palms, soles, buttocks, and scrotum. This may progress to exfoliation. CNS symptoms include irritability, headache, and restlessness, seizures, and coma, depending on the exposure. GI symptoms include nausea, vomiting, and diarrhea. Acute tubular necrosis may lead to renal failure.^{3,20}

Disposition

This category of cosmetic poses a greater threat to health owing to the toxicity of bromates and borates in addition to the oxidizer H₂O₂. Few deaths are reported. With rapid symptomatic and supportive care, benign outcomes can be expected.

HAIR STRAIGHTENERS

Of all the hair care products, hair straighteners pose the greatest threat to health and are extremely toxic.^{1-3,19,20,25} They contain 1% to 3% sodium hydroxide, ammonium hydroxide, potassium carbonate, or bicarbonate. Precise adherence to application instruction is critical when using these products. They are highly alkaline and pose a risk for liquefaction necrosis. The typical pH is 13. Prolonged exposure with hair and scalp may cause injury.² Ingestion or ocular exposure must be considered a medical emergency.^{2,20,25}

Diagnosis

Most exposures are readily identified by history.

Laboratory testing should be tailored to the clinical situation and ingredients of the preparation. No test is required if the ingestion is no more than a "sip."²⁰ Otherwise, complete blood count (CBC), serum electrolytes, and renal function tests should be obtained. In patients exhibiting respiratory symptoms, arterial blood gases and chest radiographs should be obtained. For patients with suspected perforation, abdominal radiographs should be obtained in addition to chest radiographs. Gastrointestinal endoscopy should be performed within 24 hours of a large ingestion or for patients who have diminished voice, stridor, drooling, or vomiting.

Toxicology and Management

Hair straighteners are highly toxic alkaline agents that can cause severe burns, irritation, and erosions. They should be treated as aggressively as any other caustic exposure. Ingestion requires immediate referral to an HCF. Treatment should focus on airway control, keeping in mind that severe GI damage including strictures and obstructions may occur. Hemodynamic function and assessment of burn function are critical.^{2,3,20,25} Because the rate of GI and esophageal mucosal injury is rapid there is concern about using dilution as an intervention. Symptomatic and supportive care are critical, as is referral to gastroenterology and general surgery for evaluation. Steroids such as dexamethasone 0.1 mg/kg or prednisone 1 to 2.5 mg/kg for 3 weeks have been recommended for grade II burns to reduce stricture formation by some but are considered controversial. Steroids are not usually necessary for grade I burns and are to be avoided in grade III exposures because of the risk of perforation. Hypovolemia and shock, bleeding, tissue necrosis, metabolic acidosis, and renal failure are usual complications.

Disposition

Deliberate ingestions usually are large doses and result in complications or death.^{19,20,25} Long-term sequelae include anatomic changes to the GI tract including pyloric stenosis, bleeding, stricture formation, fistula, or perforation. Patients who develop esophageal burns and stricture are at increased risk for esophageal cancer.²⁰ Children with small “sip” or “taste” exposures usually have benign outcomes.¹⁹

HAIR SPRAYS

Hair sprays are one of the least toxic categories of hair care product.^{2,3,19,20} When ingested, quantities and concentrations usually are small. There are two delivery formulations: liquid pump and aerosols that rely on propellants such as butane, propane, or isobutane. Hair spray products contain a solvent—usually denatured ethanol—and resin polymers—vinyl acetate, methyl vinyl ether, and acrylamides.^{2,3} The resins are delivered in the solvent. Ethyl alcohol can constitute up to 95% of the product preparation.

Diagnosis

Blood ethanol levels, CBC, electrolytes, and frequent glucose levels should be obtained in moderate- to large-dose ingestions of ethanol-containing products.

Toxicology and Management

Hair sprays are generally low toxicity products posing little risk when ingested in small quantities, sprayed on intact skin of nonsensitive individuals, or sprayed in the eye in a small amount. There are no specific antidotes. Symptomatic and supportive care is the mainstay of therapy. Ingestions of large volumes of ethanol-based hair sprays should be treated as any ethanol toxic exposure. Ethanol is metabolized by the enzyme alcohol dehydrogenase. Ethanol overdose can cause hypoglycemia and CNS depression in addition to electrolyte

derangement. If hair spray is sprayed into the eyes, rinsing with clean warm water or saline is usually sufficient, and a benign outcome is expected. If symptoms persist, evaluation by an ophthalmologist is recommended.

Disposition

Most exposures are unintentional and thus low in dose with expected benign outcomes. Long-term sequelae are not expected.

SHAMPOOS, CONDITIONERS, SOAPS, AND BATH OILS

This category of cosmetics is of very low toxicity. Most shampoos are composed of anionic and nonanionic surfactants, perfumes, and high levels of water. They may contain small amounts of ethanol. Dry shampoos contain methanol or isopropyl alcohol. Bath salts are primarily inorganic salts—usually sodium chloride—which is nontoxic. Electrolyte derangements can occur in large ingestions. Soaps and bubble bath preparations are similar to shampoos and are generally considered nontoxic. Mild toxicity and GI irritation can occur in moderate ingestions. Bath oils are primarily composed of surfactants, emulsifiers, preservatives, and mineral or vegetable oils, which are nontoxic.^{2,20} Aspiration of bath oils like other oils can cause a chemical lipoid pneumonia. Some bath oils have essential oils as ingredients, including eucalyptus or pennyroyal. Pennyroyal (pulegium) is an essential oil found in *Hedeoma pulegioides* and *Mentha pulegium* plants as well as some herbal teas. Skin exposure is rarely problematic unless the individual is sensitive to one or more of the ingredients in which case a hypersensitivity reaction or cosmetic dermatitis may occur.^{1,2,20}

Epidemiology

There were 6175 exposures reported to TESS of which 4827 involved young children.¹⁹ There were no deaths, and only 2 exposures were considered major toxicity exposures. The majority were considered nontoxic or minor toxicity exposures.¹⁹

Kinetics

Isopropyl alcohol is rapidly absorbed and distributed, with a volume of distribution of 0.6 L/kg. It is metabolized by alcohol dehydrogenase to acetone with a half-life of 2.5 to 3 hours. The toxic oral dose of 70% isopropyl alcohol is 0.5 to 1 mL/kg.

Diagnosis

Laboratory tests are unnecessary for most ingestions in this category. For essential oil or alcohol ingestions or symptomatic exposures, electrolytes, CBC, glucose monitoring, coagulation studies, liver and renal function tests, urinalysis, electrocardiogram (ECG), and aspirin and acetaminophen levels should be obtained. For patients who have ingested isopropyl alcohol, the following laboratory tests should be obtained: serum isopropyl alcohol, acetone level, serum osmolality and osmolar gaps, electrolytes, glucose, renal function tests, arterial blood gases, and oximetry. Cardiopulmonary function should be monitored.

Toxicology and Management

Shampoos, conditioners, soaps, and bath salts are generally considered nontoxic products. If ingested, shampoo is nontoxic and will most likely cause mild GI discomfort and nausea. Large ingestions of isopropyl alcohol or other alcohol-containing products should be managed as any potential alcohol toxicity, with special attention to hypoglycemia, electrolytes, and airway management. Isopropyl alcohol is a significant CNS depressant that can lead to coma or respiratory arrest. Large ingestions can cause myocardial suppression and hypotension.²⁶ There are no antidotes. Owing to the rapidity of absorption and distribution, emesis is not likely to confer benefit and may be deleterious. Activated charcoal may be useful in spite of the fact that it has marginal adsorbing ability for alcohol; however, it is estimated that 1 g of activated charcoal can bind 1 mL of 70% alcohol²⁶ (see Chapter 31).

Ocular exposures usually require only copious irrigation with warm water or saline. Long-term damage to the eye is unlikely. Symptomatic and supportive care is the mainstay of therapy.

Bath oils containing essential oils such as safe, eucalyptus, turpentine, pine, pennyroyal, and cinnamon contain alcohols, esters, and ketones.^{2,3} These can cause allergic contact dermatitis that begins within 12 hours.³ Essential oils are mucosal irritants.³ Concentrated preparations of essential oils can cause seizures and CNS depression at 10 mL doses. The alcohol content can cause hypoglycemia, especially in children.^{1-3,20} Pennyroyal may pose a more significant toxicity.²⁰ Large ingestions can cause GI irritation accompanied by nausea, vomiting, and abdominal pain. CNS effects may occur. When pennyroyal is an ingredient, toxicity is possible. The active toxic volatile is pulegone, which is metabolized to a liver and lung toxin. Toxicity may develop at a dose of 5 mL and death is associated with a 15-mL ingestion. Hepatic injury and abdominal pain along with altered mental status occur early in a toxic exposure. Hypotension and metabolic acidosis along with protracted emesis, GI bleeding, and hematuria can occur. Renal failure is common in large pennyroyal ingestions. Although there is no specific antidote, since pennyroyal can deplete hepatic glutathione, use of *N*-acetylcysteine (NAC) has been suggested. The exact dosing regimen has not been determined.²⁰ Symptomatic and supportive care is critical (see Chapter 101).

Disposition

With the exception of pennyroyal and other essential oil products, the remaining products in this category are considered nontoxic; outcomes are expected to be benign.

COLOGNES AND PERFUMES

As for other categories of cosmetic products, toxicity depends on the ingredients and their concentration in the formulation.^{1-3,20} Colognes and perfumes usually contain ethanol at concentrations ranging from 50% to

95% as well as oils, which can be either volatile or essential oils. The toxicity of these products is dependent on the ethanol concentration and amount ingested. Since skin is an intended area of application, these products are not expected to cause toxicity via the dermal route except in hypersensitive individuals. Cosmetics and perfumes can be irritating to the eyes but are not expected to cause long-term damage.

Epidemiology

There were 17,627 perfume and cologne exposures in 2004 reported to PCC, of which 14,917 involved young children.¹⁹ There was only one death and 11 major toxicity cases, while the majority (7808) were considered nontoxic or of mild toxicity.

Diagnosis

Most acute exposures are readily identified by history. An elevated blood ethanol level and the development of hypoglycemia, especially in children, are important clues to significant toxic exposures.

Blood ethanol levels, CBC, electrolytes, anion gap, and renal function tests along with frequent monitoring of blood glucose are recommended. Attention should be paid to respiratory function, seizure precaution, and fluid status.

Toxicology and Management

Depending on the concentration and amount ingested, especially by young children owing to their increased risk of hypoglycemia from ethanol as well as CNS effects, perfumes and colognes should be managed like toxic ethanol exposures. Symptomatic and supportive care is the mainstay of intervention. There are no specific antidotes. For skin irritation, soap and water should be sufficient. Ocular exposures require copious irrigation with warm water or saline.

Disposition

Most cologne or perfume exposures are considered low toxicity events, and benign outcomes are expected

NAIL CARE PRODUCTS

This category comprises nail polishes and nail polish removers. Nail polish contains hydrocarbon solvents such as xylene, toluene and acetone, plasticizers, resins, and alcohol solvents. Methanol may also be used. The likelihood of toxicity from ingestion is generally small owing to the small volume contained in nail polish bottles. GI irritation is the most likely result of ingestion. Skin irritation is rare. In the event of an ocular exposure, copious irrigation with warm water or saline should be sufficient.

Nail polish removers are also solvents containing acetone or ethanol. These too are generally considered

low toxicity products although bottles of nail polish remover are larger than nail polish bottles and thus pose a greater ingestion risk but still of low toxicity.

False or acrylic nails have been removed with acetonitrile, which is a highly toxic chemical (vinyl cyanide). Although these nail products have been reformulated by removal of acetonitrile, the potential of toxicity exists if older products are still available in a household. Artificial nail glue removers can also contain nitroalkane and nitroethane.

Epidemiology

There were 50 acrylic nail remover-related calls to American Association of Poison Control Centers in 2004.¹⁹ There were no deaths; 27 cases involved young children. There were 10,876 nail polish-related calls, of which 9,775 involved young children. The majority of exposures were nontoxic or of mild toxicity, and there were no deaths. For nail polish removers, there were 2742 acetone preparation calls, 2114 with other ingredients and 8178 with unknown active ingredient. Most were nontoxic and involved children. There were no deaths.

Kinetics

Acetonitrile is metabolized by the cytochrome P-450 microsomal system to several metabolites, including cyanohydrin, which is subsequently metabolized to aldehyde and cyanide.^{20,27,28}

Nitroethane is metabolized to aldehyde and nitrite. Nitrite is an oxidizer. Nitroethane has a half-life of 6 hours.

Diagnosis

The diagnosis of nail care products can usually be established by the history.

For exposures of old nail products containing acetonitrile, arterial and venous blood gas analysis and serum lactate levels are useful. An increased lactic acidosis suggests cyanide toxicity. Cyanide levels may not be readily available and may not correlate with severity; thus treatment should be based on the clinical situation.

For exposures of nail products containing nitroethane, electrolytes, renal function tests, and methemoglobin levels are useful to monitor. Cardiopulmonary monitoring maybe necessary in symptomatic patients.

For exposures to nail products containing ethanol, see above and Chapter 31. For exposures to nail products containing acetone, see Chapter 32.

Toxicology and Management

For acetone toxicity, see Chapter 32. For ethanol toxicity, see Chapter 31.

The clinical manifestations of acetonitrile are similar to those of cyanide although they may be delayed from 3 to 24 hours. Acetonitrile ingestion requires immediate medical attention. One swallow of acetonitrile-containing artificial nail glue remover can cause death in a toddler. The prudent clinician will be mindful that

acetonitrile patients may be stable on presentation but can develop significant delayed toxicity. Clinical symptoms include respiratory distress and cyanosis. Cardiovascular symptoms including hypotension may occur. Headache, agitation, and CNS effects including altered mental status, seizures, and tremor may occur. Cherry red skin is usually a terminal event. Nausea and vomiting as well as abdominal pain occur with inhalation or ingestion. The cyanide antidote kit should be available, since it contains the three agents approved for cyanide intoxication by the FDA: amyl nitrate, sodium nitrate, and sodium thiosulfate. Activated charcoal has minimal binding affinity for cyanide. However, 1 g is considered adequate to bind 100 to 500 mg.²⁶

Of note, acrylic fingernails that contain *N,N*-dimethyl-*p*-toluidine have been reported to produce methemoglobinemia.^{15,16} Nitroalkane and nitroethane can also cause methemoglobinemia. Cyanosis, tachypnea, and chocolate-colored lips are manifestations. Methylene blue may be useful therapy.

Disposition

With most nail products, benign outcomes are expected. Acetonitrile ingestions can cause death. If the patient survives the exposure, unless anoxic brain injury has occurred, the long-term outcome is expected to be benign.^{2,20,27,28}

ORAL HYGIENE PRODUCTS AND DENTIFRICES

Toothpastes, powders, liquids, and gels for cleaning teeth are generally considered nontoxic.^{2,3,20} These products contain calcium phosphates, abrasants such as silica or calcium carbonate, flavoring, and coloring. Some may contain stannous fluoride or sodium monofluorophosphate, which are low solubility/low toxicity chemicals. Most exposures can cause GI irritation. Although toothpaste may contain up to 1 mg fluoride per gram of toothpaste, generally the low concentration of fluoride in these products is unlikely to produce clinically significant toxicity.²⁹ Denture cleaners are similar products but may contain bleaching products such as potassium persulfate, sodium perborate, trisodium phosphate, and sodium carbonate.

At-home teeth whitening products contain peroxides, often in the form of 18% carbamide peroxide, which is the equivalent of 6.5% hydrogen peroxide.³⁰ Studies support the safety of this product for daily use as directed. Toxicity in a large ingestion would be referable to H₂O₂.

Mouthwashes contain alcohol, flavoring, and sweeteners. Toxicity is proportional to alcohol content but generally is considered low.

Epidemiology

According to 2004 TESS data,¹⁹ there were 24,180 toothpaste with fluoride exposures of which 21,890

involved young children. There were few referrals to an HCF. There were no deaths and none developed major toxicity exposure, with the majority being mild to nontoxic. For toothpaste without fluoride, 1616 exposures were reported, with 1398 involving young children. No deaths were reported, and few were treated at an HCF. Denture cleaners resulted in 1440 exposures, with 288 involving children. There was one death.

Kinetics

Fluoride absorption peaks in approximately 1 hour. Volume of distribution is 0.5 to 0.7 L/kg. Fluoride is not protein bound. Elimination half-life is 2 to 9 hours but is prolonged in patients with renal failure. Doses of 3 to 5 mg/kg elemental fluoride can cause GI symptoms including abdominal pain and vomiting. Death has been reported in a 3-year-old child who ingested 16 mg/kg and in adults with doses above 32 mg/kg.²⁹

Diagnosis

The diagnosis of fluoride or borate intoxication is usually determined by obtaining a history of exposure to oral hygiene products.

Specific fluoride levels may be difficult to obtain and should not be relied on in the acute management of an ingestion. Albumin, magnesium, and calcium levels; renal function tests; cardiovascular status; fluid status; and electrolytes should be obtained. For nonfluoride ingestions, obtain tests based on ingredients. The basic assessments should include renal function tests and electrolytes with cardiorespiratory monitoring.

Toxicology and Management

Sodium perborate breaks down into sodium borate and peroxide. These are irritating agents. Borate poisoning can ensue, resulting in CNS irritability, acute tubular necrosis, and renal dysfunction and the classical finding of “boiled lobster appearance.”^{2,20} As discussed above, peroxide ingestion is strongly irritating to the GI tract and can cause vomiting, diarrhea, and hematochezia. Symptomatic and supportive care is the mainstay of therapy. Activated charcoal has limited ability to absorb boric acid. An in vitro study demonstrated that 30 g of charcoal was required to adsorb 38% of a 1-g boric acid dose. No specific antidotes are recommended.³¹ Hemodialysis, peritoneal dialysis, and exchange transfusion may enhance elimination.

Mouthwash toxicity is directly proportional to the ethanol concentration. Large unintentional ingestions are unlikely. With large ingestions, management is consistent with treatment of ethanol overdose.^{2,3}

Products involving fluoride pose a toxicity risk related to both cytotoxicity and metabolic effects.²⁹ Fluoride is cytotoxic and binds to calcium and magnesium, which can lead to hypocalcemia and hypomagnesemia. Impaired oxidative phosphorylation and glycolysis, impaired blood coagulation, and myocardial irritability can result as well as impaired neurotransmission and possibly tetany.²⁹

Disposition

Most exposures are of low toxicity. Benign outcomes are expected; however, there are exceptions: a 75-year-old woman unintentionally applied denture powder to her dentures while they were still in her mouth. On emergency department evaluation she was found to have severe burns to the lips, mouth, and oropharynx with swelling and drooling. She required endotracheal intubation for respiratory distress secondary to increased secretions and irritation. She developed profound hypotension and died.¹⁹

FACIAL/BODY PAINTS AND MAKEUP

Ingestions of facial makeup such as lipstick, rouge, mascara, blushers, and other products are considered nontoxic.^{2,32} These preparations are composed of water, waxes, and vegetable oils. Some products contain talcs. The primary risk of talcs is to the respiratory system, but owing to their small volume, this risk is negligible. If ingestion of makeup occurs, the small packaging size precludes the likelihood of toxicity.^{1-3,11,19,20} Of note, use of henna is increasing. Henna is a vegetable dye from dried leaves of *Lawsonia intermis*, which grows in Egypt, Tunisia, and India. Historically, henna has been used by Indian and Pakistani families to decorate the hands and feet as part of special celebrations such as weddings. Increasingly, henna is being adopted in Western cultures as a hair treatment and body makeup. The active ingredient is lawsone (2-hydroxy-1,4-naphthoquinone). Contact dermatitis has not been documented unless henna is adulterated by other chemicals including purified protein derivative (PPD), which is believed to be causal.^{1,33} One case report suggested that a woman experienced an allergic reaction including wheezing and coryza after handling henna.³³

Body paints are similar to colognes and perfumes in that their predominant ingredients are ethanol, color additives, pigments, emulsifiers, and preservatives.^{2,11,32} These are considered low toxicity products, with most of the risk associated with alcohol content.²

Lipstick is made with waxes, water, and occasionally camphor. The low dose of camphor in lipstick makes ingestion virtually nontoxic.

Epidemiology

According to TESS, there were 1192 lipstick with camphor exposures, of which more than 90% involved children; most ingestions were nontoxic or of minimal toxicity, and there were no deaths. Of the 4467 exposures involving lipstick without camphor, 4189 were in young children. Most exposures were nontoxic,¹⁹ and again there were no deaths.

Kinetics

Ethanol is readily absorbed after ingestion, peaking in 30 to 120 minutes. Volume of distribution is 0.5 to 0.7 L/kg. Elimination is via hepatic oxidation following zero order kinetics.³⁴

Diagnosis

Diagnosis is by history. A patient who exhibits signs and symptoms consistent with alcohol toxicity in whom pigmentation or a scent is present also suggests the diagnosis.

No specific laboratory studies are associated with makeup. However, serum ethanol levels, electrolytes, and renal function tests should be obtained. Additional studies should be guided by clinical presentation, including cardiopulmonary monitoring.

Toxicology and Management

Alcohol content is the primary toxicant in this category. Since 0.7 mg/dL ethanol will produce a blood ethanol level of 100 mg/dL (0.1 g/dL), which is considered legally intoxicated, and 300 mg/dL can cause coma in novice drinkers, ingestions of body paints would have to be considerable to achieve these ethanol levels. Toxic cases should be managed as any alcohol exposure (see Chapter 31). CNS depression and hypoglycemia are the primary manifestations of alcohol toxicity. Alcohol is hepatotoxic.

DISPOSITION

Most exposures are of low toxicity. Benign outcomes are expected.

HYGIENE PRODUCTS: DEODORANTS AND ANTIPERSPIRANTS

Deodorants, like most other cosmetic products, are considered nontoxic in spite of the fact the primary ingredients are alcohol, water, and a deodorizing agent. Antiperspirants are deodorants with a sweat-inhibiting agent, usually aluminum hydroxychloride.^{2,3}

Deodorants and antiperspirants are found as sticks, roll-on products, and aerosols.

Epidemiology

As reported in 2004, there were 17,566 deodorant category exposures, of which 15,277 involved young children. There were no deaths; most exposures were nontoxic or minimally toxic.¹⁹

Diagnosis

The diagnosis of acute ethanol toxicity from hygiene products is usually determined by obtaining a history of exposure to these products.

No specific laboratory studies are associated with makeup. However, serum ethanol, serial glucose level, electrolytes, and renal function test should be obtained in exposures to alcohol-containing products, especially in children. Additional studies should be guided by clinical presentation, including cardiopulmonary monitoring.

Toxicology and Management

Skin and eye irritation as well as mild GI irritation are the primary effects. Contact dermatitis is possible.^{3,35} Toxicity would be related to alcohol ingestion. However, owing to the small concentration and quantity contained within the package, toxicity is unlikely. Management depends on the ingredients of the product and should be guided by clinical presentation. Symptomatic and supportive care is the mainstay of treatment. Products with alcohol content should be managed as for other toxic alcohol exposures. Other than hypersensitivity, these products are safe as intended for dermal contact. Ocular exposures may cause mild and transient corneal epithelial irritation, but no persistent injury has been reported. These require copious irrigation, for at least 15 to 20 minutes, with benign outcome expected.^{2,3,11,32}

Disposition

Most exposures are of low toxicity. Benign outcomes are expected.

DEPILATORIES

Unlike the majority of cosmetic products, which are considered nontoxic or mildly toxic, depilatories (otherwise known as hair removers) are considered moderately toxic because of their sodium hydroxide (1% to 10%) or calcium hydroxide content. These hydroxides are alkaline caustics. Thioglycolate may also be present and is alkaline, capable of toxicity similar to sodium hydroxide. Depilatories also contain water and other ingredients not dissimilar to those in soaps or skin lotions. These ingredients are relatively nontoxic.

These alkaline agents dissolve hair or damage the hair shaft, resulting in hair loss.

Epidemiology

There were 1959 depilatory related exposures reported to TESS, of which 541 involved young children. There were no deaths, and only 4 developed major toxicities.¹⁹

Toxicology

Depilatories are skin irritants because of the alkaline ingredients. Sodium hydroxide (NaOH) is a caustic alkali that can cause severe burns. Fumes or mists are irritating to mucosa, eyes, skin, and the respiratory tract.^{2,36}

Ingestion of corrosives can cause burns of the esophagus as well as the oral cavity, resulting in dysphagia, drooling, and pain in the mouth, oropharynx, chest, or abdomen. The damage is dependent on the concentration and volume.^{2,36} Ocular exposure can cause conjunctivitis and even blindness. Skin exposure results in pain, erythema, blistering, and penetrating necrosis.

Alkalies such as NaOH cause liquefaction necrosis with saponification such that continued penetration

from the surface to deeper tissues occurs and results in significant damage.³⁶ While there is no generally accepted toxic dose of depilatory owing to the wide variety of concentrations and volumes of solutions, the concentration or pH of the product is indicative of its potential for damage and toxicity. The concentration of the base, also referred to as the titratable alkalinity, is a good predictor of corrosive risk.³⁶

Management

Unlike acids, which produce coagulation necrosis that can lead to an eschar, thereby limiting the damage somewhat, alkali burns can produce liquefaction necrosis. Exposure requires copious irrigation until a neutral pH is attained. Usually, this requires in excess of 20 minutes of irrigation with warm water or saline. Ocular involvement should be considered a medical emergency. Immediate irrigation for a minimum of 20 minutes and at least 1 L of warm water or saline should be initiated without delay. While the use of pH paper can help guide irrigation toward a neutral end point, extensive irrigation of the eye and consultation with immediate referral to ophthalmology are required. For skin exposures, the area should be washed with large volumes of warm water or saline (see Chapter 98).

Disposition

Minor, low concentration, and unintentional exposures generally result in minimal toxicity and benign outcomes. Larger exposures or ocular involvement can lead to scarring, blindness, or significant toxicity.

SUMMARY

Cosmetic products are generally considered nontoxic. There are ingredients, such as alcohol, peroxides, or other oxidizers, that when ingested in quantity can lead to toxicity and even death although this is generally rare. Some products such as hair straighteners and acrylic nail removal preparations contain highly toxic chemicals but in low dose. These nonetheless can cause significant symptoms. When used strictly as directed, they pose a low toxicity risk. With few exceptions, the management of toxic cosmetic exposures is symptomatic and supportive. Emesis is not recommended. Activated charcoal may confer benefit in specific situations. Antidotes are not readily available except for a few products.

Most unintentional cosmetic product exposures involve children. Caution must be exercised in storing these products, just as for other chemicals, toxicants, and household products.

JACK MAYPOLE, MD ■ ALAN DAVID WOOLF, MD, MPH

At a Glance...

- Essential oils are a family of plant-derived hydrocarbons that possess (or are believed to possess) a broad range of therapeutic benefits.
- Essential oils of clinical and/or toxicologic importance include cinnamon, eucalyptus, pennyroyal, tea tree, peppermint, and clove.
- All essential oils contain concentrated amounts of volatile aromatic hydrocarbons, such that ingestion can result in aspiration which in turn results hydrocarbon pneumonitis.
- The same principles of treatment employed after hydrocarbon aspiration should be used in managing a patient with essential oil aspiration.

Since the early 1990s the use of herbal products by the general public has increased in North America, in parallel with the use of complementary and alternative medicines. Herbs that are used for medicinal purposes come in a variety of forms; active parts of a plant may include leaves, flowers, stems, roots, seeds, and/or berries. Herbal products may be taken internally as pills or powders, dissolved into tinctures or syrups, or brewed in teas and decoctions. Salves, ointments, shampoos, pessaries, suppositories, or poultices may be applied to wounds, the skin, scalp, or mucous membranes.

Many plants contain the so-called essential oils (EOs), aromatic hydrocarbon-based oils. The highly concentrated, volatile EOs, which have pungent odors and rapidly evaporate in room air, are distilled as extracts, packaged, and sold unregulated to the public for medicinal purposes. In terms of their therapeutic effects, herbalists believe EOs have pharmacologic, physiologic, and psychological actions on the body. Box 101-1 defines some terms useful in understanding herbal therapy involving EOs. The increasing accessibility and popularity of the therapeutic use of EOs have been mirrored by a rise in inadvertent poisonings, and toxicity associated with their use and misuse.

THERAPEUTIC USES

EOs from many spices and herbs have antimicrobial and antifungal properties, attributable in part to their monoterpene constituents. These properties underlie the ability of EOs to prevent food spoilage and treat health problems, although there is limited scientific data regarding the therapeutic benefits of EOs. The traditional individualized therapeutic approach conflicts with the scientific research demand for empiric, controlled studies. The distinctive aromatic nature of

EOs also contributes to methodologic problems in conducting blinded randomized controlled trials.

Antiseptic/Antimicrobial

A growing body of evidence supports the potential usefulness of EOs for their antimicrobial and antiseptic effects. Tea tree oil (TTO), lavender, mint, sandalwood, and thyme have been found to possess in vitro antibacterial and antifungal activity against such organisms as methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus faecium*, *Escherichia coli*, and *Candida albicans*.^{1,2} Lavender, geranium, sandalwood, TTO, ylang ylang, patchouli, myrrh, and bergamot have demonstrated activity against both gram-positive and gram-negative microorganisms and *C. albicans* in laboratory studies. TTO contains terpinen-4-ol and other terpenes that may be responsible for its antimicrobial action. The mechanism is thought to be the disruption of the cell membrane, allowing potassium ion leakage, which leads to loss of chemiosmotic control and, therefore, causes rupture and destruction of the bacterial or fungal cell walls.¹ Terpinen-4-ol, has been demonstrated in vitro to suppress inflammatory mediator production by activated human monocytes.³

Such antimicrobial actions, as well as specific actions against *Staphylococcus mutans* (causing plaque and gingivitis) have led to the inclusion of EOs in dental

BOX 101-1 DEFINITIONS

Essential oils ("volatile oils," "ethereal oil"): Any of a class of highly concentrated, volatile oils composed of a mixture of complex hydrocarbons (usually terpenes) and other chemicals extracted from a plant, typically by a method of distillation. Essential oils give a plant its characteristic pungent or fragrant aroma and will evaporate quickly off skin or another surface.

Essence: A concentrated fragrance or perfume.

Fixed oil: A nonvolatile oil made of long-chain fatty acids (such as castor oil or saffrole).

Carrier oils: Essential oils are too concentrated to be applied directly to the skin during therapeutic use. Frequently, only a few drops of the essential oil are diluted into the carrier oils, such as safflower oil.

Aromatherapy: The use of volatile oils via inhalation in the treatment of certain health problems.

Carminative: An agent that aids in expelling gas from the gastrointestinal tract.

Rubefacient: An agent that reddens the skin and causes a localized feeling of warmth via cutaneous vasodilation.

Emmenagogue: An agent that influences menstruation and addresses problems related to menstrual flow.

Abortifacient: An agent that induces abortion.

hygiene products, including mouthwash, toothpaste, rinses, implants, and temporary amalgams used in dental repairs.⁴ TTO has purported antiseptic, antifungal, and antimicrobial properties when applied topically to mucous membranes and is used in the treatment of vaginal candidiasis, chronic cystitis, tinea pedis, genital herpes, and acne. TTO and other EOs have also been added to soaps, lotions, liniments, creams, and salves used to treat skin infections and improve wound healing.

Psychological Effects

EOs have been used in the management of behavior problems, stress reduction, relaxation therapy, and sleep disorders. Aromatherapy links EO odors to a healthy lifestyle by boosting awareness, stimulating the senses, and facilitating memory and learning.

Other Uses

EOs are used to enhance digestion, stimulate appetite, and lessen abdominal discomfort (e.g., inflammatory bowel disease or menstrual problems). EOs are used to manage muscle spasm or soreness after strain or injury and for nerve or dental pain. EOs have also been used for weight loss, although coriander and bergamot are reportedly appetite stimulants.

GENERAL TOXICITY

As food additives, essential oils are regulated by the Food and Drug Administration (FDA). A ceiling concentration limited to less than 300 ppm makes toxicity through ingestion of flavored foodstuffs unlikely, although allergic reactions are still possible.⁵ All EOs contain concentrated amounts of volatile aromatic hydrocarbons, such that unintentional ingestion can result in aspiration and hydrocarbon pneumonia. As plant derivatives, EOs can cause allergic skin reactions as well, including allergic or irritant contact dermatitis, other skin eruptions, phototoxic reactions, and urticaria. Systemic anaphylactoid reactions are also possible. Occupational workers in settings where EOs are present, such as aromatherapists, dentists and dental hygienists, fruit pickers, beauticians, physiotherapists, and cosmeticians, are particularly vulnerable to such reactions.⁶ Some EOs exhibit genotoxicity, with *in vitro* studies revealing chromosome aberrations (e.g., sister chromatid exchanges).⁷

SPECIFIC ESSENTIAL OILS

Cinnamon (*Cinnamomum cassia* *nee ex blume*)

Cinnamon is harvested from the bark of the *Cinnamomum cassia* *nee ex blume* plant, a member of the Lauraceae family. Besides its use as a spice, cinnamon's EO is promoted for a variety of medical conditions related to its properties as a stimulant, astringent, and carminative agent. Historically, it was used with other EOs and herbs

as a treatment for chronic bronchitis. Up to 80% of the fresh oil is cinnamic aldehyde, which can have sensitizing properties. Patients who develop cinnamon sensitivity usually develop an allergic, potentially "systemic" dermatitis or urticarial lesions upon reexposure. Cinnamic aldehyde is metabolized to cinnamic acid and excreted as benzoic and hippuric acids.

While ingestion of large amounts of cinnamon oil has been rarely reported, as little as 5 to 10 mL taken orally may cause central nervous system effects, possibly including seizures, and respiratory depression.^{8,9} A 7-year-old child who ingested about 2.5 mL/kg developed gastrointestinal symptoms, dizziness, lethargy, and rectal burning, which resolved over a 5-hour period.¹⁰

In sensitive patients, the use of cinnamic aldehyde-containing products such as toothpaste may produce white mucosal lesions in the mouth similar to leukoplakia seen with squamous cell carcinoma—in fact, squamous cell carcinoma has been associated with chronic oral cinnamon use.^{11,12}

Additionally, oral cheilitis, welts, erythema, ulcers, and vesicles may be observed. The patient may complain of burning pain from such lesions. The condition, known as *stomatitis venenata* and *mucositis*, can develop into orofacial granulomatosis and must be differentiated from lupus, lichen planus, oral candidiasis, lichenoid mucositis, cheek biting, and malignant conditions.^{13,14} A history of chronic cinnamon exposure—noted in cases of occupational exposure of bakers, or in health care providers using cinnamon oils topically¹⁵—reveals the correct etiology of the lesions, and abstinence from cinnamon results in their resolution. Immunoglobulin E (IgE) and radioallergosorbent tests are unhelpful for the diagnosis. A skin biopsy reveals characteristic perivascular infiltrates.

The practice of sucking on cinnamon oil-dipped toothpicks or hard candy by adolescents as a recreational activity has been reported.¹⁶ Self-limited signs of acute cinnamon toxicity, including facial flushing, oral burning, shortness of breath, tachycardia, dizziness, and abdominal pain, resulted. Typically, only supportive management is required.

Eucalyptus Oil (*Eucalyptus globulus*)

Eucalyptus oil has been recommended for the treatment of upper respiratory and other viral infections, and is also used in a liniment for muscle aches and strains. The yellowish oil has a distinctive camphor-like, pungent odor, which lingers on the breath of a poisoned patient. The active ingredient in the EO is eucalyptol, made of 1, 8-cineole plus tannins, in up to a 70% concentration. Hydrocyanic acid, present in lesser amounts, is also a contributor to the oil's toxicity.¹⁷ Eucalyptus oil is capable of hepatic microsomal induction, and thus may affect the metabolism of other drugs and chemicals. It is rapidly absorbed and has primary neurotoxicity (seizures, coma). Elimination of eucalyptol may be largely via the pulmonary route.

Although 80% of 42 children with eucalyptus poisoning remained asymptomatic in one study,¹⁸ two other case

series have documented symptoms in 65%¹⁹ and 59% of victims.²⁰ In one Australian telephone survey, eucalyptus oil was a leading agent associated with hospitalization for poisoning/ingestion among children younger than five years; 74% of preschoolers gained access to eucalyptus oil via a home vaporizer unit, most frequently placed at ground level.²¹

Diagnosis is evident after unintentional ingestion of eucalyptus oil because of its pungent odor on the breath. Small amounts may cause a rapid onset of nasal and epigastric burning, vomiting, gastrointestinal distress, miosis, weakness, headache, drowsiness, ataxia, or coma. In a review of fatalities caused by eucalyptus oil, oral burning, emesis, and abdominal pain were early symptoms of poisoning.²² Bronchospasm, bronchorrhea, hyperpnea, dyspnea, and pneumonia are also associated with aspiration of the volatile oil.²² Cyanosis, coma and seizures are sometimes seen, especially in infantile poisoning, and have been associated with respiratory depression and death.¹⁹ As little as 0.6 to 5.0 mL of 100% eucalyptus oil causes severe illness in children. Seizures and death were reported in an 8-month-old child after ingestion of 30 mL of the oil.¹⁹ In adults, symptoms may occur with an ingestion of as little as 1 to 2 teaspoons of eucalyptus oil, although an adult died after reportedly ingesting only 4 mL of eucalyptus oil.²³

Topical application of eucalyptus oil may also cause toxicity. A 6-year-old girl presented with rapidly progressing slurred speech, ataxia, muscle weakness, and unconsciousness following the widespread application of a eucalyptus oil-containing home remedy for urticaria.²⁴

Some victims of eucalyptus oil may only require close observation; however, in known large ingestions or when a poisoned patient presents early with clinical symptoms, the clinician may consider decontamination with activated charcoal, with elective intubation to protect the airway.¹⁸⁻²⁰ Respiratory support, antiemetics, and vasopressors are indicated in the management of some patients. Symptoms may be delayed for several hours, so the suspected victim deserves a longer period of monitoring than usual.

Nutmeg (*Myristica fragrans*)

Nutmeg is the seed kernel of the evergreen tree *Myristica fragrans*, the outer shell of which is also the source of the spice mace. Originally grown in the Malucca Island of the South Pacific, nutmeg was transplanted to Grenada, Trinidad, and other “spice islands” of the Caribbean, where it is grown commercially today. Besides its common culinary use as a spice, fresh nutmeg is recommended by herbalists as a gastrointestinal stimulant, as a carminative, for the treatment of rheumatism, for neurologic complaints, and as an emmenagogue. Nutmeg was introduced as a spice in the 12th century, and abuse of the spice was recorded as early as the 1500s. It is well known among sailors, jail inmates, and, more recently, adolescents as a cheap, readily available euphoriant. Unfortunately, the euphoria is short lived and is accompanied by such an array of unpleasant side effects, including severe headache and vomiting, that, after the first experiment, repetitive abuse is unlikely.

The oil of the nutmeg spice contains a mix of aromatic allylbenzenes, including the active principal, myristacin, as well as other complex hydrocarbons, including alamecin, borneol, safrole, isoeugenol, geraniol, and eugenol. Myristicin has been characterized as causing both hallucinogenic as well as amphetamine-like symptoms. It can be metabolized endogenously to 5-methoxy-3, 4-methylenedioxyamphetamine, which may be the proximal mediator of some of its toxic effects. Alamecin may also be metabolized to a hallucinogenic agent. These compounds have been described as having LSD-like and monoamine oxidase inhibitor properties as well.

Fresh nutmeg contains much higher concentrations of the EO than the dried, powdered spice. An estimated one to three whole nutmegs can cause moderate toxicity when ingested, which translates to 5 to 15 g of the freshly ground spice.²⁵ A dose of 18 g of fresh ground nutmeg has been associated with obtundation in a patient; such very large doses (14 to 21 g, or 280 to 420 mg/kg) may be associated with liver failure and death.^{26,27}

Usually, ingestion of 10 to 50 g of fresh nutmeg produces clinical intoxication. Prominent nausea, vomiting, headache, and chest and abdominal pain are invariably an early part of the clinical picture and limit the abuse potential of the EO. Patients may experience a sense of impending doom, which precedes uncontrollable retching. Flushed skin, decreased salivation, tachycardia, and slightly elevated blood pressure may remind the clinician of the anticholinergic syndrome. But these patients differ from those with an anticholinergic syndrome in that they present early on with pinpoint rather than dilated pupils and a depressed body temperature rather than fever. Patients may develop other neurologic symptoms besides hallucinations, including agitation, tremors, lethargy, confusion, delirium, or psychosis. The hallucinations are said to be visual and auditory, with distortions in color, time, and space. Symptoms may persist for up to 2 to 3 days.

Many cases of nutmeg abuse have been described, but only one fatal case of poisoning has been reported. Myristicin (4 µg/mL) and flunitrazepam (0.072 µg/mL) were detected in the postmortem serum of a 55-year-old woman.²⁷ From 1996 to 1998, seven poisonings with nutmeg were recorded by the Erfurt Poison Information Centre. Even where higher doses (20 to 80 g of powder) had been ingested, a life-threatening situation was never observed. In one of these cases, a myristicin blood level of 2 µg/mL was measured 8 hours after ingestion of 2 to 3 tablespoons of nutmeg powder (approximately 14 to 21 g, or 280 to 420 mg/kg).²⁷ Management of nutmeg poisoning includes oral decontamination with activated charcoal, supportive care including antiemetics, and, where necessary, sedation with a benzodiazepine medication. Reduction of visual and auditory stimuli is also helpful in calming the agitated patient.

Pennyroyal (*Squaw Mint*) Oil (*Hedeoma pulegiodes*)

Pennyroyal oil is distilled from *Hedeoma pulegiodes* or *Mentha pulegium* and may be prescribed for a variety of

medical conditions, including for toothache, as a flea and tick repellent, for chronic bronchitis or asthma, as an anti-inflammatory agent, or for genitourinary complaints. Use of pennyroyal oil as an emmenagogue or as an abortifacient has been described in young women.²⁸ Yerba buena, an herbal tea made from mint leaves, is popular in Latino and other cultures as an indigenous cure for infantile abdominal pain and colic. However, when pennyroyal oil-containing mint is used, life-threatening poisoning among treated infants has been reported.²⁹

Studies of pennyroyal oil in mice have established its ability to cause hepatic and pulmonary necrosis at doses of 400 mg/kg.³⁰ The active chemical in pennyroyal is pulegone, an aromatic ketone that undergoes bioactivation to menthofuran, a cyclohexanone. Both of these compounds, as well as other reactive intermediates derived from the metabolism of pulegone, can bind to subcellular proteins and cause cellular damage.^{31,32} Pulegone and menthofuran also deplete cellular glutathione levels and make hepatocytes vulnerable to attack by oxidizing radicals.³² Menthofuran can be detected by gas chromatography in the urine, blood, and other tissues of a poisoned patient.

Gastrointestinal symptoms, delirium, and seizures are noted at doses of pennyroyal oil as low as 3.5 mL, with cases of centilobular hepatitis following ingestion of 30 mL or more. Signs of poisoning are apparent soon after ingestion and may include a burning in the throat, nausea, vomiting, dizziness, abdominal pain, gastrointestinal bleeding, and hematuria.^{33–36} Chemical hepatitis is usually detectable within 24 hours of ingestion. Later the patient will manifest liver dysfunction with secondary complications including coagulopathy, renal failure, seizure, and death.³⁶ One young woman who ingested 30 mL of pennyroyal oil to induce an abortion quickly developed a rash and repeated retching, followed by severe hepatorenal failure, disseminated intravascular coagulation, metabolic acidosis, pneumonia, and death 7 days later.³⁶ Autopsy confirmed the presence of pulmonary consolidation and widespread hepatic necrosis. A second case report of pennyroyal-induced death in a 24-year-old woman noted a variety of pathologic findings at autopsy, including hemolysis, renal tubular necrosis, pulmonary consolidation, and cerebral edema.²⁸

Management of the affected patient includes oral decontamination by lavage if performed soon after ingestion and administration of activated charcoal, although charcoal's efficacy is unproven. The similarity of the pathogenesis of pennyroyal-induced centrilobular hepatic necrosis to that produced by acetaminophen suggests a prominent role for *N*-acetylcysteine (NAC) as an antidote. Indeed, NAC was given to a child who had ingested life-threatening amounts of pennyroyal oil and the patient did not subsequently develop hepatitis.²⁸ Recent investigations of pulegone toxicity of a mouse model suggest some mitigation of liver damage when combination pretreatment with cytochrome CYP1A2 inhibitors (cimetidine and disulfuram) prevents formation of the toxic furan metabolite, although the clinical utility of such inhibitors has not been established.³⁰

Tea Tree Oil (*Melaleuca alternifolia*)

TTO extract is derived from oil of the *Melaleuca alternifolia* tree, indigenous to Australia. Distillation of the leaves yields a pale, colorless oil that is approximately 50% terpenes and 6% to 8% cineol, with a variety of other compounds. Active ingredients include terpinen-4-ol, found also in eucalyptus oil. There are no clear data in humans to indicate a dose range associated with acute toxicity. TTO ingestion has also been reported in dogs and cats, with the primary symptoms appearing to be depression, weakness, incoordination, and muscle tremors. Acute oral toxicity in rats occurs at doses of 1.9 to 2.6 mL/kg.³⁷

TTO shows promise as an effective treatment for a number of microorganisms commonly associated with otitis externa and otitis media, but its possible ototoxicity may discourage such uses. The ototoxicity of tea tree oil was examined in the guinea pig by measuring the thresholds of the compound auditory nerve action potential (CAP) to tone bursts before and after instillation of TTO into the middle ear. After 30 minutes of instillation, 100% TTO caused a partial CAP threshold elevation at 20 kHz, although a 2% concentration did not cause any significant lasting threshold change.³⁸

Contact dermatitis and/or systemic hypersensitivity reactions have been seen after topical administration of TTO, although the incidence of such reactions is thought to be infrequent.³⁹ Topical administration has been associated with the formation of blisters and sores, as well as flare-ups in individuals with a history of eczema.⁴⁰ Australian TTO has been used as a veterinary antiseptic for many years and, more recently, this indication has been extended into human use. There have been many reports of allergic contact dermatitis and other dermal toxicity reactions, but TTO has never been implicated in immediate systemic hypersensitivity. A 38-year-old man experienced immediate flushing, pruritus, throat constriction, and lightheadedness after topical application of Australian TTO. The patient had a positive wheal and flare reaction on intradermal testing with TTO. No specific IgG or IgE was detected.⁴¹

Confusion, obtundation, coma, and a neutrophil leukocytosis have been associated with ingestion of TTO. Toxicity of the individual components of the oil has not been clearly established, but it is thought that terpinen-4-ol and other terpenes are responsible for its toxic effects. Symptoms may also include a strong mint-like aromatic odor to the breath.⁴² A 23-month-old boy demonstrated mental status changes and ataxia after ingesting less than 10 mL of a TTO preparation. His symptoms lasted for approximately 5 hours.⁴² Ingestion of half a cup of neat TTO by an adult caused coma that lasted about 48 hours.⁴³ Management of TTO poisoning consists of supportive care.

Peppermint/*Mentha* (*Mentha piperit*)

There are a wide variety of *Mentha* species of mint, all of which contain various amounts of the chemicals menthol and menthone. In two separate analyses, more than 30 other chemicals were identified from different mint

species, including pinene, limonene, menthofuran, pulegone, eugenol, menthyl acetate, diosphenol, and others.^{44,45} Peppermint is not only an herbal remedy for abdominal pain and other discomforts, but also a ubiquitous flavoring in everything from gum to toothpaste. Peppermint is used as a breath freshener, decongestant, and antitussive. It is an intestinal antispasmodic, aiding in dyspepsia, flatulence, and colic and has been administered to patients to decrease symptoms in irritable bowel syndrome, inflammatory bowel disease, and biliary tract disorders. Menthol is used in shaving creams, mouthwash, lip balm, and many other personal hygiene products.

The actions of peppermint oil on the gut are complex. Some have found that it relaxes smooth muscle via effects on calcium channel receptors, whereas others have found that it stimulates intestinal smooth muscle and can cause cramps and the urge to defecate and urinate.⁴⁶ EOs from two different *Mentha* species produced central nervous system depression and hypothermia when fed to rats.⁴⁵ Seizures, ataxia, and respiratory depression were seen in rats after acute menthol dosing (median lethal dose [LD₅₀] 2.5 g/kg).⁴⁷ Chronic dosing at 40 to 100 mg/kg/day in rats over a 3-month period produced cystic lesions in the cerebellum and a progressive nephropathy.⁴⁸

The clinical toxicity of peppermint includes a dermatitis associated with hypersensitivity to menthol. Chronic urticaria, “hot flashes,” and gastrointestinal irritation are common in susceptible individuals. Diagnosis is possible by challenging the allergic individual with mint; besides eliciting the symptoms, a characteristic basopenia is observed in the blood count after provocative testing. Because a wide variety of everyday foods and household products contain mint flavoring, strict surveillance to avoid offending foodstuffs is difficult.

Acute *Mentha* reactions in humans can also include neurologic changes such as tremor, ataxia, drowsiness, or even coma. In one instance, menthol drops were mistakenly instilled into the nose of a 2-month-old infant, who subsequently developed dyspnea, unconsciousness, hyperextension of the extremities, and a metabolic acidosis.

A variety of other toxic effects are occasionally seen. Peppermint may precipitate hemolysis and jaundice in newborns with glucose-6-phosphate dehydrogenase deficiency,⁴⁹ and it was implicated in the development of pneumonia in an infant exposed to aerosolized peppermint.⁵⁰ Peppermint oil is also an irritant of the eyes and skin. It can cause burns of the skin or oral cavity and gingival and pharyngeal edema. It can cause gastrointestinal symptoms, perianal burning, cramps, and diarrhea. Myalgia and bradycardia have been reported. Management of peppermint poisoning consists of supportive care and may include activated charcoal for recent ingestions.

Clove Oil (Clove Plant)

Eugenol, a phenol, is the ingredient that makes up more than 90% of clove oil. Other ingredients of clove oil include caryophyllin and vanillin. Clove oil is used widely

as a fragrance or to flavor a variety of products, including foods, candles and incense, soaps, and toothpastes. Eugenol’s disinfectant and analgesic properties have led to its use to treat dental pain and gingivitis, and it is commonly used during dental procedures and cleaning. According to Poisindex, the clinical effects of eugenol in clove oil resemble those of phenol, but are not as severe.⁵¹ Clove oil may manifest its toxicity via direct injury to tissues, as seen when instilled directly into the trachea of rats, where eugenol caused interstitial hemorrhage, acute emphysema, and acute pulmonary edema.⁵²

Toxicity of clove oil must be extrapolated from animal studies due to a lack of data defining specific toxic doses in humans. Dogs given oral doses of 0.25 g/kg of eugenol manifest with vomiting, weakness, lethargy, and ataxia.⁵³ In rat studies, eugenol was shown to cause coma and death within 24 hours with doses of 0.5 g/kg. The LD₅₀ of eugenol has been determined to be 1.8 mL/kg (1.93 g/kg), with evidence of cardiovascular collapse.⁵³ The relatively low LD₅₀ (11 mg/kg) of clove oil administered via the pulmonary route suggests the danger if clove oil is aspirated.⁵²

In humans, a case of ingestion of oil of cloves by a young child was reported, which resulted in coma, seizures, a coagulopathy, and acute liver damage.⁵⁴ A reported case of accidental oral administration of clove oil resulted in central nervous system depression, urinary abnormalities, and large anion-gap acidosis.⁵⁵

Topical exposure to clove oil can cause irritation to the skin, eyes, and oral mucosa. Clove oil splashed into the eye may cause acute pain, blepharospasm, lacrimation, and conjunctival edema, with loss of corneal epithelium.⁵⁶ It has been responsible for cases of contact dermatitis, stomatitis, and systemic allergic reactions. Orally, the initial stinging and irritation noted after topical exposure may progress to permanent local anesthesia and anhidrosis if contact is prolonged.⁵⁷

Clove oil is also used in “bidi” cigarettes, an Indian product, which has been popularly used as a tobacco substitute. Clove cigarettes (approximately 40% dried clove and 60% tobacco) may also cause toxicity. Principally, bidi cigarettes are imported from Asia, and are available throughout the United States and Canada. Respiratory and systemic side effects of bidi cigarettes are numerous, and they include nausea, vomiting, dyspnea, bronchospasm, pulmonary edema, hemoptysis, and epistaxis. Side effects may be due to the direct effects of eugenol, including eugenol-induced anesthesia of the mucous membranes. In turn, this permits deeper inhalation of smoke and may result in greater tissue irritation and injury.⁵⁸

Management of ingestion of clove oil may begin with dilution with water or milk prior to gastric evacuation. Concern for aspiration makes emesis undesirable, but activated charcoal may be indicated although direct evidence of its efficacy is lacking.⁵¹ Topical exposures to the eye or mucous membranes should be addressed with vigorous and lengthy irrigation. Mild to moderate allergic reactions, including anaphylaxis, may be treated with antihistamines with or without inhaled β agonists, corticosteroids, or epinephrine.

MANAGEMENT OF POISONING BY ESSENTIAL OILS

Exposure of the eyes or skin to undiluted EOs will likely cause pain and irritative reactions. Treatment of skin exposures should include immediate thorough washing with soap and water. Skin eruptions may necessitate steroid-containing creams or other local therapy. Generalized allergic rashes, urticaria, or anaphylaxis may require the use of oral or parenteral antihistamines, subcutaneous epinephrine, intravenous steroids, and other anti-inflammatory and resuscitative measures.

Eye exposures may cause pain, erythema, photophobia, lacrimation, blepharospasm, and even corneal clouding and more serious burns. Exposed eyes should be flushed with a cool stream of water or an eye wash solution for at least 15 to 20 minutes. Patients with lingering photophobia, conjunctival injection and irritation, or other symptoms despite initial dilution efforts will require ophthalmologic consultation and management.

Ingestion of EOs can lead to allergic symptoms or, depending on the specific EO, other toxic effects in target organ systems (Table 101-1). Patient assessment includes obtaining a careful history and performing a thorough physical examination, during which it should be determined whether a splash event for aspiration has also occurred. Gastric emptying using ipecac may increase the risk for aspiration during vomiting and is not recommended. Oral administration of activated charcoal, with care to avoid inducing emesis extending to elective endotracheal intubation to protect the airway, may be helpful if the patient presents to medical care in a timely fashion, although its value in improving patient outcome after EO ingestion is uncertain.

Eos contain aromatic or branched hydrocarbons with high volatility and low viscosity. Toxic effects of many EO also include central nervous system depression and a depressed gag reflex. These properties place the patient at high risk for aspiration. When aspirated, the effects of EOs are similar to those of hydrocarbon aspiration, with

possible bronchospasm, pneumonia, and pulmonary edema. Patients who have aspirated an EO require and assessment for aspiration pneumonia, including serial chest radiographs and white blood cell counts, both of which may become progressively more abnormal as time goes on. Patients in respiratory distress may require transport to a facility with intensive care capabilities and expertise in advanced cardiovascular and respiratory medical care.

Patients in acute respiratory distress require close monitoring of arterial blood gases, with the administration of oxygen and supportive measures. In life-threatening aspirations, such measures may include endotracheal intubation and artificial ventilation. The value of steroids in such patients is controversial.⁵⁹ The use of bronchodilators may be necessary for patients who exhibit bronchospasm; antibiotics may be needed for patients who develop secondary pulmonary infections. High-frequency oscillatory ventilation and extracorporeal membrane oxygenation might be considered in patients with severe, life-threatening pulmonary failure due to aspiration unresponsive to conventional measures, but are still considered experimental measures.⁶⁰

Other complications of oral EO poisoning include allergic reactions whose treatment is described above and EO-specific toxicities such as hepatitis or central nervous system depression. Treatment of hepatitis or coma requires frequent monitoring of the patient's status, with supportive measures as indicated. Hemodialysis may be indicated for patients in acute renal failure, but has not been shown to enhance elimination of a clinically significant amount of an EO. Ingestion of pennyroyal oil may require early consideration of administration of the antidote, NAC, to prevent hepatic injury.

RESOURCES

Box 101-2 provides information on Internet resources for herbs, dietary supplements, and essential oils.

TABLE 101-1 Selected Essential Oils and Their Toxicities

ESSENTIAL OIL	BOTANICAL NAME	PURPORTED INDICATIONS	TOXIC INGREDIENTS	SYMPTOMS/TOXIC EFFECTS
Chamomile	<i>Chamaemelum nobile</i>	Eczema, asthma	Tiglic oil	Somnolence, gastrointestinal upset, allergic reactions, bronchospasm, increased bleeding time, uterine stimulant
Absinthe	<i>Artemisia</i> species	Malaria, antihelminthic	Thujone	GI upset, seizures, coma, psychosis, memory loss
Chenopodium	American wormseed, Jerusalem oak	Anti-parasitic agent	Ascaridole, cymene, camphor, limonene	Nausea, vomiting, abdominal pain, dizziness, paresthesias, seizures, coma, impaired vision, optic atrophy, hepatitis
Cinnamon	<i>Cinnamomum zeylanicum</i>	Flavoring, stimulant, carminative	Cinnamic aldehyde	Hypersensitivity reactions, dermatitis, stomatitis, nausea, vomiting, abdominal pain, facial flushing, dizziness, oral lesions, skin burning sensation

**TABLE 101-1** Selected Essential Oils and Their Toxicities—*cont'd*

ESSENTIAL OIL	BOTANICAL NAME	PURPORTED INDICATIONS	TOXIC INGREDIENTS	SYMPTOMS/TOXIC EFFECTS
Clove	<i>Eugenia</i> species	Toothache, flavoring, disinfectant as used in dental procedures	Eugenol, caryophyllin, vanillin	Oral and skin irritation, allergic reactions, nausea, vomiting, respiratory symptoms, hepatic necrosis, lethargy, ataxia, seizures
Eucalyptus	<i>Melaleuca alternifolia</i>	Antitussive	1,8 cineole (eucalyptol), hydrocyanic acid	Vomiting, abdominal pain, bronchospasm, bronchorrhea, pneumonitis, respiratory depression, dizziness, headaches, ataxia, obtundation, coma, seizures
Hyssop	<i>Hyssopus officinalis</i>	Nervous exhaustion, grief, emmenagogue	Pinocamphone	Seizures, hypertension
Juniper	<i>Juniperus communis</i>	Arthritis, antibacterial, carminative, diuretic	Terpinen-4-ol	Uterine spasm, tachycardia, dermatitis
Lavender	<i>Lavandula</i> species	Many dysfunctions, including sedative, anxiolytic, antimicrobial	Cintronellal, others	Allergies
Lemon grass	<i>Melissa officinalis</i> , lemon balm, sweet balm	Flavoring, sedative, antidepressant	Citral	Dermatitis
Myrrh	<i>Comiphora molmol</i>	Anti-inflammatory, GI upset, asthma	Sesquiterpenes	Tachycardia, dermatitis, abortifacient
Nutmeg	<i>Myristica fragrans</i>	Toothache, GI upset, halitosis	Myristacin	Nausea, vomiting, abdominal pain, diarrhea, hallucinations, coma
Pennyroyal	<i>Hedeoma pulegioides</i>	Abortifacient	Pulegone	Nausea, vomiting, abdominal pain, hepatitis, centrilobular hepatic necrosis, kidney failure, pneumonia
Peppermint	<i>Mentha</i> species	Antispasmodic, carminative, used in irritable bowel syndrome	Menthol, menthone	Hypersensitivity reactions, ataxia, myalgia
Pine	<i>Pinus</i> species	Disinfectant	Monoterpene, aromatic pine oil, other hydrocarbons	CNS effects, respiratory failure
Rose	<i>Rosa</i> species	Aphrodisiac, anxiety	Hydrocarbons	Aspiration pneumonia, nephrotoxic
Sandalwood	<i>Santalum album</i>	Flavor, anxiety	Santalol	CNS effects, mucous membrane irritant, GI upset, kidney pain
Sassafras	<i>Sassafras albidum</i>	Pediculosis capitis, abortifacient	Safrole, pinene, camphor	Vomiting, dizziness, stupor, shock, hepatocarcinoma
Tea tree	<i>Melaleuca alternifolia</i>	Antibacterial	Terpinen-4-ol	Stupor, ataxia, sores
Yarrow	<i>Achillea millefolium</i>	Anti-inflammatory, antispasmodic	Sesquiterpene lactones, polyacetylenes, simple coumarins, flavonoids	Allergy, antispermatogen

At a Glance...

- Household cleaning products generally have a low level of toxicity.
- Toxicity is more often due to local effects than systemic effects.
- Personal care soaps, hand dishwashing detergents, household laundry detergents, and household bleaches may be irritants.
- Automatic dishwashing detergents and cationic disinfectants can be corrosive.
- Ocular tissues and respiratory mucosa tend to be more sensitive than gastrointestinal mucosa or skin to exposures by household products.
- Inhalation or aspiration of household products may warrant medical attention.
- Powdered products may cause mechanical irritation as well as chemical irritation, especially to the eye.

Exposures to household cleaning products account for a large proportion of calls to poison control centers in the United States. The 2003 Annual Report of the American Association of Poison Control Centers (AAPCC) reports that cleaning products, as a category, rank second (to analgesics) in number of exposures to humans of all ages (9.4% of exposures), second (to cosmetics and personal care products) in number of exposures to children younger than 6 years (9.7% of exposures), and third (to analgesics and sedative-hypnotics and antipsychotics) in number of exposures to adults older than 19 years (8.9% of exposures). Of these exposures to cleaning products, only 0.011% resulted in the death of the exposed individual.¹ As categorized by the AAPCC, household cleaning products include, but are not limited to, bleaches, soaps, detergents, ammonia, disinfectants, glass cleaners, acids, and alkalis. This chapter examines the toxicologic aspects of bleaches, soaps, and detergents. Tables 102-1 and 102-2 summarize the AAPCC 2003 Annual Report's age-related and outcome data for these types of cleaning products.

SOAPS AND DETERGENTS

A *soap* is defined as the salt of a fatty acid (most often the sodium or potassium salt) and is one of the simplest and earliest examples of a household cleaning agent. Soaps belong to the broader category of substances called *surface-active agents*, or *surfactants*. Surfactant molecules contain both polar and nonpolar regions, which effectively decreases the surface tension of water. This helps water to wet surfaces more effectively and results in more efficient cleaning and washing. Surfactants can

also help remove dirt, disperse soil, and emulsify oil or grease in the wash water.² A major limitation of soap as a cleaning agent is its decreased effectiveness when used in hard water. Hard water contains minerals such as calcium, magnesium, iron, or manganese that can combine with the fatty acids in soap and form a precipitate known as soap scum or film. This film does not rinse away easily, leaving deposits on clothing and surfaces. In addition, because some of the soap is removed from the wash water in this precipitate, the amount of soap available for cleaning is reduced. The development of detergents that perform well under a variety of conditions has reduced this problem.³

Like soaps, detergents are surfactants, but are more variable in structure and function. Detergent surfactants fall into one of four categories corresponding to the electrical charge on the polar portion of the molecule: nonionic, anionic, cationic, and amphoteric. Box 102-1 lists common examples of each type of surfactant. Household detergents usually contain nonionic or anionic surfactants, or a combination of the two. Cationic and amphoteric surfactants are used to a lesser extent in household detergents.² Soaps are anionic surfactants and, therefore, could be considered a subtype of detergents. In its common usage, the term *detergent* encompasses cleaning products that contain detergent surfactants as well as additional ingredients that enhance the cleaning efficacy of the surfactants. This usage is employed for the remainder of this chapter, with detergent surfactants being referred to as *surfactants*.

In addition to surfactants, many detergent products contain alkaline builders that enhance or maintain the cleaning efficacy of the surfactants. The primary function of builders is to reduce water hardness by inactivating hardness minerals. Builders can also supply and maintain alkalinity, prevent redeposition of soil during washing, and emulsify oily and greasy soils. Common builders found in household detergents include complex phosphates, sodium carbonate, sodium silicate, and sodium metasilicate.³ Due to concern that began building in the late 1960s over the contribution of phosphates to eutrophication of lakes, phosphates are now banned in most states in the United States. For manufacturing convenience and cost-effectiveness, the detergent industry phased out the use of phosphates in domestic laundry detergents by 1996.⁴

A few detergent products contain small amounts of enzymes such as proteases, amylases, lipases, and cellulases that catalyze the breakdown of organic stains. This improves detergent performance and reduces required wash temperature and cycle time.⁵ Detergents may also contain whiteners, colorants, softeners, fragrances, and bleaches.² Concentrations of these additives are

typically too low to result in clinically significant toxicity, but sensitization may occur. Medicinal soaps contain small amounts of antibacterial agents that do not contribute significant toxicity.⁶

Sources

The term *soap* generally refers to personal care soaps such as bar soaps and liquid hand and body soaps. The term *detergent* generally refers to, but is not limited to, hand dishwashing detergents, automatic dishwasher detergents, and laundry detergents. Some liquid hand and body soaps also contain mild detergents.

Personal care soaps and hand dishwashing detergents generally contain anionic, nonionic, or amphoteric surfactants. Laundry detergents generally contain anionic or nonionic surfactants. Automatic dishwasher detergents generally contain nonionic surfactants because they are lower sudsing than anionic surfactants.^{3,7} Fabric softeners generally contain cationic surfactants, and some disinfectants contain cationic surfactants.^{3,8,9} Builders are typically included in laundry and automatic dishwashing detergents and account for much of the toxicity related to these products.²

Toxicity

The surfactants and builders contained in these products are the major contributors to product toxicity. The relative toxicity of surfactants can be graded according to the type of surfactant involved. Nonionic and amphoteric surfactants have the lowest toxicity, anionic surfactants have intermediate toxicity, and cationic surfactants have the highest toxicity.¹⁰ Nonionic, anionic, and amphoteric surfactants are irritating to the gastrointestinal (GI) mucosa and conjunctiva.^{11,12} Cationics are classified as irritants at concentrations below 7.5%, but can be corrosive at concentrations above this. Cationic surfactants can also cause systemic toxicity if ingested at higher doses or concentrations (see later).^{8,13} Surfactants of any type may cause or contribute to dermal irritation by increasing permeability of the skin.¹⁴ Therefore, the surfactant itself may cause irritation, as well as contribute to increased sensitivity to other substances with which the skin may come in contact.

Builders are alkaline compounds that are irritants at low concentrations but can be corrosive at higher concentrations. For example, corrosive injury can result from a 0.5% solution of sodium metasilicate or a 15%

Adapted from Watson WA, Litovitz TL, Klein-Schwartz W, et al: 2003 annual report of the American Association of Poison Control Centers Toxic Exposure Surveillance System. *Am J Emerg Med* 2004;22(5):335-404.

solution of sodium carbonate.^{13,15,16} Sodium silicate is less corrosive but can produce corrosive injury at concentrations of 20% to 40% or more. Complex phosphates are the least toxic builders; however, they can be corrosive at high concentrations with prolonged contact.^{15,17} Systemic effects related to hyperphosphatemia can result from substantial ingestions of phosphate-containing detergents.¹³

If the concentration of a builder or other possibly corrosive substance in a product is unknown, the product's pH can be used to assess probable corrosiveness. A general rule is that corrosive injury becomes a risk at pH lower than 2 or higher than 12.¹⁸ However, product pH should not be used as the sole determinant in the assessment of an exposed patient. In addition, it must be recognized that some substances with a neutral pH can cause tissue damage (such as quaternary ammonium cationic surfactants) and that the concentration and other physical properties of a substance also contribute to corrosiveness.

Enzymes exhibit a very low level of toxicity, with adverse effects being limited to the development of hypersensitivity and irritation of the skin, eye, and other mucosal sites. Enzymes have also been linked to occu-

pational asthma in employees of detergent manufacturing plants; however, encapsulation of enzymes has decreased the inhaled dust and the associated incidence of asthma in the industry. If used as directed in laundry products, enzymes are not generally irritating.¹⁹

Manifestations

PERSONAL CARE SOAPS AND HAND DISHWASHING DETERGENTS

Personal care soaps and hand dishwashing detergents are of low toxicity. Ingestion may cause GI irritation with associated complaints of nausea, vomiting, and diarrhea.^{2,7,12} There is a slight risk for aspiration of foam or vomitus after ingestion of these products, which can result in respiratory irritation, chemical pneumonitis, or pulmonary edema with associated coughing, gagging, dyspnea, or stridor.^{11,12} Ocular exposure to these products is associated with irritation and mild conjunctivitis without damage to the corneal epithelium.² However, some heavy-duty personal care soaps contain abrasives that can cause mechanical injury to the corneal epithelium and conjunctiva. Although uncommon, some sensitive individuals may experience dermal irritation

with prolonged exposure, especially in cold, dry climates where the skin may already be compromised. This would manifest as dryness, pruritus, or erythema.²

LAUNDRY DETERGENTS

Laundry detergents contain builders as well as surfactants, adding another dimension of toxicity. However, most household laundry detergents, whether liquid or granular, do not generally contain high enough concentrations of builders to be considered corrosive. Like soaps and hand dishwashing detergents, laundry detergents are irritants, and ingestion is associated with nausea, vomiting, and diarrhea.^{2,7,12} A small number of laundry detergents may contain high enough concentrations of builders to cause mucosal injury on ingestion, which, by law, should be indicated on the label. Aspiration of product or vomitus may lead to respiratory irritation or chemical pneumonitis with associated symptoms discussed previously. Ocular exposure typically results in irritation, stinging, and erythema of the conjunctiva, with granular laundry detergents contributing greater toxicity owing to the risk for abrasive injury.² Whether liquid or granular, formulations containing sodium carbonate have been shown to have greater potential for ocular irritation, possibly leading to corrosion and opacity of the cornea.⁷ Dermal exposure may result in similar manifestations as those due to soaps

and hand dishwashing detergents, with a small number of sensitive individuals experiencing irritation, pruritus, and erythema, especially in cold, dry climates where the skin may already be compromised.²

In countries other than the United States, phosphates may be a major ingredient of laundry detergents. Despite their low toxicity, there is a case report of a 30-year-old patient in the United Kingdom developing hyperphosphatemia as a result of the intentional ingestion of an unknown amount of a laundry detergent containing more than 30% phosphates. This was associated with hypocalcemia and hypomagnesemia due to chelation by the phosphate. The hypocalcemia resulted in ventilatory failure due to respiratory muscle spasm. Supportive measures were instituted, and the patient survived.²⁰

A less common but potentially serious complication of ingestion or inhalation of *powdered* laundry detergents is respiratory distress. Case studies appearing in the literature describe the development of drooling, stridor, retractions, and respiratory distress in pediatric patients who ingested or inhaled non-phosphate powdered laundry detergents. Symptoms were often accompanied by erythema and edema of the vocal cords and epiglottis. There was no damage to the esophageal mucosa in most cases and only minimal damage in the remainder.¹ The irritant effect of powdered laundry detergents is of little clinical significance in the GI tract, but if the vocal cords or epiglottis are affected, erythema and edema may result in significant airway compromise.^{21,22}

AUTOMATIC DISHWASHER DETERGENTS

Automatic dishwasher detergents are more alkaline than the other detergents described previously because of higher concentrations of alkaline builders, possibly up to 70% to 80%. The high alkalinity is required for product performance, but unfortunately, increases the risk for corrosive injury.¹⁷ Ingestion of even small amounts of granular or liquid products is associated with nausea, immediate vomiting, and possibly diarrhea.² Corrosive injury to the upper GI tract is possible, symptoms of which may include burns to the mouth and oropharynx, coughing, drooling, vomiting, chest or throat pain, stridor, and dysphagia.^{2,6} Endoscopy may reveal edema of the epiglottis and vocal cords as well as erosion of the esophageal mucosa. Development of strictures (although uncommon) may follow esophageal injury.¹⁷ It is important to note that the presence of oral injury does not necessarily correlate with the presence of esophageal or gastric injury.^{2,15,17} Additionally, it has been reported that a small number of asymptomatic individuals may have esophageal lesions revealed on endoscopy.¹⁷ As with other soaps and detergents, aspiration of product or vomitus can result in chemical pneumonitis and respiratory distress. Because of the alkalinity of automatic dishwasher detergents, sequelae due to aspiration may be more severe, and death has been reported.¹⁹

Ocular exposure to automatic dishwasher detergents generally produces conjunctival irritation with the potential for corrosive injury. Because the tissues of the eye can be more sensitive to exposure than the tissue of the GI tract, the incidence of symptoms from ocular

exposure is greater than that from ingestion. In a study of exposures to liquid automatic dishwasher detergents, most patients with eye exposures presented with minor corneal abrasions, whereas a minority of the patients had more severe abrasions. Because liquid automatic dishwasher detergents are aqueous slurries of solute, whether the exposure is to a liquid or granular product, it is difficult to determine if the ocular irritation is secondary to mechanical abrasion or to alkaline injury.²³

Dermal exposure to automatic dishwasher detergents, like other detergents, may result in irritation, pruritus, erythema, and rash.² Blistering has been reported infrequently. Because of product alkalinity, symptoms are more frequent than with hand dishwashing and laundry detergents, yet only occur in a minority of exposures.²³ Contact with undiluted product has been rarely associated with contact dermatitis.²

CATIONIC DETERGENTS

Fabric softeners and some disinfectant cleaners contain cationic surfactants. Generally, the cationics used in household fabric softeners have a much lower order of toxicity than those in disinfectants. Fabric softeners and disinfectants with cationic surfactant concentrations below 7.5% are GI and dermal irritants, with manifestations similar to exposure to hand dishwashing or laundry detergents.^{2,8} Ocular tissues are more sensitive to cationic surfactants, with even one drop of a 2% solution having the potential to cause corrosive injury and severe corneal damage.⁸ Symptoms often include irritation, tearing, erythema, and burning. Disinfectants with cationic surfactant concentrations higher than 7.5% can cause corrosive injury to any tissue. Symptoms associated with ingestion include drooling; vomiting; hematemesis; burning pain in the mouth, throat, and abdomen; and possibly oral burns. Esophageal burns may be discovered on endoscopy.^{8,13}

Because cationic surfactants are rapidly absorbed from the GI tract, ingestion can result in systemic symptoms that include hypotension, restlessness, confusion, central nervous system depression, renal insufficiency, circulatory collapse, convulsions, and coma. The mechanism of these toxic effects is unknown.^{13,24} Because of a structural similarity to curare-type skeletal muscle relaxants, ingestion of quaternary ammonium-type cationics has been associated with muscle weakness and paralysis, possibly preceded by transient muscle fasciculation. This may progress to weakness of the respiratory muscles, dyspnea, and asphyxial death.^{8,10,13,24} Death due to circulatory failure or asphyxia may occur within 1 to 2 hours of ingestion.¹³ Human deaths due to benzalkonium chloride ingestion have been seen at doses of 100 to 400 mg/kg and at 1 to 3 g total.²⁴ Some observations of cholinesterase inhibition have been demonstrated in vitro by several cationic surfactants. A 50% inhibition of red cell, but not plasma, cholinesterase was observed after intraperitoneal injection of cationic surfactants in rats; however, no symptoms were observed. It was therefore concluded that toxicity due to cholinesterase inhibition is improbable,¹³ especially after expected routes of household exposure.

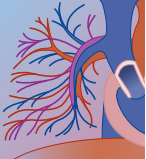

Dermal exposure to concentrated cationic surfactants can cause dermal necrosis, exacerbated by occlusion of the skin.⁸ Cationic surfactants have also been associated with occupational asthma, allergic contact dermatitis, and ocular hypersensitivity.^{9,25}

Management

INGESTION

Most sources suggest that ingestion of soaps, hand dishwashing detergents, and laundry detergents can be managed at home by dilution with milk or water. If an animal is exposed, water is suggested because other fluids may cause further GI irritation. Oral fluid intake should be limited to 4 oz for children and 8 oz for adults, so as not to distend the stomach. Other sources advocate no oral dilution because of a possible risk for “sudsing” and aspiration. GI decontamination by any means is unnecessary, with spontaneous vomiting often occurring nonetheless. If vomiting or diarrhea is excessive, fluid and electrolytes should be replaced and monitored as necessary, possibly in a health care facility. Any patient who experiences spontaneous vomiting should be monitored for 6 to 8 hours for signs of aspiration of product or vomitus. Manifestations, including coughing, gagging, dyspnea, or stridor, warrant an emergency department visit for chest radiograph and supportive care. Management of ingestion or inhalation of *powdered* laundry detergent must also include careful monitoring of respiratory function. In cases of respiratory complications, the onset of symptoms may occur between 2 and 12 hours after exposure. Development of symptoms necessitates an immediate emergency department visit for supportive care and evaluation.²¹ If a large concentration of a phosphate-containing laundry detergent is ingested, electrolyte levels should be monitored for 4 to 6 hours (including phosphorus, calcium, magnesium) and treated appropriately. Phosphate binders such as Sevelamer may be a better treatment than calcium supplementation because of the risk for precipitation of calcium phosphate crystals in soft tissues.²⁰

Ingestions of automatic dishwasher detergents should be managed based on the properties of the particular detergent and on the individual's symptoms. GI decontamination is unwarranted in any exposure to automatic dishwasher detergents and could be harmful with corrosive ingestions. For detergents with pH lower than 12, which are less likely to cause corrosive injury, patient symptoms can guide treatment. If the exposed individual is asymptomatic, dilution at home with 4 to 8 oz of water or milk should suffice initially. The individual should then be observed for an additional 6 to 8 hours for symptoms of oral or esophageal injury. Symptom manifestation warrants emergency department care for corrosive injury (see Chapter 98). If the exposed individual is symptomatic at the outset, immediate evaluation for corrosive injury should be sought. Dilution with a small amount of water or milk (2–4 oz) may be beneficial in rinsing the product from the affected area. If detergent pH is higher than 12 and the

patient is symptomatic, emergency care for corrosive injury should be sought. Again, dilution with 2 to 4 oz of water or milk may be helpful in rinsing the product from the affected area. Animals exposed to automatic dishwasher detergent may not have the ability to display symptoms of corrosive injury nor vocalize their discomfort. Therefore, all ingestions of automatic dishwasher detergents in animals should be evaluated by a veterinarian for corrosive esophageal injury.

Ingestions of cationic detergents should be managed based on the concentration of the cationic compound in the product and the individual's symptoms. Small ingestions of products with concentrations below 7.5% can be managed similarly to hand dishwashing and laundry detergents. Ingestions of concentrated cationic detergents (>7.5%) should be managed as corrosive exposures. If a very large amount of a dilute product or more than a few swallows of a concentrated product has been ingested (fatal dose estimated to be 1 to 3 g), the individual should be observed in a health care facility for symptoms of systemic toxicity for an additional 2 to 4 hours with supportive care as necessary.

OCULAR EXPOSURE

Eye exposures to soaps and hand dishwashing detergents should be managed by gently irrigating the eye on-site with lukewarm water or saline continuously for 15 minutes. On the rare occasion that ocular irritation lasts longer than 2 to 3 hours after irrigation, or the exposure was to a product containing an abrasive, emergency department care is warranted, including a slit-lamp examination with fluorescein dye.

Ocular exposures to laundry detergents and very dilute cationic surfactants (<2%) should be irrigated as described previously. However, greater discretion is warranted in these cases, with immediate medical evaluation necessary if irritation persists for more than 1 to 2 hours after irrigation. It should be kept in mind that the presence of alkaline builders in laundry detergents or an exposure to granular detergent can be associated with an increased risk for corrosive or mechanical injury to the eye. Eye exposure to any laundry detergent with pH > 12 or to any cationic surfactant with a concentration of 2% or greater should be managed as a corrosive.

Because ocular exposure to automatic dishwasher detergents is associated with a high incidence of corneal abrasions as well as corrosive injury to the eye, all exposed patients should have an emergency department evaluation after thorough on-site irrigation for 20 minutes with lukewarm water or saline.²³

DERMAL EXPOSURE

Management of dermal exposure to any of the above products should begin with irrigation of the exposed area for 5 to 10 minutes with lukewarm water. Exposed clothing should be removed to prevent further contamination. In the rare instances of irritation by noncorrosive products, application of cold packs, vitamin E lotions, or aloe vera gels or lotions may reduce discomfort. If irritation is due to a drying effect of the product,

moisturizing creams may be applied. Dermal exposure to potentially corrosive products can be managed similarly, although oil-based creams or ointments should be avoided. If skin becomes blistered or broken, or begins bleeding or oozing, the care of a physician should be sought. At the discretion of the physician, treatment may include topical corticosteroids in the early stages, topical antibiotics, and wet-to-dry dressings. The rare case of contact dermatitis is best referred to a dermatologist.

BLEACHES

The predominant types of bleach on the market are one of two types: chlorine-releasing aqueous solutions of sodium hypochlorite, or oxygen-releasing powders containing sodium percarbonate/sodium carbonate or sodium perborate/sodium carbonate.² Because the hypochlorite ion in chlorine bleach is unstable in acidic solutions, chlorine bleaches generally contain a small percentage of sodium hydroxide.¹² Some chlorine bleach may also contain a very small percentage of cationic surfactants that slightly increases product viscosity.

Sources

Chlorine bleaches are the most common and familiar bleaching agents for household use. Traditional household laundry bleach generally contains 4% to 6% sodium hypochlorite (most commonly, 5.25%) and up to 0.5% sodium hydroxide. The newer "ultra" or "advanced" household bleaches generally contain 5% to 10% sodium hypochlorite and 0.5% to 2% sodium hydroxide. Some hard surface cleaners contain 1% to 4% sodium hypochlorite in combination with surfactants.²⁶ Oxygen bleaches are all-fabric bleaches that generally contain 5% to 15% sodium percarbonate, sodium perborate, or both, plus up to 75% sodium carbonate. The newer "oxy"-type stain removers contain as much as 89% sodium percarbonate, with the remainder being sodium carbonate. Some of these stain removers may also contain up to 5% sodium metasilicate. Sodium percarbonate is more commonly used than sodium perborate in oxygen bleaches because sodium perborate does not dissolve as readily at cooler wash temperatures.

Toxicity

Although there has been much controversy in the literature during the past 40 years regarding the corrosiveness of chlorine bleaches, it is generally agreed that household chlorine bleach is a mild to moderate mucosal irritant.^{11,27,28} The deleterious effects of bleach are related to both the sodium hypochlorite concentration and the pH (or hydroxyl ion concentration). When a sodium hypochlorite solution is ingested, the acidic environment of the stomach transforms the sodium hypochlorite to hypochlorous acid and chlorine gas. At the levels produced from household bleach, hypochlorous acid and chlorine gas are both irritants to

mucous membranes. Sodium hypochlorite solutions of less than 10% are mild to moderate mucosal irritants, whereas solutions of greater than 10% are considered corrosive.^{26,27} Sodium hydroxide concentrations of less than 2% are considered irritants, whereas concentrations of greater than 2% may be corrosive.²⁹ Household bleach solutions generally do not exceed 10% sodium hypochlorite or 2% sodium hydroxide. Most household bleaches have a pH between 11 and 12, also supporting a lack of corrosiveness. Some sources state the critical pH for corrosive injury from bleaches is 12.5.^{27,30} It must be noted that bleaches manufactured in countries outside the United States or bleaches manufactured with inadequate production controls may have higher sodium hypochlorite concentrations and higher sodium hydroxide concentrations.^{6,27}

The extent of irritation from household chlorine bleach depends on the volume ingested, the concentration, viscosity, and duration of contact. Corrosive injury rarely results and is often due to ingestion of a very large quantity (>5 mL/kg) or a concentrated solution (>10%).^{10,12} Dermal exposure may result in mild to moderate irritation, whereas ocular exposure can cause moderate irritation with superficial damage to the corneal epithelium at concentrations of 5.25% sodium hypochlorite or greater.^{28,30}

If chlorine bleach is mixed with certain other household cleaning products, toxicity may result from inhalation of gaseous by-products. For example, if chlorine bleach is mixed with a strong acid, chlorine gas evolves. If chlorine bleach is mixed with ammonia, chloramine gas evolves. Both gases can be very irritating to the nasal and oral mucosa, respiratory tract, and ocular surfaces. When chlorine gas comes in contact with moist tissue, it is transformed to hydrochloric acid and nascent oxygen. When chloramine gas contacts moist tissue, it is transformed into hydrochloric acid, gaseous ammonia, and nascent oxygen. The oxygen radicals generated are strong oxidizing agents that, along with the acids and ammonia, can cause corrosive effects and cellular injury.^{31,32}

Very little experimental data exist regarding the toxicity of the powdered all-fabric oxygen bleaches and oxygen stain fighters. The bleaching system in these products is commonly sodium percarbonate or sodium perborate, with stabilization and alkalinity contributed by sodium carbonate. A review of several manufacturers' material safety data sheets reveals that sodium percarbonate and sodium perborate powders are generally classified as mild to moderate mucosal, dermal, and respiratory irritants, and as moderate to severe eye irritants.

On contact with moisture, sodium percarbonate breaks down into hydrogen peroxide and sodium carbonate, whereas sodium perborate breaks down into hydrogen peroxide and sodium borate. The concentration of these by-products in the traditional all-fabric bleaches is generally of a level that may cause mucosal irritation on ingestion, although borates could cause systemic toxicity. (Borates are discussed in Chapter 99.) However, some of these all-fabric bleaches contain more than 70% sodium

carbonate, which has been reported to be corrosive in solutions of 15% or more.¹⁶ The concentration of by-products from the oxygen stain removers could theoretically be high enough to cause corrosive injury, but as of yet, this effect has not been reported. It would likely depend on the quantity of moisture available in the exposed area. In addition, some of these products contain up to 5% sodium metasilicate, which may be corrosive in solutions of 0.5% or more.^{13,15} Further research and experience in this area are needed.

Manifestations

CHLORINE BLEACH

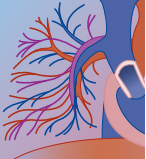

Ingestion of small amounts of household chlorine bleach is generally associated with nausea, vomiting, abdominal pain, diarrhea, and coughing.^{26,27,33,34} Less common symptoms include dyspnea, drooling, temporary dysphagia, skin burns, and oral burns.²⁷ Most investigations in the literature show no evidence of esophageal injury, but a minority show self-limiting erythema and exudates, still without mucosal ulceration. If corrosive injury is present, symptoms may include vomiting, drooling, chest or throat pain, and dysphagia. Progression to stricture has been reported, but is very rare, as are fatalities. Such outcomes are generally due to large intentional ingestions or to co-ingestants.^{12,26-28,35,36} Large ingestions of chlorine bleach have also been shown to lead to hyperchloremic acidosis and hyponatremia. The conversion in the stomach of sodium hypochlorite to hypochlorous acid and chlorine contributes to the hyperchloremic acidosis, whereas fluid loss and sodium overload (from the sodium salt of hypochlorite) contribute to the hyponatremia.^{34,37}

Aspiration of bleach or bleach-containing vomitus can rarely lead to respiratory complications such as airway edema and pneumonitis manifested as wheezing, tachypnea, stridor, and retractions. These symptoms may be present without concomitant esophageal injury. It is speculated that respiratory epithelium may be more sensitive to household bleach than pharyngeal and esophageal mucosa.^{12,28} This is similar to the inhalation of powdered laundry detergents discussed previously.

Ocular exposure to chlorine bleach can be associated with a burning sensation, tearing, erythema, injection, photophobia, and blepharospasm. If thorough irrigation is performed immediately, sequelae are limited to superficial loss of corneal epithelium, slight corneal epithelial haze, and conjunctival edema, all of which subside within 48 hours. If the bleach is left on the eye for a longer period time, tissue necrosis may spread through the entire thickness of the corneal epithelium, possibly leading to irreversible damage and infection.³⁰ Dermal exposure to chlorine bleach may infrequently cause irritation, erythema, and pruritus. Allergic contact dermatitis has been rarely reported.^{26,38}

CHLORINE BLEACH MIXED WITH OTHER PRODUCTS

Exposure to chlorine or chloramine gas can cause irritation and cellular injury to the moist surfaces of the

nasal passages, oral and respiratory mucosa, and eyes. The extent of injury depends on the concentration of gas, duration of exposure, and preexisting cardiopulmonary disease. With home exposure, it is very difficult to determine the amount or concentration of gas in the immediate area. Acute mild exposures to chlorine or chloramine gas are generally limited to the upper respiratory tract and may manifest as coughing, dyspnea, stridor, hoarseness, and sore throat. Other common symptoms include chest pain, dizziness, vomiting, ocular irritation, and nasal irritation. Severe exposure can progress to tracheobronchitis, pneumonitis, pulmonary edema, pneumomediastinum, and, ultimately, respiratory failure.^{31,39} This is rare in the household setting, but may occur as a result of continued exposure long after initiation of respiratory and ocular irritation. Residual interstitial infiltrates, dyspnea on exertion, and reduced vital capacity have been reported after prolonged exposure.⁴⁰ Death occurs very rarely and may be more common in individuals with previous respiratory illness or dysfunction.³⁹

OXYGEN BLEACHES

Ingestion of the powdered all-fabric oxygen bleaches and oxygen stain removers may result in nausea, vomiting, and diarrhea. Because these products are powders, mucosal contact time may be prolonged, which could result in epithelial damage to the mouth and esophagus.² Ocular exposure to these products can produce moderate irritation and erythema with the possibility of severe irreversible eye damage with prolonged contact.^{41,42} The granular nature of the products may also contribute to abrasive injury. Dermal exposure to the dry product may be mildly irritating, with exposure to the wet product possibly producing mild to moderate irritation, erythema, and dryness. Allergic contact dermatitis has not been reported. Inhalation of dust from the products may cause mild respiratory irritation with associated coughing and dyspnea.^{41,42}

Management

INGESTION

Management of chlorine bleach ingestion is dependent on the properties of the specific product and on the individual's symptoms. Ingestion of regular household bleach (4% to 6% sodium hypochlorite) can initially be managed at home by dilution with milk or water. If an animal is exposed, water should be used because other fluids may cause further GI irritation. Oral fluid intake should be limited to 4 oz for children and 8 oz for adults, so as not to distend the stomach. GI decontamination by any means is unnecessary, with spontaneous vomiting often occurring nonetheless. If vomiting or diarrhea is excessive, fluid and electrolytes should be replaced and monitored as necessary, possibly in a health care facility. Observation should continue at home for the next 8 hours for symptoms of esophageal damage or of aspiration. Symptoms such as drooling, dysphagia, chest or throat pain, and vomiting warrant emergency department investigation for corrosive injury. Symptoms

such as wheezing, tachypnea, stridor, and retractions warrant a chest x-ray and respiratory supportive care. Animals exposed to chlorine may not have the ability to display symptoms of corrosive injury nor vocalize their discomfort. Therefore, all ingestions of chlorine bleach in animals should be evaluated by a veterinarian for corrosive esophageal injury.

Ingestion of "ultra" or "advanced" bleach may require more diligent monitoring owing to the higher concentrations of sodium hypochlorite and sodium hydroxide, as well as the possibility of increased contact time with mucosal surfaces because of increased product viscosity. However, management still begins in the home and follows the same steps described previously. All ingestions of a large amount of chlorine bleach (>5 mL/kg), regardless of whether they are regular or ultra preparations, should be managed in a health care facility because of the possibility of systemic effects and a greater chance of local tissue injury. Management should include supportive care, investigation for corrosive injury, and 4 to 6 hours of monitoring of arterial blood gases, serum pH, and serum electrolytes, with appropriate treatment.

Despite the uncertainty over the true toxicity of powdered oxygen bleach products, it is suggested that ingestions be managed similarly to those of chlorine bleach, as described previously, with diligent monitoring for symptoms of esophageal injury.

OCULAR EXPOSURE

Eye exposures to regular household bleach should be managed by immediately irrigating the eye on-site with lukewarm water or saline continuously for 15 minutes. If irrigation cannot be performed immediately or if irritation persists immediately after irrigation, emergency department care is warranted, including a slit-lamp examination with fluorescein dye. Eye exposure to an ultra or advanced chlorine bleach or powdered oxygen bleach-stain remover should be irrigated for 20 minutes on-site, followed by an emergency department evaluation for corneal injury. If exposure to chlorine or chloramine gas causes significant ocular irritation, eye irrigation should be performed for 20 minutes, followed by slit-lamp examination if irritation persists for 1 to 2 hours after exposure.

DERMAL EXPOSURE

Management of dermal exposure to any of the bleaches should begin with irrigation of the exposed area for 5 to 10 minutes with lukewarm water. Exposed clothing should be removed to prevent further contamination. Occlusive creams or ointments should be avoided in the early stages. If skin becomes blistered or broken, or begins bleeding or oozing, the care of a physician should be sought. The rare case of contact dermatitis to chlorine bleach is best referred to a dermatologist.

INHALATION

Inhalation of chlorine or chloramine gas can often be managed on-site or at home with fresh air, cool oral liquids, and inhaled steam. Most patients with exposure

to chlorine or chloramine gas will have resolution of symptoms within 6 hours of exposure. If symptoms worsen at any time or persist for longer than 6 hours, emergency supportive care is warranted.³⁹ Patients with preexisting respiratory conditions may be more sensitive to exposure, but can still be monitored at home if symptoms are mild and air exchange is not compromised.³¹ Anecdotal evidence has suggested that nebulized sodium bicarbonate may be an effective adjunct for chlorine gas exposure. Prospective, randomized, controlled trials have not been carried out. A nonrandomized, nonblinded investigation of its use in chloramine gas exposure did not find a significant difference compared with oxygen alone.³² Inhalation of powdered oxygen bleach can be managed with fresh air and cool oral fluids. If symptoms persist for more than 6 hours after inhalation, emergency supportive care should be sought.

103 *Principles of Emergency Management and Management of Hazardous Materials Incidents*

JAMES CISEK, MD, MPH

At a Glance...

- Disaster preparedness and management should be based on an “all-hazards approach,” leading to comprehensive, risk-based, and integrated responses.
- Immediate disaster response is local. Communities must plan an initial response to all disasters based on available resources. Regional and national response must not be relied on primarily, but disaster management plans should readily integrate components at all levels as they come into play, emphasizing partnership and flexibility.
- The disaster life cycle is composed of four elements: (1) mitigation (long-term efforts to prevent or reduce the probability of disasters or lessen the consequences of a disaster), (2) preparedness (establishment of authorities and responsibilities for emergency actions and collection of resources to support them), (3) response (prompt critical actions to save lives and property), and (4) recovery (restoration of vital infrastructure, assessment of damage, and timely restoration of economic activity and rebuilding of the community).
- Hazardous materials releases may be unintentional or intentional. Chemical terrorism has occurred and will likely reoccur.
- Although most hazardous materials releases result in few or no casualties, disastrous exceptions, such as the releases of methyl isocyanate in Bhopal, of radionuclides in Chernobyl, of hydrogen sulfide and natural gas in Gaoqiao, and of deadly explosive materials in Neyshabur, remind us of their terrifying potential for human tragedy.
- Although the all-hazards approach provides a base for response to chemical disasters, additional expertise and elements will be required, including hazard identification, exposure assessment, decontamination, and prehospital and hospital management, including the appropriate use of antidotes, which may be needed in large quantity.
- The approach to hazardous materials emergencies is multidisciplinary, requiring consultation and cooperation from all involved specialists.

PRINCIPLES OF EMERGENCY MANAGEMENT

This chapter begins with a generalized discussion of disaster management and then focuses on management aspects of a unique disaster involving hazardous materials. All disasters are unexpected events, require a rapid response to save life and property, generate more need than available resources can manage, and require unusual procedures for resolution. Disasters may be natural (e.g., infections, drought, hurricanes, floods, severe winter storms, earthquakes, wildfires), human made (e.g., industrial, transportation, power outage), or national security threats (attack, terrorism). It is important to remember that early disaster declaration by an appropriate local, state, or federal official is an essential step that allows authorities to suspend regulations, allows the expenditure of funds for purchasing and hiring of elements for disaster control, grants authority to order evacuations, puts extensive liability protections into place, and creates the expectation that the government is primarily responsible for controlling the impact of the event.

In 1979, The Federal Emergency Management Agency (FEMA) coined the term *comprehensive emergency management* (CEM) to reflect a change in orientation from preparedness for a single hazard toward an “all-hazards” approach to potential disasters that threaten life and property.¹ CEM strives to minimize the impact caused by an emergency in a locality. FEMA stresses the importance of disaster planning being integrated, comprehensive, risk based, and all-hazard in approach. The similarities among all types of disasters suggest strongly that many of the same management strategies will apply to all such emergencies. It is critical to remember that all disasters are initially a local event, so that all disaster management must begin at the local

level. Effective disaster management requires a close partnership between all aspects of government (local, county, state, regional, federal) and the private sector. FEMA developed the Integrated Emergency Management System (IEMS) so as to integrate these critical partnerships into an all-hazards approach to emergency management. The IEMS as defined by FEMA focuses on four specific goals:

1. Promotion of a full federal, state, local, and tribal government partnership with emphasis on flexibility for achieving common goals
2. Emphasizing emergency management measures with known proven effectiveness
3. Achieving more complete integration of emergency management planning into policy-making and operational systems
4. Building on established emergency management plans, systems, and capabilities to enhance their applicability to the full spectrum of possible hazards

FEMA has defined a four-phase disaster life cycle for CEM that involves mitigation, preparedness, response, and recovery. These four phases appear in a circular association such that activities in one phase overlap those of the previous (Fig. 103-1).

Mitigation involves long-term efforts to prevent or reduce the probability of disasters or lessen the consequences of a disaster once it has occurred. Examples of mitigation activities include the issuance of flood insurance, flood hazard mapping with the prohibition of home building or the removal of homes within a flood plane, improved building safety for earthquakes or tornados, the opening of shelters in emergencies, and the relocation to temporary housing in the aftermath of a disaster.

Although mitigation can improve community safety, it does not eliminate susceptibility for all hazards. Disasters evolve rapidly and are too complex for effective extemporization. Localities must be prepared for disasters that cannot be mitigated away. Emergency management

mandates that preparedness actions be taken before an emergency has occurred. Preparedness establishes the authorities and responsibilities for emergency actions and collects the resources to support them. Preparedness mandates that jurisdictions have a plan for response, trained personnel to respond, and necessary structural and equipment resources with which to respond. FEMA states that preparedness planning covers three objectives:

1. Maintaining existing emergency management capability in readiness
2. Preventing emergency management capabilities from themselves falling victim to emergencies
3. Augmenting the jurisdiction's emergency management capability

The *preparedness* process begins with a comprehensive community hazard assessment done in collaboration with community, state, and federal personnel. This assessment begins with the accurate identification of community hazards and their potential consequences and then compares and prioritizes these risks. This is the approach required of all jurisdictions and agencies that intend to be compliant with the National Fire Protection Association's Standard on Disaster/Emergency Management and Business Continuity Programs.² It then proceeds through a capability analysis that evaluates personnel and equipment needs, and moves to the development of an operations plan. The most important aspect of preparedness is the creation of an all-hazards emergency operations plan (EOP). Training and exercises are clearly defined in the EOP. Training allows personnel to become familiar with their assigned responsibilities and to acquire the skills necessary to perform those tasks. Exercising allows for the testing of plans and the evaluation of skills acquired by response personnel. In addition, the EOP assists in the rapid response that is required for effective disaster relief. Response activities that are time sensitive are clearly defined so as to be performed most efficiently. The EOP includes a listing by position and organization of what kinds of tasks are to be performed. When more than one organization performs a task, one should be given primary responsibility, and the others should be given a supporting role. The EOP must be attentive to relevant local and state laws, federal regulations, and mutual aid agreements. Finally, the EOP provides an adaptable emergency management minimum set of procedures that can be relied on when responding to an unknown disaster. Hazard-specific appendices provide additional critical information relevant to a particular hazard (e.g., hazardous materials, hurricane).

Response is the third phase of emergency management and covers the period during and immediately after a disaster. The response phase of a disaster begins with a need for prompt critical actions to save lives and property. In addition, procedures must be initiated to stabilize the situation so that the locality can reorganize. Critical actions include emergency notification of emergency management personnel, warning and evacu-

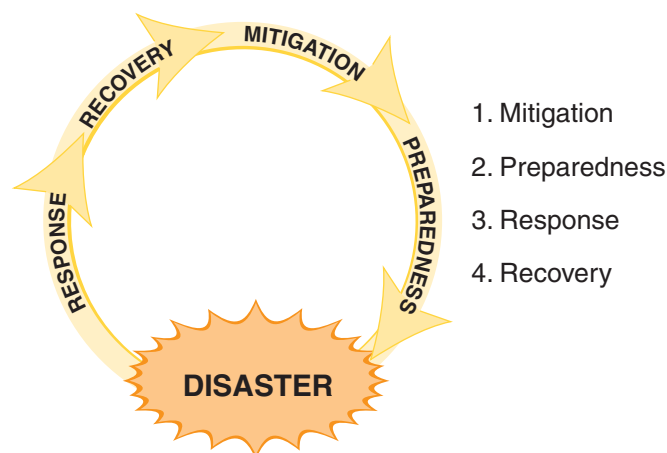

FIGURE 103-1 The disaster cycle.

ating or sheltering the population, keeping the population informed, rescuing individuals, providing medical treatment, maintaining the rule of law, assessing damage, addressing mitigation issues that arise from response activities, and requesting help from outside the jurisdiction.

Recovery is the fourth and final phase of the emergency management cycle. It continues until all systems return to normal operation. Short-term recovery begins to restore vital utilities (e.g., power, water, sanitation, communications), transportation infrastructure, the removal of debris, and the assessment of damage. Once some stability is achieved, the jurisdiction can begin recovery efforts for the long term, restoring economic activity and rebuilding community facilities and family housing with attention to long-term mitigation needs. Recovery should incorporate mitigation as demonstrated by a town relocating portions of its flood-prone community and transforming the area into a park.

MANAGEMENT OF HAZARDOUS MATERIALS INCIDENTS

Epidemiology

Exposure to hazardous materials is unfortunately as much a fact of modern life as are such things as vehicular crashes and infectious diseases. The term *hazardous material* is used here to mean any substance that can be harmful to humans, animals, or the environment when released in any uncontrolled manner. This chapter focuses on the management principles applicable to acute exposure to hazardous materials, including large-scale incidents. It does not address the issues surrounding chronic lower-level exposure or terrorism-related events. It must be clearly understood that planning and responding to a hazardous materials incident has many similarities to those needed in a terrorism-related event. An attack on the United States might focus on the release of a toxic chemical from a fixed facility or during transportation. Prehospital providers must think about the potential for terrorism in their response to all hazardous materials events. The potential for a secondary device (e.g., explosive) with potential harm to first responders is a consideration at all hazardous materials events. Terrorism and weapons of mass destruction are discussed in other chapters of this book.

One need not live near a chemical manufacturing plant, heavy industry, or a chemical dump site to be at risk for exposure to hazardous materials. A source of potential exposure is the nearest road, railroad track, or waterway. In 2002, the U.S. Department of Transportation reported 15,399 hazardous materials incidents, with 515 that were considered serious.³ During 2002, the Chemical Transportation Emergency Center (CHEMTREC) logged more than 121,809 telephone calls for hazardous materials emergency assistance.⁴ Most of these voluntary calls were informational: Medical emergencies represented only 18% of the calls.

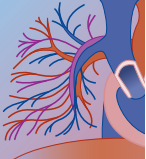

According to the Occupational Safety and Health Administration (OSHA), more than 575,000 chemicals

are used in the workplace. More than 1.5 billion tons of hazardous cargo is shipped nationwide each year by air, rail, sea, and land. These include flammable liquids, pressurized gases, explosives, poisons, and radioactive material. The U.S. Department of Transportation indicates that about 800,000 shipments of hazardous materials are transported each day.⁵ In regard to bulk rail shipments, the industry uses roughly 200,000 rail tank cars. A subset of these cars moves more than 275,000 shipments of chlorine, anhydrous ammonia, propane gas, and gasoline every year. The motor carrier industry dedicates more than 400,000 large trucks to the transportation of hazardous materials. A subset of this fleet participates in about 18 million shipments of gasoline and 125,000 shipments of explosives a year.

In 1990, the Agency for Toxic Substances and Disease Registry began an active, state-based Hazardous Substances Emergency Events Surveillance (HSEES) system to define the public health implications of the release of hazardous substances. The HSEES system collected data from 16 states in 2001.⁶ This most recent information indicates that 75% of the events occurred at fixed facilities, with equipment failure (38%) and operator error (30%) being the most common factors associated with the release. Of the transportation events, 85% occurred during ground transport (e.g., truck, van), and 10% involved transport by rail. Fewer events involved water, air, pipeline, or other transportation modes. Most events involved the release of one substance (91%), whereas two substances were released in 4%. Air releases were involved in 42% of cases, followed by spill releases (40%), fires (4%), and threatened releases and explosions (0.8%). Ammonia, sulfur dioxide, and carbon monoxide were the substances most commonly released. Human victims were involved in 8% of the releases. Of the events with victims, 62% involved only one victim, and 79% involved one or two victims. Multiple-casualty events were uncommon. Of the total victims, 89% were injured in fixed-facility events. Employees (51%) were the population group most often injured, followed by the general public (21%), students (8%), and responders (13%). The substances released most often were not the most likely to result in victims. As an example, chlorine was released in only 1.2% of the events, but 19% of the chlorine releases resulted in injury. The most commonly reported injuries in fixed-facility events were respiratory irritation (31%), headache (12%), eye irritation (11%), and gastrointestinal problems (10%). Transportation-related events were associated with a greater incidence of trauma (32%) than fixed facilities (2%) were. In total, 1% of all victims died.

Hazardous Materials Events of Greatest Magnitude

Hazardous materials incidents occur with great frequency, and keeping up with the details of releases from across the United States can be very challenging. Previous hazardous materials events must be studied so that history does not repeat itself and for the development of better prevention strategies. The U.S.

Chemical Safety Board is an excellent resource to facilitate the dissemination of objective information regarding larger-scale incidents. The U.S. Chemical Safety Board is an independent federal agency whose mission is to prevent industrial chemical accidents and save lives.⁷ This is accomplished by investigating chemical incidents and hazards, determining fundamental causes of a release, and issuing safety recommendations to government agencies, industry, labor unions, trade associations, and other organizations. This organization determines the causes of accidents, but does not issue fines or penalties. The investigative staff includes chemical and mechanical engineers, industrial safety experts, and other specialists drawn from the private and public sectors. The board can be accessed at the website www.chemsafety.gov.

Four world events involving the release of hazardous materials deserve brief overview. The events involving Bhopal, Chernobyl, Gaoqiao, and Neyshabur are discussed here. The release of sarin in Tokyo is discussed in Chapter 105A.

BHOPAL

The events in Bhopal, India, represent the largest modern hazardous materials incident outside of warfare and terrorism. On the night of December 3, 1984, a cloud of methyl isocyanate gas leaked from a storage tank at the Union Carbide plant in Bhopal, India. Methyl isocyanate is used in the manufacture of carbamate insecticides. As a liquid, it has a low boiling point and is heavier than air in its gaseous form. It has a strong odor and is irritating to the eyes, skin, and respiratory tract. It may be toxic both by inhalation and cutaneous exposure. At the time of the incident, no plans existed to alert the local population in the event of a disaster. Population-based methods for protection and evacuation did not exist. The plant was located in a densely populated area, with poorly constructed housing adjacent to the plant. Knowledge of the hazardous materials being used and the products manufactured was lacking among the employees, and there were no standard operating practices and few engineering controls. About 50,000 lb of methyl isocyanate in liquid and vapor form was released into the atmosphere when a valve on a storage tank opened for about 2 hours. Light winds prevented rapid dispersal of the heavier-than-air cloud. The accident happened at night, when most of the residents were asleep. Because of the rapid onset of symptoms and the large numbers of people affected, local hospitals were rapidly overwhelmed. Many patients were treated in the hospital garden. Local citizens helped each other in the initial rescue attempt. No local medical authority on methyl isocyanate was immediately available.

More than 200,000 people were exposed, and about 500 people in the surrounding area were killed before reaching medical treatment. The total death count was about 2500. One hospital alone treated 25,000 patients in the first 24 hours. Immediate respiratory problems consisted of severe coughing, dyspnea, pharyngitis, and pulmonary edema. Severe conjunctival irritation and corneal ulceration developed. Gastrointestinal symptoms

consisted of increased salivation, nausea, vomiting, abdominal pain, and defecation. Central nervous system symptoms were manifested by coma, seizures, dizziness, limb weakness, and tremors.⁸

Ninety-five percent of the dead and severely injured came from the neighborhood immediately adjacent to the plant. A crowded railway station situated 1 km from the plant had more than 100 dead: 200 people were unconscious, and 600 were lying about injured. Several studies of survivors were undertaken 3.5 months after the incident.⁹ Patients in these studies were categorized according to their distance from the plant on the night of the accident. Group 1 consisted of those 0.5 to 2 km from the plant, and group 2 was composed of those at least 8 km from the plant. Both groups were matched socioeconomically and demographically. All of the group 1 sample and 42% of group 2 had symptoms at the time of the incident. At the time of the study, 80% of group 1 and 28% of group 2 had continued respiratory complaints consisting of cough, with or without sputum production; breathlessness; and chest pain. Fifty-seven percent of group 1 had abnormal chest radiographs, 49% had documented restrictive defects, and 21% had obstructive defects. Smokers constituted 12%. It is unclear whether previous pulmonary disease was present or whether some patients had both restrictive and obstructive pulmonary disease.

In a group of children categorized in the same manner, most symptoms occurred in the immediate area of the plant, although the more remote group was not without symptoms. Ninety-five percent of children from group 1 had immediate cough, and 74% experienced breathlessness.¹⁰ Three months later, 84% noted persistent cough, and 48% suffered from continued breathlessness. Abnormal radiographs were found in 66% of group 1 children, compared with 8.1% of group 2 children. Pulmonary testing was performed on children older than 7 years. Obstructive defects were found in 28 of 33 children. Persistent abdominal pain and anorexia were found in the group 1 children only. Group 1 children experienced persistent conjunctivitis, and 10% demonstrated visual abnormalities. No persistent eye abnormalities were found in group 2. Persistent neurobehavioral symptoms consisted of poor memory and weakness. Comprehensive psychological testing was not performed. Some children who later developed obvious psychic disturbances had been classified as dead at the time of the accident and had been initially placed in morgues. Others had witnessed the deaths of parents or siblings.

A recent study found selective growth retardation in boys, but not girls, who were either exposed to the released gases as toddlers or born to exposed parents.¹¹ It is theorized that methyl isocyanate is quickly degraded into trimethylamine, which in mice has been reported to produce selective growth retardation of male progeny mice. This is associated with a decrease in the serum testosterone in the mice.

CHERNOBYL

Late in the evening of April 25, 1986, the fourth reactor at Chernobyl was shut down for routine maintenance

and testing. This electrical generating plant is located 130 km north of Kiev, near the current convergent borders of Ukraine, Belarus, and Russia. Inadequate safety precautions and operational errors during the testing resulted in a sudden increase in heat production, which ruptured part of the nuclear fuel. The water-cooled, graphite-moderated reactor did not have a concrete containment vessel. By 1:30 AM (April 26), hot fuel particles, reacting with water, had caused a steam explosion. Within seconds, this was followed by a second explosion. The explosions totally destroyed the Unit 4 reactor core and roof of the building. By 5:00 AM, although more than 100 local firefighters succeeded in extinguishing conventional fires, a graphite moderator fire began and was not extinguished until May 6. This fire was responsible for the dispersion of radionuclides into the atmosphere. Seven months later, the remains of the destroyed reactor and building were enclosed in a concrete sarcophagus designed to provide some containment of the damaged nuclear fuel and to reduce further releases of radioactivity until a more permanent containment facility could be designed and implemented. Thankfully, only 3% to 5% of the total amount of radiation was released. Fifty thousand people were evacuated from the nearby town of Pripjat after a delayed public announcement a day and a half after the release began. It is estimated that a total of 135,000 persons were evacuated and permanently rehoused outside of the 30-km exclusion zone; in addition, 500,000 mothers and children from the surrounding area were reportedly sent to resorts along the Black Sea, and another 300,000 were sent to other locations. It was estimated that 30 to 60 km² of topsoil and road surfaces would have to be removed to properly decontaminate the area.¹²⁻¹⁵

Firefighters and plant personnel suffered the highest radiation exposures and casualties. No members of the general public received sufficient radiation doses to induce acute radiation syndrome. Three deaths were immediately associated with the accident. Two hundred thirty-seven patients were admitted for acute radiation syndrome, of which 28 died. Bone marrow transplantation was performed in 13 patients, with death occurring in all but 2 of these patients.

Fifty tons of radioactive dust was dispersed over 140,000 square miles of mainly Belarus, Ukraine, and a part of Russia. Seventy percent of the radiation was deposited over Belarus. The doses to individuals outside of this area were small and varied depending on whether rainfall occurred during the passage of the radioactive cloud. The plume moved predominately northward and then over Western Europe. The initial international detection came from Sweden, when radiation alarms went off 2 days after the accident. The accident was announced that evening by the Soviet Union. The isotopes of greatest concern were iodine-131 (¹³¹I) and cesium-137 (¹³⁷Cs). The affected area was large because of the dispersion of small particles into the upper atmosphere and the duration of the release. Almost 5 million people were exposed to either internal or external radiation. The major routes of human exposure

to radiation were from the ingestion of cow's milk contaminated with ¹³¹I (resulting in internal exposure), contact with γ/β radiation from the radioactive cloud, and contact with ¹³⁷Cs deposited on the ground (resulting in external exposure). Children who consumed fresh cow's milk in May and June 1986 received the highest doses to the thyroid.

Estimates of cancer increases were initially said to be "no more than 1000" and have risen in the past 10 years since the accident. Most of the pilots who helped to entomb the reactor are dead or have leukemia. More and more of the cleanup workers have required treatment for radiation-induced diseases. Thyroid cancer has increased a 100-fold in Belarus. The World Health Organization (WHO) predicts that one third of all the children from the area around Gomel who were between 0 and 4 years of age at the time of the accident will develop thyroid cancer during their lifetime—a total of 50,000 children in this group alone. The negative social and psychological consequences of this event have been profound. There was no identified increase in congenital anomalies, adverse pregnancy outcomes, or other radiation-induced disease in either the contaminated area or in Western Europe. The WHO established the International Program on the Health Effects of Chernobyl Accident to further define the long-term significance of this accident.

GAOQIAO

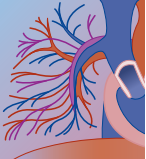

In December 2003, there occurred a release of natural gas and hydrogen sulfide at the Chuandongbei gas field in China. The gas field is run by the China National Petroleum Corporation. Although the exact cause of the release is unclear, it led to the evacuation of more than 41,000 people in a 25-km² area. The mountainous terrain and muddy roads made it difficult for villagers to flee and hindered rescue work. At least 233 people died, and more than 10,000 people were treated for hydrogen sulfide toxicity. Thousands of animals died as the gas devastated villages and poisoned farms.

NEYSHABUR

In February 2004, 48 rail cars derailed and caught fire outside of Neyshabur, Iran. This community is an ancient city of 170,000 people in a farming region 400 miles east of the capital, Tehran. Firefighters had nearly put out the blaze when an explosion occurred about 5 hours after the derailment. The cars contained sulfur, gasoline, fertilizer, and cotton. The explosion killed 320 people and injured 460 others. Nearly 200 of the dead were rescue workers who were fighting the fires when the blast occurred. The blast was so powerful that Iranian seismologists recorded a quake of magnitude 3.6 at the time of the explosion, and the blast shattered windows 6 miles away.

Hazardous Materials Preparedness

In planning for chemical, radiation, and biologic disasters, one must consider all the possibilities, from human error, to employee sabotage, to mentally ill workers, to

terrorism. A specific hazardous materials appendix to the EOP must be developed. This hazardous materials appendix must be updated regularly, simple to follow, and cost effective; must provide for resources that are immediately available; and should minimize manpower needs. This appendix should contain detailed instructions to follow, including emergency response operations; a roster of emergency assistance phone numbers; a description of each service's legal authority and responsibility during an emergency; a description of the structure and responsibility of the designated response organization; a section on resource laboratories for analysis of chemical and patient data; and a cleanup and disposal equipment resource section.

Hazardous materials planning begins with the Emergency Response Commission, established in each state under the Superfund Amendments and Reauthorization Act of 1986 (SARA). This commission, appointed by the governor of the state, must coordinate with the Local Emergency Planning Committees (LEPCs) in their development of plans for emergency response to hazardous materials emergencies. It is the responsibility of the LEPC to develop plans to define and coordinate contaminated areas, to decontamination and triage on scene, to optimize resource and information management, and for the transportation to definitive medical care. This preplanning begins with developing a clear understanding of the potential toxic chemicals stored, transported, and used within a community. A community's "right to know" is mandated by the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) amendments of 1986, otherwise known as SARA, Title III. Title III of SARA, the Emergency Planning and Community Right to Know Act, encourages state and local planning and provides planning groups with information concerning chemical releases and the potential chemical risks in their communities. A list of 402 extremely hazardous materials, published in the Federal Register (November 17, 1986), gave threshold planning quantities. If these materials are produced, used, or stored in quantities exceeding the thresholds, they become subject to the emergency planning requirements. Additionally, requirements were set for emergency notification whenever a release of hazardous material exceeded a reportable quantity.

In addition to community notification, workers are protected by the OSHA Hazard Communication Standard, which states that "hazards of all chemicals produced or imported by chemical manufacturers or importers [must be] evaluated, and information concerning their hazards [must be] transmitted to affected employers and employees within the manufacturing sector. This transmittal of information is to be accomplished by means of comprehensive hazard communication programs, which are to include container labeling and other forms of warning, material safety data sheets (MSDS), and employee training" (29 CFR 1910.1200). Workers must know the hazards of the chemicals with which they work and methods to protect themselves in the event of an accident or incident. There should also be some training in first aid and decontamination procedures at the plant.

Ideally, a plant's MSDS should be on file in the emergency department, and emergency physicians should be familiar with them. Additionally, patients should be transported from the plant to the department along with copies of the appropriate MSDS.

Surveying the major pipelines in one's area and knowing major road, rail, and water shipping routes in one's community are critical. Prevention strategies should include consideration of restricted transportation routes and times of access to these venues. Little regulation exists to limit the routes and times of day that may be used for hazardous materials transportation. The District of Columbia and New York City have enacted bills to require shippers of certain hazardous materials to obtain a permit and conform to routes, times, and other safety conditions when traveling into or out of these cities. This was in response to recent terrorism concerns.

Hazardous materials training of first responders is paramount.¹⁶ Rescuers must be trained in the use of protective equipment and in decontamination procedures to minimize contamination of citizens, medical personnel, vehicles, medical facilities, and the environment. Persons using a self-contained breathing apparatus (SCBA) must be properly fit tested, be trained in their use, and understand the limitations of the equipment. Specifically, the time limitations of the supply tank and the reserve tank must be understood so that egress from the contaminated area can be accomplished before loss of supply air. Local hazardous materials response units with special training and equipment exist in many communities. These units are responsible for evaluation and management of scene hazards and decontamination before transport. With multiple casualties, the real possibility exists that many patients will present to local hospitals while still contaminated. All medical facilities should have plans to identify contaminated patients, protect personnel and the hospital environment, and provide for decontamination with protective equipment.^{17,18} Sheltered off-site locations for treatment should be available if a hospital is overwhelmed or must be evacuated. Warning mechanisms and a plan for early evacuation will minimize injuries to hospital personnel.

Planning for the treatment of persons exposed to chemicals involves all levels of the health care team, from firefighters to hazardous materials teams to emergency medical services personnel to hospital providers. It is important to establish a unified command approach such that the prehospital plan seamlessly interfaces with that of the hospital. It is essential to ensure that exposure is limited to the smallest number of people possible. Guidelines must be established for triage, decontamination, and medical management.¹⁹ Patients may require specialized care and early transportation to hospitals providing medical specialists in burn and trauma care, hyperbaric oxygen, and medical toxicology. Important resources may include an emergency physician, a medical toxicologist, a trauma surgeon, a pharmacologist, an industrial hygienist, an occupational medicine specialist, testing laboratories, and chemists. Plans must also include members from the mental health community,

media relations, and security. Large amounts of antidotes specific to the potential exposures must be available at the scene and within the hospital.

Plans should include sources of specialized equipment that may be needed for a given hazard. Planning must include the provision of equipment for air sampling, decontamination, handling of spills (e.g., absorbent materials, diking equipment), and protective equipment for rescuers. This equipment must be strategically located in the community, and its location must be known to all responders. An adequate supply of air tanks and SCBAs and equipment to refill tanks with adequate-quality breathing air must be available.

Planning must include concerns for the environment. Environmental liability resulting from critical life-saving actions has been a concern for first responders. Section 107 of CERCLA addresses this issue. Section 107(d)(1), often known as the “Good Samaritan” provision, states: “No person shall be liable under this subchapter for costs or damages as a result of actions taken or omitted in the course of rendering care, assistance, or advice in accordance with the National Contingency Plan (NCP) or at the direction of an on-scene coordinator appointed under such plan, with respect to an incident creating a danger to public health or welfare or the environment as a result of any releases of a hazardous substance or the threat thereof.” This does not preclude liability for costs or damages as a result of negligence. In addition, section 107(d)(2) provides that state and local governments are not liable under CERCLA “as a result of actions taken in response to an emergency created by the release or threatened release of a hazardous substance generated by or from a facility owned by another person.” In response to a hazardous materials event, prehospital providers should undertake any necessary emergency actions to save lives and protect the public and themselves. Once any imminent threats to human health are addressed, first responders should immediately take all reasonable efforts to contain the contamination and avoid or mitigate environmental consequences. The Environmental Protection Agency (EPA) will not pursue enforcement actions against state and local responders for the environmental consequences of necessary and appropriate emergency response actions. The EPA cannot prevent a private person from filing suit under CERCLA. However, first responders can use CERCLA’s Good Samaritan provision as a defense to such an action.

Hazardous Materials Response

In general terms, the sequence of events in a disaster is as follows: An accident occurs. Knowledge of it is transmitted to appropriate agencies; these agencies respond and gather more data. They may activate additional resources. Fire and the hazardous materials team assume charge and direct law enforcement to control and secure the scene. The scope of the problem is defined. The necessary plans for the solution of the problem are activated, and follow-up and evaluation are accomplished.

First and foremost is notification of appropriate agencies, that is, police, fire department, hazardous

materials team, emergency medical system, local disaster coordinator, county and state officials, and federal agencies. It is beyond the scope of this chapter to indicate who must be notified in any given incident. This varies with the incident and with local and state regulations. Various local and state agencies may have jurisdiction over a particular kind of hazard. These interests may overlap, depending on the nature of the chemical, the location of a spill, and the various laws in a state. The fire chief and the hazardous materials team assume charge and usually have the police set up perimeters and evacuate the surrounding area, if necessary. If the hazardous materials release involves terrorism, the Federal Bureau of Investigation assumes charge of the scene. Crowd control and control of access to the site are also the responsibility of the police agency. A fire agency has responsibility to respond to the chemical or fire hazard and to initiate mitigation, extrication, decontamination, and first aid to casualties. An Emergency Medical Service (EMS) agency is responsible for medical decisions and treatment. Other agencies may have jurisdiction and authority or serve in an advisory capacity, such as the Agency for Toxic Substances and Disease Registry (ATSDR), the Centers for Disease Control and Prevention (CDC), the EPA, OSHA, FEMA, and the state health department. Local municipal authorities must know how to gain access to other sources of help, including state and federal agencies. At all times, it is critical for all responders to know who is in control. The agency that assumes control may change as more information concerning the exact nature of the hazard becomes available or during different phases of the entire operation, including cleanup.

Identification of the Release

Identification of the hazardous material should be attempted before approach to the spill. Community preplanning should identify the specific sites that contain hazardous materials. One can read the placarding on the truck or train car from afar (Fig. 103-2). Be aware that placarding may be wrong 40% of the time, and manifest papers may be wrong 35% of the time. Binoculars are an invaluable aid. The bill of lading (cargo manifest) is located in the cab of a truck, but it may not be accessible without full protective gear. The diamond-shaped placard on the side of a tank or rail car with the Department of Transportation (DOT) number on it will identify the specific material, and the DOT Emergency Response Guidebook will provide the hazard class and general emergency information as well as evacuation distances.²⁰ Some states also have numbered placards with emergency telephone numbers to call. These telephone numbers are a good first resource. Follow-up continues by contacting the shipper and confirming materials that are in the container or vehicle. The various symbols within the diamond-shaped placard should identify the general class of material being shipped. The absence of a placard should not lead one to believe that danger is absent. An empty tank car is considered to be one that

FIGURE 103-2 Table of placards and applicable response guide pages. (From Office of Hazardous Materials Regulation: Emergency Response Guidebook. Washington, DC, Materials Transportation Bureau, U.S. Department of Transportation, 1980.)

Class Number
A number 2 at the bottom of a placard without any name means that the material in the tank is a gas. Specific chemical group is at the center.

contains less than 300 gallons of material. One should treat a chemical spill and injuries from an un placarded vehicle with the same caution. Identification of the shipper may be possible by reading the markings on the truck or train car from a distance. The shipper may be contacted to assist in chemical identification and provision of resources. On a train, the waybill can be found with the conductor. Call the nearest company trainmaster, relay the number of the car and the location, and get information and handling information from the tracking computer. The waybill contains a standard transportation code (STC) number that identifies the specific chemical. Chemicals whose numbers begin with 49 are classified as hazardous. The waybill contains specific chemical names and handling information. With train cars numbered from engine to caboose, one can thus learn what chemical the car contains.

Packaging configuration can provide valuable information for hazard identification. There are three categories of packaging: stationary bulk storage containers at fixed facilities that come in a variety of sizes and shapes; bulk transport vehicles for truck and rail transportation; and labeled fiberboard boxes, drums, or cylinders for smaller quantities of hazardous materials. The shape and configuration of the container can often be a useful clue to the presence of hazardous materials.

Rapid emergency information can be obtained by calling CHEMTREC at 800-424-9300 in an emergency situation and giving the name of the compound. In an emergency, CHEMTREC will connect emergency personnel with the manufacturer's and/or shipper's personnel, who can advise on emergency handling. CHEMTREC can then advise what sort of rescue gear may be needed and what decontamination, if any, is needed at the site. Injuries that involve human exposures and injuries will be referred to an appropriate poison control center. The Agency for Toxic Substances and Disease Registry can be accessed at any time by calling 404-498-0120. ATSDR can provide additional valuable information and also has physicians available to provide medical treatment recommendations.

EXPOSURE ASSESSMENT

The assessment of exposure risks in the hazardous materials scene environment requires equipment and methods from the field of industrial hygiene. The industrial hygienist can perform qualitative and quantitative studies both on site and in the laboratory. Members of the hazardous materials team perform exposure assessments in the setting of an acute release of a toxic substance. Before discussing actual monitoring methods, however, it would be useful to define some terms and review some fundamental industrial hygiene concepts.

First, any chemical can be handled safely if proper precautions are taken. In an uncontrolled chemical release, hazardous environments can be approached with proper personal protective equipment. In most major incidents and in some minor incidents, this

includes full-body suits that are impermeable to the hazardous material, and a positive-pressure demand style of SCBA. Personnel wearing an SCBA must be fully trained in its use, limitations, and what to do if the equipment fails. These persons must be medically cleared for SCBA use before acceptance as part of an emergency response team. The SCBA must have been properly inspected, maintained, and cleaned at regular intervals. A full respirator program as required by OSHA (29 CFR 1910.134) must be in place. This includes periodic medical monitoring.

Second, any chemical, no matter how nontoxic, can be hazardous if handled inappropriately. For example, a release of methane or nitrogen in an enclosed space can cause asphyxiation. Numerous reports have been published of attempted rescues in such "nontoxic" environments, in which the initial victim and the rescuers all died of simple asphyxiation.

The identity of the specific agent is only one of a number of factors affecting the actual hazard. Other factors include the air concentration, potential for skin contact, duration of exposure, temperature of the material, and individual susceptibility of the exposed persons.

Inhalation of air contaminants is the most frequent route of exposure for hazardous materials. Air contaminants may be found in a variety of forms, such as gases, vapors (the gaseous form of a substance that is primarily liquid or solid at room temperature), dusts (solid particles entrained in air), fumes (tiny solid particles often formed when a metal is heated, as in welding), mists (liquid particles entrained in air), and smoke (carbon or soot particles from incomplete combustion). Fumes, dusts, and smokes are measured in mass units of contaminant per volume unit of air (e.g., milligrams per cubic meter or parts per million). These two units can be easily interconverted if molecular weight, temperature, and altitude are known. Because fumes are minute solid particles, respirators designed specifically for protection against fumes will have no efficacy against vapors or gases, and vice versa.

Once an air concentration is determined, several criteria exist for assessing the risk for exposure. The level that is immediately dangerous to life and health (IDLH) "represents a maximum concentration from which, in the event of respirator failure, one could escape within 30 minutes without experiencing any escape-impairing or irreversible health effects." The IDLH level is used to determine the unquestionable need for a reliable positive-pressure demand SCBA. Standby personnel with full protective gear and a lifeline should be available when the IDLH level is exceeded. Specific IDLH values can be found in the National Institute for Occupational Safety and Health (NIOSH) *Pocket Guide to Chemical Hazards*.²¹

The most widely used criteria for assessing exposure levels are the threshold limit values (TLVs) for hundreds of common industrial chemicals, which are updated and published annually by the American Conference of Governmental Industrial Hygienists.²² They "represent conditions under which it is believed that nearly all

workers may be repeatedly exposed day after day without adverse effect.” Most TLVs are established for 8-hour time-weighted average exposures (TWAs). In general, these values protect against the effects of a lifetime of chronic exposure. However, short-term exposure limits and ceiling limits for some substances are also included in the TLV list.

TLVs are designed to protect a population of healthy workers and are not meant to be applied to a general community population that may include infants, elderly people, and infirm people. Thus, care should be exercised when clinical interpretations based on TLVs are made at a hazardous materials scene. In addition to TLVs, a set of legally enforceable workplace standards, known as permissible exposure limits (PELs), has been established.

A common fallacy is the use of odor as a measure of exposure. Information about odor may sometimes be helpful in the qualitative identification of agents or as a crude guide to the exposure level. Odor thresholds for a wide variety of materials have been published. However, wide variations between reference sources and considerable individual variation in the ability to perceive specific odors may occur. For example, up to 40% of the population cannot detect the almond-like odor of cyanide. Some materials have excellent warning properties. For example, if the odor or irritation of ammonia is absent, one can be sure that there will be no toxic sequelae due to exposure to this agent. However, some materials, such as carbon monoxide, are odorless at lethal levels. Other agents, such as hydrogen sulfide, have a characteristic odor initially but induce olfactory fatigue. As a result, lethal exposures may result as exposed individuals perceive levels to be diminishing. Thus, quantitative assessments based on odor thresholds are quite unreliable and possibly dangerous.

Air concentrations can be measured at specific locations, and computer models can sometimes be used to predict worst-case ambient concentrations at downwind locations. Environmental monitoring can be performed with direct reading instruments providing real-time measurements of levels, or it can be performed by taking air samples that can be analyzed subsequently. Direct reading instruments include photoionization detectors, portable gas chromatographs, portable infrared spectrophotometers, portable carbon monoxide detectors, flammable gas detectors, and oxygen detectors. A simple direct reading method for instantaneous levels is the colorimetric detector tube.

In addition to monitoring the environment, it is important to provide medical surveillance for exposed victims and rescuers, both to assess potential health effects and to provide information about the exposure. Excellent documentation is essential because many of these incidents result in litigation. It is important to document subjective complaints and objective findings and assessments thoroughly and carefully. One should not document that symptoms are all due to a “toxic exposure” unless this is clearly the case. Describe actual clinical findings as they are manifest. The physician’s initial charting may be a deciding factor in determining

whether someone gets their deserved compensation. It may also determine whether abuses of the system occur, which cost public and private organizations large sums of money.

DIAGNOSTIC STUDIES

The diagnostic studies for each patient will depend on the clinical presentation and the specific agents to which they have been exposed. Please refer to specific chapters in this textbook for the discussion of specific toxins.

FIELD DECONTAMINATION AND TRIAGE

In the event that the chemical is unknown, the safest way to rescue any victim is for rescuers to enter the area in fully encapsulated suits (level A) with positive-pressure SCBA. The exact type of level A suit is determined by the nature of the chemical involved. Firefighters are trained in use of this gear, whereas many EMS rescue teams are not. Under medical guidance, the firefighters begin decontamination and rescue of casualties and begin first aid. The fire department is the most qualified to assess the potential for fires and explosions and to advise medical personnel of such.

The smallest number of rescuers possible should enter the contaminated area. At least two should go in together, employing a buddy system, to ensure each other’s safety. A backup person with a similar level of protective gear should remain at the boundary to assist the rescuers in the event of an accident. Hyperthermia and dehydration can occur quickly in the fully encapsulated level A suits. Adequate hydration and close attention to rescuer vital signs are important.

Standard principles of triage apply in a chemical disaster. The sequence for field decontamination is illustrated by the following example: A truck transporting a concentrated liquid chemical turns over on a highway, and the tank begins to leak. A large pool of chemical is rapidly filling a low section of roadway, and a hazy cloud begins to form over the pool. The driver and companion, who are both injured, begin to move away under their own power. They begin to cough and choke, and then they pass out. Several bystanders enter to help and are overcome and lose consciousness. In the meantime, all the victims have chemical on their clothing. Without going into specific details of particular chemicals, how might rescue be accomplished? The first responders must attempt to identify the chemical from the placard on the truck. Especially note the logo **W**, which means USE NO WATER. The chemical may ignite, explode, or produce toxic fumes with water. The responders should notify central dispatching for fire department, police, and EMS backup and indicate that specialized resources or expertise may be required for a hazardous materials incident. If the placard can be read, the dispatcher can call CHEMTREC for specific handling information. Police, fire department, or EMS personnel should have access to the DOT *Emergency*

Response Guide: Emergency Handling of Hazardous Materials in Surface Transportation. Access to other guides, Poisindex, or a poison control center for further information should be available, if possible. A triage or medical station should be set up upwind from the site at a “safe” distance. Distances are listed in the DOT *Emergency Response Guidebook*. An area designated as contaminated or hot should be defined (Fig. 103-3). An intermediate or containment area should be established. Rescuers can continue decontamination and emergency treatment in this area.

Cutaneous decontamination is not required for all patients exposed to a hazardous material. Exposure to an inhaled toxicant (e.g., carbon monoxide or arsine gas) poses little risk for skin injury, mucous membrane injury, or secondary contamination such that decontamination

is not required. Many gases and vapors (e.g., isocyanates, chlorine) can cause skin and mucous membrane injury and necessitate formal decontamination. Any liquid or solid material must be removed promptly. If uncertainty exists, then prompt decontamination is mandatory.

The nature of the hazard and the necessary protective equipment must be determined before first responders enter an area of chemical spill (e.g., equipment for extrication and diking, decontamination showers, oxygen, protective gear, and transportation vehicles). Rescuers should enter the contaminated area with full protective gear unless the hazard assessment indicates otherwise. If the details of the release are uncertain, level A protective gear is essential. Level A suites are composed of various materials, and proper suit selection is important.

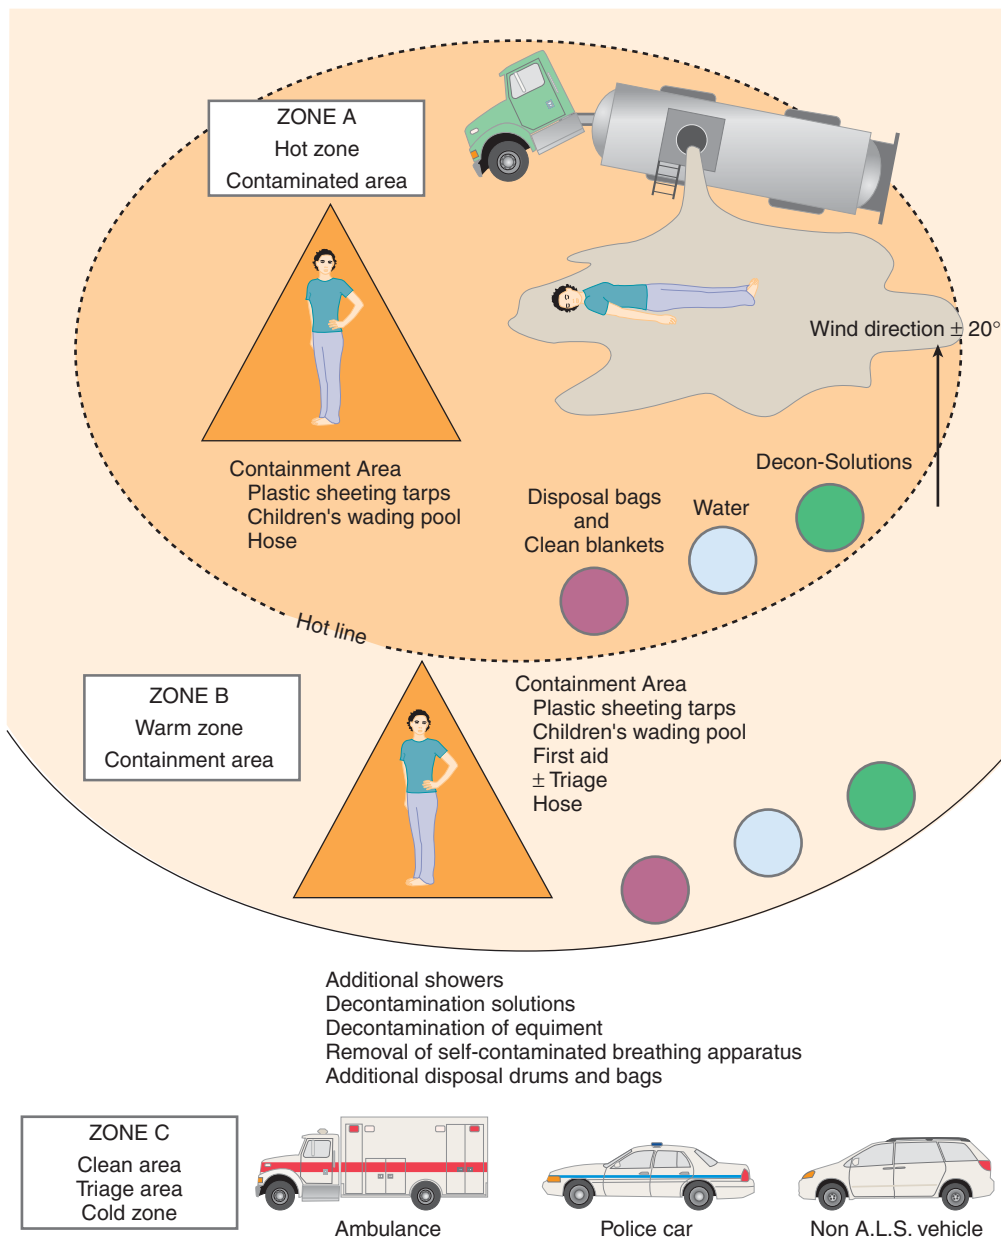

FIGURE 103-3 Sequence for field decontamination.

Only a minimum of first aid, such as attention to the cervical spine and exsanguinating hemorrhage, should be attempted in a highly toxic environment. Do not intubate or establish intravenous access in a highly toxic environment. Move victims from the immediate area of the spill. Remove all clothing. In general, wash the entire body, including the hair, quickly with water. Exceptions to this rule include contaminants that are elemental metals, such as sodium, which react violently with water. All the wash water should be contained (if possible). This can be done in a number of ways. Children's plastic wading pools or plastic sheeting may be used with an earthen dam or brick border to prevent used wash water from entering ground water. Three fire ladders may be laid sideways in a triangle and tarpaulins placed over them to form a pool. All waste water, hoses, tarpaulins, pools, and so on are left inside the "hot zone" for the environmental cleanup team (see Fig. 103-3). In the event of mass decontamination, the effluent water does not need to be contained and can be allowed to flow into the sewer or other location.

The victims may then move into the warm zone for further decontamination. Rescuers then discard outer layers of gloves, boot covers, and suits and place these in disposal containers. SCBAs may need to be left on and are the last piece of equipment removed. In the containment area, more thorough washing should take place. This may be done in a similar manner by setting up a hose or some type of shower. If possible, all waste water must be contained so as not to spread contamination.

More thorough attention to injuries and advanced airway management can be given in this warm zone. With very toxic materials, rescuers still will be hampered in their efforts by protective suits and SCBA.

The victims are wrapped again in clean blankets as they move from zone B (containment area) to zone C (cold zone). Rescuers discard additional protective clothing, and the SCBA is removed last, on entering the cold zone. All contaminated equipment and clothing are placed in bags and drums for later decontamination or disposal. Here, more extensive triage can take place, and intravenous lines and other advanced life support treatment can take place. Note that all movement is upwind from the spill.

Because one cannot be absolutely sure that decontamination is complete in the field, one should use a non-advanced life support vehicle if possible. Decontamination of an advanced life support vehicle is time consuming and costly, and availability is extremely limited. To have one out of service for decontamination imposes a hardship on the community.

The selection of receiving hospitals must be based on the number of victims and the hospital's ability to manage concomitant trauma, burns, contamination, and systemic toxicity. All equipment and gear in vehicles and in the emergency department should be protected from any contamination by layers of plastic and blankets, if possible.

Decisions about evacuation are based on the identification of the chemical, information from the transporter or manufacturer, chemical characteristics,

explosive characteristics, danger of fire, means of safe evacuation, and weather conditions.

REGIONAL ASSESSMENT OF EXPOSURE

A major hazardous spill may raise fears in the general population of possible long-term toxic effects. Patients and workers immediately exposed to the chemical hazard, as well as firefighters, EMS personnel, and police, may require ongoing medical surveillance. The long-term environmental impact also must be assessed. If a survey of the immediate area and patient population shows no significant hazard, then the public may be reassured. In the event a persistent hazard is determined to exist, local and national authorities may need to expand testing in concentric circles from the exposure site.

The health care providers must be aware of the mass psychogenic component that is commonly present in perceived environmental exposures. Whether or not patients are suffering toxic effects, it is likely that they also will experience symptoms and signs of catecholamine release. Some individuals may have nonspecific symptoms, such as headaches, nausea, vomiting, hyperventilation, chest pain, and paresthesias.²³

HOSPITAL MANAGEMENT

Decontamination is *always* best performed before hospital arrival. A patient is never too unstable to have clothing removed and a brief decontamination performed in the field. Secondary decontamination procedures should be considered at the hospital after field decontamination. Initial decontamination will be required at the hospital for those patients not evaluated at the scene. The Tokyo sarin gas experience indicates that at least 80% of hospital patients will independently appear at a healthcare facility, without transport by first responders.²⁴

Decontamination may occur inside the hospital in specially designed facilities equipped with a separate ventilation system that will provide adequate air flow. Air return from this room must never recirculate within the hospital and must be directly vented outside. Some specialized sites have floor drains leading to holding tanks that are easily accessed by hazardous waste contractors for toxicant removal. These holding tanks are expensive and should not preclude a hospital from participating in decontamination.

An expenditure of large amounts of money is not necessary for the safe, efficient management of patients. Most hospitals decontaminate patients outside the emergency department. Portable curtains provide privacy, and warm water can be delivered outside in all weather. Portable decontamination stretchers allow for synchronous decontamination and resuscitation. Portable wading pools are an inexpensive means of containment of irrigation fluid for ambulatory patients. If a large-scale decontamination effort is needed, the effluent can be allowed to flow into the sewer.

Contaminated patients must always be decontaminated before entry into the main emergency department. All hospital protocols must focus on efficient rapid patient processing. Hospitals must not rely on fire departments for decontamination because they will likely be deployed to the site of the release.

Cutaneous surface swipes before and after dermal cleansing can provide valuable information on the extent of contamination and efficacy of removal. Portable radiation detectors guide the duration and intensity of decontamination. Assessing the adequacy of chemical decontamination is more difficult in that the laboratory analysis takes more time. The physician will often not know “how clean is clean?” and will be forced to terminate decontamination based on less objective criteria.

Protection of hospital personnel is of primary importance.²⁵ Most health care facilities are poorly prepared to handle contaminated casualties. The medical team must always be equipped with a level of protection consistent with the contamination of the victim. Patient care must never be initiated before the donning of appropriated protection. There is a great deal of controversy regarding what level of personal protective equipment is appropriate for hospital personnel. Recent consensus opinions for health care facility-based personnel recommend level C personal protective equipment with OSHA operations-level training curricula modified to the health care environment.^{26,27} Level C includes a nonencapsulating chemical-resistant suit and an air-purifying respirator. Hospitals may choose a powered air-purifying respirator (more expensive) because the work of breathing is much less with these devices, and fit testing is not required. An SCBA or air-supplied respirator is not required if the decontamination occurs outside of the hospital. Chemically resistant clothing and gloves are vital for the safe management of patients.

Water irrigation, mild soap, and gentle washing are the initial approach for all toxicants except elemental metals (e.g., sodium, lithium). These metals explode on contact with water and should be removed by other methods before the application of water. Occasionally, detergents are required to remove viscous materials. The irrigation of contaminated wounds should take priority to lessen system absorption of toxicants. Care must be taken not to allow irrigation runoff to contaminate clean skin.

A small number of dermal toxicants require special attention. Phenol is best removed with 200- to 400-molecular weight polyethylene glycol or isopropanol. Small amounts of water could increase dermal absorption of phenol. “Deluge” quantities of water are required when polyethylene glycol is not available. Limited data indicate that hexavalent chromium may be treated with topical ascorbic acid to allow reduction to the trivalent (less toxic) state. White phosphorus fumes or flames spontaneously on contact with air. Before débridement, the phosphorus should be covered with a moistened gauze. A Wood’s lamp allows visualization of phosphorus in tissues. Copper sulfate irrigation of wounds for phosphorus visualization can cause copper

TABLE 103-1 Antidotes for Common Hazardous Materials Toxicants

ANTIDOTE	TOXIN
Lilly cyanide antidote kit	Cyanide
Methylene blue	Methemoglobin
Atropine or pralidoxime	Organophosphates, carbamates, nerve agents
Calcium	Hydrofluoric acid
Oxygen or hyperbaric oxygen	Carbon monoxide, cyanide, hydrogen sulfide
Prussian blue (Radiogardase)	Cesium, thallium
Chelators (DTPA, BAL, DMSA)	Heavy metals

toxicity and provides little benefit over a Wood’s lamp. Calcium gluconate is the antidote in hydrofluoric acid (HF) exposures (Table 103-1). HF is a weak acid but causes systemic and local toxicity through its strong affinity for calcium and magnesium ions. Severe exposure to concentrated HF is associated with rapid hemodynamic compromise. Intravenous calcium must be administered early in these cases to control arrhythmias and shock. Dilute HF (<20%) typically causes delayed pain and tissue injury presenting as late as 24 hours after exposure. Topical application of a 2.5% calcium gluconate gel and parenteral narcotics constitute the initial management of dermal injury. If this fails to relieve pain, then calcium gluconate can be infiltrated into the wounds at a dose of 0.5 mL/cm². Hand wounds with persistent pain that do not respond to topical therapy are best managed with an intra-arterial infusion of calcium gluconate (10 mL of a 10% solution mixed with 40 mL of saline infused over 4 hours) until pain is resolved. Patients should not be discharged home with persistent pain. Table 103-1 provides specific commonly used antidotes in hazardous materials events that should be available to both prehospital and hospital health care providers.

RONALD E. GOANS, PHD, MD, MPH

At a Glance...

- Radiation incidents have historically been classified into five major categories:
 1. High-level external radiation exposure with late systemic symptoms, often neutropenia and sepsis 2 to 3 weeks postexposure.
 2. Low-level external exposure, with a normal physical examination.
 3. Local radiation injury to an extremity or other localized part of the body, generally with minimal systemic symptoms.
 4. Inhalation or ingestion of radioactive material accompanied by a normal physical examination.
 5. Hospital-related incidents, generally related to misadministration in brachytherapy, external dose, or in nuclear medicine studies.
- Victims of radiation-related terrorism require prompt treatment of medical and surgical conditions and initial evaluation for radiation exposure. Since radiation-related illness requires days to weeks to become clinically evident, patients should be triaged using traditional medical and trauma criteria, medically stabilized initially, and then assessed for radiation injury.
- An early estimation of the magnitude of the incident by the physician is crucial.
- Cobalt 60, cesium 137, iridium 192, and strontium 90 are major isotopes often involved in incidents of severe external exposure. High-level external exposure via a lost source in the public domain may cause patient death through neutropenic sepsis or multiorgan failure.
- Internal exposure rarely causes patient death, but significant regulatory issues and delayed radiation-related medical effects may ensue.
- External contamination is generally more of a nuisance issue and can be dealt with readily by removal of clothing and prompt decontamination, initially with soap and water.
- The lethal dose to 50% of an exposed population in 30 days (LD 50/30) in humans with only supportive treatment is approximately 3.5 to 4.0 Gy and may be extended to 6 to 8 Gy with modern critical care medicine. Rarely does a patient survive long-term with an acute whole body dose of 10 Gy or more, even with the most advanced medical care.

INTRODUCTION AND BACKGROUND

In the medical management of injury in a radiation terrorism event, it is important to remember that the “golden hour” is widely recognized by surgeons to be an hour of opportunity in which the lives of severely injured people may be saved if they are rapidly triaged by first response personnel and treated by trauma specialists. The presence of radiation issues must not interfere with rapid triage and removal of trauma victims from the field of injury.

Several excellent textbooks are available¹⁻⁹ in radiation medicine and in health physics that expand further on the topics in this chapter. Radiation accident medicine is often confusing to physicians and other medical personnel, mainly because the subject is not part of the traditional medical school curriculum. Common radiation terminology and radiation units are summarized in Appendix A. In addition, various examples are provided of the use of radioactive substances in medicine and in industry. Appendix B describes two additional resource organizations useful to assist in radiation accident analysis (Radiation Emergency Assistance Center/Training Site [REAC/TS] in Oak Ridge, Tennessee, and the Armed Forces Radiobiology Research Institute [AFRRI], located in Bethesda, Maryland). Several problems and medical case histories are also included in this chapter to illustrate various techniques useful in the practice of radiation medicine.

Many patients involved in radiation accidents may also be externally contaminated with radioactive particles. Removing contaminated clothing promptly will eliminate 80% to 90% of external contamination, and soap and water should be the first approach to removing remaining external contamination, particularly in exposed areas such as the face and hair. Irrigation of contaminated wounds is also readily performed using a saline jet under mild pressure. Ambient radiation levels from contaminated wounds are rarely medically significant, and hospital personnel attending the patient(s) should be reassured that their radiation dose will be minimal.

SOURCES OF RADIATION EXPOSURE

The most serious exposure scenario is high-level, high-dose rate, acute external whole body or partial body gamma irradiation. The patient may manifest significant systemic signs and symptoms associated with the acute radiation syndrome (ARS). Such an exposure could manifest from terrorist use of an improvised nuclear device or low-yield weapon (IND) or from close proximity to a radioactive dispersal device or high-level industrial source (Cs 137, Co 60, Ir 192, or Sr 90). Medical management of patients with moderate to severe radiation exposure (effective whole body dose > 3 Gy) should emphasize treatment of radiation-induced neutropenia and the prevention of infection. Initial care is directed toward reduction of pathogen acquisition through reverse isolation, low-microbial-content food and water, selective use of gastrointestinal (GI) decontamination, and consideration of antibiotic prophylaxis for opportunistic bacterial, viral, or fungal infections. Established or suspected infection in the neutropenic

patient is managed in the same manner as for chemotherapy patients. Antibiotic prophylaxis should be considered in the severely neutropenic patient and in afebrile patients at the highest risk for infection.

Second, high-level local radiation injury occasionally arises from touching lost or covertly placed industrial radiation sources. These incidents often involve significant radiation burns to either the hands or other localized anatomic regions. However, the appearance of these lesions is usually delayed in time as noted below. Acute local irradiation events may occur separately or co-exist with the ARS. Deterministic thresholds exist as follows for certain ranges of localized skin radiation dose:

1. 3 Gy threshold for epilation, beginning 14 to 21 days postaccident.
2. 6 Gy for erythema, which may be observed transiently postaccident, and appears in permanent form 14 to 21 days thereafter. The pathophysiology for erythema involves arteriolar constriction with capillary dilation and local edema.
3. 10 to 15 Gy for dry desquamation of the skin secondary to irradiation of the germinal layer. Dry desquamation results from response of the germinal epidermal layer to radiation. There is diminished mitotic activity in cells of the basal and parabasal layers with thinning of the epidermis and desquamation of large macroscopic flakes of skin.
4. 20 to 50 Gy for wet desquamation (partial thickness injury) at least 2 to 3 weeks postexposure, depending on dose. In moist desquamation, microscopically, one finds intracellular edema, coalescence of vesicles forming macroscopic bulla, and a wet dermal surface, coated by fibrin.
5. For doses of more than 50 Gy to a localized area, overt radionecrosis and ulceration occurs secondary to endothelial cell damage and fibronoid necrosis of the arterioles and venules in the affected area. A cutaneous syndrome, arising from high-level whole body irradiation along with local injury, has also been described by various researchers.^{10,11}

Third, accidents occur in either the industrial or government sector primarily involving inhalation or ingestion of radioactive material without overt systemic signs and symptoms. These accidents often involve medical misadministration of correctly prescribed radioisotopes or accidents involving nuclear medicine therapy or brachytherapy.

ACUTE RADIATION EXPOSURE

The correct diagnosis of acute radiation injury may be made approximately 85% of the time by a traditional, well-designed medical history. However, physicians often do not include radiation injury in the differential diagnosis of the usual radiation prodromal symptoms of nausea, vomiting, and diarrhea. Analysis of the recent

history of radiation medicine shows many cases of delayed diagnosis.

In a review of four recent major radiation accidents³ involving lost high-level gamma sources (Bangkok, Thailand [February, 2000]; Mit Halfa, Egypt [May, 2000]; Tammiku, Estonia [October, 1994]; Goiania, Brazil [September, 1987]¹²), the average time from beginning of the accident until definitive diagnosis averaged approximately 22 days. However, in the recent nuclear criticality accident in Tokaimura, Japan¹³ (September, 1999), awareness of the accident was essentially immediate because it occurred in an industrial environment with many witnesses.

Therefore, radiation accidents are recognized in a dichotomous fashion: either soon postaccident (industrial or medical setting), or 2 to 4 weeks or more postaccident when the patient becomes ill due to neutropenia and sepsis (misplaced sources found or stolen by a member of the public). The clinical presentation of the externally irradiated patient will be much different in these two scenarios. In addition, the patient presenting primarily with internal contamination will have few signs and symptoms and will generally have a normal physical examination.

In a terrorism event, radiation dose may be estimated early using rapid-sort, automated biodosimetry, employing such parameters such as the clinical history, the time to emesis (TE), and lymphocyte depletion kinetics.¹⁴⁻²⁰ For TE of less than 2 hours, the effective whole body dose is at least 3 Gy. If TE is less than 1 hour, the whole body dose most probably exceeds 4 Gy. Lymphocyte depletion follows dose-dependent, first-order kinetics after high-level gamma and criticality incidents. Patient radiation dose can be estimated very effectively from the medical history, serial lymphocyte counts, and TE, and subsequently confirmed with chromosome-aberration bioassay, the current U.S. and world gold standard. These data may be effectively analyzed using a computer tool developed at the Armed Forces Radiobiology Research Institute (Biodosimetry Assessment Tool [BAT]; <http://www.aftri.usuhs.mil/>). Input to BAT includes historical and clinical data, TE, and serial complete blood counts (CBCs), and the output provides a statistically weighted estimate of dose. It is possible therefore to determine the magnitude of the exposure within the first 12 to 18 hours postevent. The program is currently available free of charge for the personal computer (PC) laptop and will soon be available for the personal digital assistant (PDA).¹⁷

The medical management of patients with acute, moderate to severe radiation exposure (effective whole body dose greater than 3 Gy) should emphasize the rapid administration of colony-stimulating factors (CSF). All of these compounds decrease the duration of radiation-induced neutropenia and stimulate neutrophil recovery. For those patients developing febrile radiation-induced neutropenia, adherence to the current Infectious Diseases Society of America guidelines for high-risk neutropenia is recommended (IDSA; <http://www.idsociety.org/>).

INDUSTRIAL TOXICOLOGY OF COMMON RADIOISOTOPES

Following an accidental intake of radioactive material, dose, toxicity, and treatment methods are dependent on various factors such as the identity of the radionuclide and its physical and chemical characteristics (physical and biological half-life, particle size, chemical composition, solubility, etc.). In the inhalation pathway, particle characteristics (size, chemical composition, chemical solubility in body fluids) are important determinants of dose. The fate of inhaled particles is critically dependent on particle physicochemical properties and the size of aerosol particles determines the region of the respiratory tract where most will be deposited. Highly insoluble particles may remain in the lung for long periods of time, and a small fraction will be transported to the tracheobronchial lymph nodes by pulmonary macrophages. Insoluble particles may be swallowed and therefore excreted primarily in the feces.

Treatment considerations for internal contamination of radioisotopes are very similar to traditional poison control measures and fall into several major categories²¹:

1. Reduce and/or inhibit absorption of the isotope in the GI tract.
2. Block uptake to the organ of interest.
3. Utilize isotopic dilution.
4. Alter the chemistry of the substance.
5. Displace the isotope from receptors.
6. Utilize traditional chelation techniques.

The most common isotopes seen in the management of internal contamination will now be presented along with selected case histories. It is hoped that these case histories will give the reader some idea of the decision-making process involved in management of internal contamination cases.

CASE HISTORY: ESTIMATING THE MAXIMUM CREDIBLE INHALATION ACCIDENT

Two scientists at a government facility accidentally break the integrity of a glovebox known to contain americium 241. Nasal swipes taken within 10 minutes postaccident read 10,000 dpm and 12,000 dpm alpha for the left and right nares, respectively. The presenting issue is to estimate the maximum credible accident.

Mansfield²² has given a rough rule of thumb that the combined activity of both nasal swipes should approximate 5% of deep lung deposition, using the International Commission on Radiological Protection (ICRP) 30 lung model. Using this rule of thumb to estimate the magnitude of the incident, we have the total anterior nasal passage activity to be 22,000 dpm alpha = 9.9 nCi. The estimated lung deposition is therefore on the order of 200 nCi, or approximately 10 annual limits of intake (ALI; 1 ALI = 5 rem) for inhalation. Experience has

shown that this is generally a very conservative overestimate, but useful for initial estimates, pending the results of bioassay.²³

MEDICAL CONSIDERATIONS FOR SELECTED RADIONUCLIDES²³

Tritium (³H)

Dose to total body water is the critical issue in the management of tritium accidents. The ICRP 67 model for tritium²⁴ assumes two compartments for tritiated water, A and B, with age-dependent biologic half-lives ranging from 3 to 10 days for compartment A and 8 to 40 days for compartment B. In addition, organically bound tritium is treated in an age-dependent manner. For accident dosimetry purposes, tritium retention may be approximated by a single exponential with a half life of 10 days. For reference, the ALI for tritium is 80,000 μ Ci. Medical management of tritium intake is directed toward increasing body water turnover by increasing oral fluid intake, thereby diluting the tritium and increasing excretion by physiologic mechanisms.

An increase in oral fluids of 3 to 4 L/day reduces the biologic half-life of tritium by a factor of 2 to 3 and therefore reduces whole body dose in the same proportion.

CASE STUDIES: TRITIUM EXPOSURE

Six male teens at a government dormitory facility break an exit sign, releasing approximately 10 Ci of tritium gas. The highest levels of tritium are found on the public telephone (157,000 dpm). Urine samples are taken from all six teens and sent for tritium bioassay. From liquid scintillation counting at a national laboratory, the highest urine value is found to be 6.5 μ Ci/L in a 17-year-old boy.

Using the conservative rule of thumb from ICRP 65 that 1 μ Ci/L peak tritium concentration in urine corresponds to an integrated whole body dose of 10 mrem,²¹ the maximum estimated dose is approximately 65 mrem (0.65 mSv) whole body. Prior to receiving the urine bioassay results, all teens were instructed to increase oral hydration to 3 to 4 L/day. There were no adverse medical events from this tritium intake.

Historically, tritium exposures have resulted in relatively low whole body dose, but Seelentag and Minder²⁵ have reported cases of two fatalities possibly related to high-level tritium intake in an industrial environment over a period of years. From these cases, they concluded that there is possible evidence that two people died secondary to radiation-induced bone marrow suppression, although there was also prior exposure to strontium and radium.

Strontium

Sr 90 is the predominant isotope of interest in this chemical series, and a comprehensive model for strontium

retention, developed by Snyder and colleagues²⁶ that indicates that 73% of material in the transfer compartment is eliminated with a 3-day half-life, 10% with a 44 day half-life, and 17% with a 4000-day half-life. All chemical forms except SrTiO₃ are considered relatively soluble (class D in the ICRP 30 formalism). SrTiO₃ is considered insoluble (class Y). In the ICRP 76 treatment²⁷ of alkaline earth distribution, an age-dependent biokinetic model is given, with transfer to soft tissue, cortical and trabecular bone volume and surface, two liver compartments, and the renal system. For most forms of strontium, except titanate, bone surface is the dose-limiting organ for both inhalation and ingestion. Because of the biologically significant rate of strontium transfer to the GI tract, it is also necessary to block intestinal absorption in those cases where intake is by inhalation. The following treatments are useful in the medical management of inhalation cases with strontium:

1. Intravenous (IV) calcium gluconate 2 g in 500 mL over 4 to 6 hours (competes for strontium at bone binding sites).
2. Ammonium chloride (300 mg orally) to produce a moderate metabolic acidosis.
3. Barium sulfate 300 g orally as soon as possible postaccident to block intestinal absorption.

Iodine

The thyroid is the critical organ after intake of radioactive iodine. Retention in the thyroid is described by a three-component exponential with half-lives of 0.24 days, 11 days, and 120 days. In the ICRP 67 model, age-dependent elimination rate constants are given. In this model, uptake to the thyroid is 30%, with 70% of intake routed to prompt urinary excretion. The ICRP 67 model²⁴ for adults has a half-life of 80 days for iodine in the thyroid and 12 days for iodine in the rest of the body. For accident dosimetry, the effective half-life of iodine may be taken to be approximately 12 days.

Thyroid blocking in adults is accomplished by administering 130 mg potassium iodide (KI) orally as soon as possible postaccident and one tablet daily for 7 to 14 days. Another convenient way to administer stable iodide is five or six drops of saturated solution of KI (SSKI, 1 g/mL). In addition, potassium perchlorate (200 mg) may be used in patients with iodine sensitivity. The timing of iodine administration is as soon as possible postaccident, up to 6 hours. However, in a situation with continuing exposure, stable iodine may be 50% effective even 5 to 6 hours after exposure to radioiodine.

CASE STUDY: RADIOIODINE ADMINISTRATION IN PREGNANCY^{23,28}

A 26-year-old female nurse presents with clinical hyperthyroidism.^{23,28} During the laboratory analysis, a T₄ level is found to be 19.5 µg/dL (normal 5 to 12.5 µg/dL). She is given 9.2 mCi iodine 131 (NaI) for thyroid ablation, and the patient's hyperthyroid symptoms subside within

1 week. However, the patient is subsequently found to be 14 weeks pregnant at the time of iodine administration by ultrasound dating. The fetal self dose in this case is calculated to be 2.4 rad (0.024 Gy; dose conversion factor [DCF] = 0.068 mGy/MBq), but the fetal thyroid dose is calculated to be 88 Gy (DCF = 260 mGy/MBq). This is ablative to the fetal thyroid.

The mother and fetus were followed throughout the remainder of the pregnancy by a specialist in fetal-maternal medicine. The pregnancy was clinically uneventful, with a normal delivery. At birth, the infant was found to be profoundly hypothyroid and in the 6th percentile for growth on standard growth charts. At 1 year of age, the baby also exhibited minor developmental delay on standard neurocognitive tests.

Cesium

Following systemic uptake of cesium, the isotope is uniformly distributed in the body with distribution similar to potassium. Systemic retention for cesium is often represented by a two exponential retention function with retention half-lives of approximately 2 days and approximately 110 days. However, a range of retention half-lives has been noted.¹²

The most effective means for removing radioactive cesium is the oral administration of ferric ferrocyanate, commonly called Prussian blue (PB). Insoluble PB (ferric hexacyanoferrate, Fe₄[Fe(CN)₆]₃) is an orally administered drug that enhances excretion of isotopes of cesium and thallium from the body by means of ion exchange. One gram orally three times daily for 2 to 3 weeks reduces the biological half-life of radiocesium to about one third the normal value. PB has a high affinity for cesium, whose metabolism follows an entero-enteric cycle. Orally administered PB traps cesium in the gut, interrupts its reabsorption from the GI tract, and thereby increases fecal excretion. Thus, the biologic half-life of cesium is significantly reduced after decorporation therapy with PB.

CASE STUDY: CESIUM

The most famous case¹² involving cesium intake was the radiologic accident in Goiânia, Brazil, in 1987. In September 1987, two men removed the rotating assembly of a cesium 137 teletherapy unit and breached the capsule containing 50.9 TBq (1375 Ci) of ¹³⁷Cs. The source was in the form of soluble ¹³⁷CsCl, which is highly dispersible in the environment. The teletherapy assembly was initially sold to a junkyard and the junkyard owner believed that it had mystical power since it glowed blue in the dark (Cherenkov radiation from the cesium beta decay). Samples of the material were given to many friends and relatives, resulting in widespread contamination to people and to the environment. Residual contamination levels near the initial breach of containment were on the order of 1.1 Gy/hr.

Approximately 112,000 persons were monitored for radioactive contamination, of whom 249 were contaminated externally or internally. Four individuals died of

the acute radiation syndrome, with whole body dose in the range 4 to 7 Gy. These included the 38-year-old wife of the junkyard owner (5.7 Gy), 18- and 22-year-old employees (4.5 and 5.3 Gy, respectively), and a 6-year-old niece of the junkyard owner (6.0 Gy). The latter case represented a situation of extreme internal contamination (1×10^9 Bq) by ingestion, since the young girl was playing with a piece of the source while eating a sandwich.

Forty-six individuals, internally contaminated in this incident, were treated with PB in daily divided doses of 3 to 20 g. The use of PB reduced the average ^{137}Cs biologic half-life from 110 to 115 days to about 40 days, with a consequent reduction in dose.

Uranium

The two most common uranium isotopes seen in research and in industry are uranium 238 and 235. Acute toxicity is most closely related to chemical rather than radiologic properties, particularly with regard to the renal system. For uranium entering the transfer compartment, approximately 20% is transferred to mineral bone with a half-life of 20 days and 2.3% to bone with a half-life of 5000 days. In addition, 12% and 0.05% are transferred to the kidneys with half-lives of 6 and 1500 days, respectively. Systemic body retention of uranium is given by a five exponential retention function with half-lives of 0.25, 6, 20, 1500, and 5000 days.¹⁹⁻³¹

Uranium has an overall effective half-life of 15 days, and 85% of retained uranium resides in bone. Kidney toxicity is the basis of occupational exposure limits. In acidic urine, the uranyl ion binds with renal tubular surface proteins, and some of the bound UO_2^{2+} is therefore retained in the kidney. The kidney is the first organ to show chemical damage in the form of nephritis and proteinuria. Oral doses or infusions of sodium bicarbonate have historically been the treatment of choice and should be dosed to keep the urine alkaline by frequent pH measurements. The non-toxic uranium carbonate complex is increased by three to four orders of magnitude in alkaline urine and promptly excreted.^{30,32}

Annual occupational limits for uranium are based on levels estimated to induce renal damage. The threshold for transient renal injury is estimated to be 0.058 mg U/kg body weight or intake of 4.06 mg in a 70-kg individual. Likewise, the threshold for permanent renal damage is estimated to be 0.3 mg U/kg body weight, or 21 mg U in a 70-kg person. Permanent renal damage is shown by a permanent increase in blood urea nitrogen and creatinine, along with proteinuria and a decrease in glomerular filtration rate. From animal research, the 50% lethality level is estimated to be 1.63 mg/kg body weight, or 114 mg in a 70-kg person. A very useful Internet calculator for determining organ levels of uranium from either ingestion or inhalation is found through Martindale's Online Center (http://www.martindalecenter.com/CalculatorsD_Rad.html). This very extensive calculator originated through the WISE Uranium Project in the Netherlands.

Current research on decorporation therapy of uranium and the actinides has evaluated analogs to

siderophores.^{30,31} Siderophores are agents produced by microorganisms to obtain Fe(III) from the environment. These compounds are good candidates for trial since actinide and uranium biokinetics are associated with Fe(III) transport and storage systems. The association rate constant for actinide-ligand and uranium-ligand binding is generally found to be much greater than that for diethylenetriamine-penta-acetic acid (DTPA) binding.

Durbin and colleagues^{33,34} have considered a linear hydroxypyridinone derivative of deferoxamine: 3,4,3-LIHOPO, or simply LIHOPO. LIHOPO is readily given by IV injection in a rat model with low toxicity and has been found to be an effective chelator for both actinides and for uranium. Consider a rat model where plutonium and americium particulates are inhaled. The summary of experiments below shows relative improvement ratios for decorporation therapy using LIHOPO compared with traditional methods using DTPA.²³

1. Plutonium: LIHOPO/DTPA = a factor of 6.7 improvement for plutonium deposition in lungs.
2. Americium: LIHOPO/DTPA = a factor of 2.0 improvement for americium deposition in lungs.
3. Plutonium: LIHOPO/DTPA = a factor of 4.8 improvement for plutonium deposition in skeleton.

In a plutonium wound model in rats, LIHOPO was found to be 2 to 40 times more effective than DTPA in chelation therapy, depending on the nature of the experiment and route of LIHOPO administration. In another series of experiments, small oral doses of LIHOPO mobilized more americium than plutonium from liver and bone. Furthermore, in rat experiments using injected uranium, LIHOPO was 3.6 times more effective in renal protection than NaHCO_3 and 1.7 times more effective in decreasing dose to bone volume.³² These experiments appear to be quite promising for eventual human use.

Durbin and colleagues³³ have also recently presented experiments designed to identify the most effective multidentate 1,2-HOPO and Me-3,2-HOPO ligands for chelation of Pu(IV) in vivo. Nine HOPO ligands, when injected or given orally, were found to be superior to Ca-DTPA for reducing plutonium 238 retention in the mouse model. These tetradentate and hexadentate compounds are found to be highly effective, but moderately toxic, and deserve more intensive study prior to human studies. While these experiments to date appear quite promising, U.S. Food and Drug Administration (FDA) phase I human trials have not yet begun. Therefore, the compounds will not be available in the clinic for several years. A recent review article³⁴ provides additional details of this preclinical research.

Henge-Napoli and colleagues^{35,36} have evaluated the efficacy of ethane-1-hydroxy-1,1 bisphosphonate (EHBP, etidronate, Didronel [Proctor and Gamble, Mason, OH]) in experiments to obtain compounds that will reduce the fixation of uranium in its main target organs of bone and kidney. Etidronate, a synthetic analog of pyrophosphate, is used in the treatment of moderate to severe Paget's disease, heterotopic ossification, and hypercalcemia associated with malignant neoplasms. The

work of Henge-Napoli and colleagues showed that one injection of EHBP (50 to 100 mol/kg), given acutely after uranium inhalation in animals, reduced uranium deposition in the renal system by a factor of five, and still a factor of two when given 30 minutes postexposure.

This work is particularly important since Etidronate is currently approved by the FDA for reduction of bone resorption, is clinically accepted, and has a well-studied adverse reaction profile. Etidronate has pharmacologic actions that are similar to pyrophosphate, a salt of phosphoric acid, which occurs naturally in the body and acts to inhibit bone metabolism. In contrast to the endogenous compound, etidronate is resistant to enzymatic metabolism. The drug decreases both normal and abnormal bone resorption, thereby reducing bone turnover and slowing the remodeling of pagetic or heterotopic bone.

In another series of animal experiments, Destombes and colleagues³⁷ compared the carbonic anhydrase inhibitor acetazolamide (Diamox [Barr Pharmaceuticals, Pomona, NY]), with bicarbonate in the treatment of internal contamination with uranium. This work is quite important since acetazolamide is also currently approved by the FDA and could be adapted easily for use in cases of uranium contamination in a mass casualty terrorist incident.

Carbonic anhydrase is an enzyme responsible for forming hydrogen and bicarbonate ions from carbon dioxide and water. By inhibiting this reaction, acetazolamide reduces the availability of these ions for active transport. Hydrogen ion concentrations in the renal tubule lumen are therefore reduced by acetazolamide, leading to an alkaline urine and an increased excretion of bicarbonate, sodium, potassium, and water. A reduction in plasma bicarbonate results in a metabolic acidosis, which rapidly reverses the diuretic effect.

Acetazolamide is classically used for the prophylaxis and treatment of altitude sickness, and as an adjunct treatment for glaucoma and epilepsy. It has also long been approved by the FDA for use as a diuretic. Acetazolamide is rapidly absorbed from the GI tract, and peak serum concentrations for the tablets and extended-release capsules are achieved in 2 to 4 hours and 8 to 12 hours, respectively. For use in urinary alkalization, the adult dose is 5 mg/kg IV or as needed to maintain an alkaline diuresis. In their recent animal work, Destombes and colleagues³⁷ noted that acetazolamide is three times more effective than bicarbonate in reducing the renal content of uranium, but has no effect on skeletal content. These experiments appear quite promising clinically and deserve to be extended.

Actinides

Plutonium is the model element in this series. After plutonium enters the transfer compartment, approximately 45% translocates to the liver and 45% to bone. The retention time is assumed to be 20 years in the liver and 50 years in bone. The classical plutonium retention function is given by Durbin³⁸ based on her data and that of earlier work by Langham.³⁹ The Durbin model for

plutonium uses a five-component exponential with half-lives of 1.2, 5.5, 42, 300, and 4000 days. The retention functions for other actinides are similar to that for plutonium.

Trisodium calcium diethylenetriaminepentaacetate (Ca-DTPA) and Zn-DTPA chelation therapy are the treatment of choice for inhalation accidents involving actinides. Ca-DTPA is a calcium salt of DTPA, and Zn-DTPA is similar, except for the substitution of Zn for Ca. Ca-DTPA appears to be approximately 10 times more effective than Zn-DTPA for initial chelation of transuranics; therefore, Ca-DTPA should be used whenever larger body burdens of transuranics are involved. Approximately 24 hours after exposure, Zn-DTPA is, for all practical purposes, as effective as Ca-DTPA. This comparable efficacy, coupled with its lesser toxicity, makes Zn-DTPA the preferred agent for protracted therapy. The route of administration may be either slow IV push of the drug over a period of 3 to 4 minutes, IV infusion (1 g in 100 to 250 mL D₅W, Ringer's lactate, or normal saline), or inhalation in a nebulizer (1:1 dilution with water or saline). The Centers for Disease Control and Prevention (CDC) has included both Zn- and Ca-DTPA in the Strategic National Stockpile.

THE RADON ISSUE

Radon (radon 222) is the sixth element in the radioactive decay chain of ²³⁸U, one of the major natural isotopes on earth. Radon gas poses an environmental risk because of its potential carcinogenic properties (increases in small cell and squamous cell carcinomas of the lung). This risk is not primarily due to radon's chemical and radiologic characteristics (noble gas; physical half-life 3.825 days), but mostly to the short-lived, reactive alpha-emitting progeny that occur after radon in the decay chain.

Radon is formed in soil and rock from the radioactive decay of its parent, radium (radium 226, half-life 1622 years), and can easily diffuse from its source. Radon tends to accumulate in enclosed structures, including mines, buildings, and basements, as a combination of diffusion from the soil and flow from air pressure differentials. Most biologic damage in human lungs is caused by its alpha-emitting progeny, particularly polonium (polonium 218 and 210, half-lives 3.11 min and 138.4 days, respectively) and lead 214. The conventional radiologic units associated with radon dose are particularly confusing and derive from historical epidemiologic considerations of working populations in underground mines.

Radon activity may be expressed in pCi/L (equal to 37 Bq/m³ in SI units) and one working level (WL) is equivalent to a radon concentration of 100 pCi/L at equilibrium and to approximately 200 pCi/L at 50% equilibrium, which is typical of many buildings. The working level is therefore a unit of radioactivity per liter of air or water. One working level month (WLM) is historically defined as a month of occupational exposure (170 hours) to one WL of airborne radon activity. One

WLM equates to approximately 5 pCi/L-year under typical conditions of equilibrium and an assumption of 75% occupancy. In addition, one WLM (5 pCi/L-year) results in approximately 0.5 rad (0.5 cGy) of absorbed alpha dose to the lung.

The current Environmental Protection Agency (EPA) voluntary indoor air action level is 4 pCi/L air, and most recent documents⁴⁰⁻⁴² continue to use the correlation that 10,000 pCi/L of radon in water correlates to 1 pCi/L in air (transfer coefficient of 10^{-4}). In poorly ventilated residences, typical radon concentrations are in the range 0.5 to 1.5 pCi/L, somewhat dependent on weather, proximity to the basement substructures, and human use patterns. Typical residential exposures are about 0.2 WLM per year, equivalent to 1 pCi/L-year

PATIENT ASSESSMENT IN RADIATION TERRORISM EVENTS

Victims of radiation terrorism events require prompt diagnosis and treatment of medical and surgical conditions as well as conditions related to radiation exposure. Hospital emergency personnel should triage victims using traditional medical and trauma criteria. Radiation dose can be estimated early postevent using rapid-sort, automated biodosimetry and clinical parameters such as the clinical history, TE,^{43,44} and lymphocyte depletion kinetics. Patient radiation dose can be estimated very effectively from the medical history, serial lymphocyte counts, and TE, and subsequently confirmed with chromosome-aberration bioassay, the current gold standard. These data are effectively analyzed using the Armed Forces Radiobiology Research Institute Biodosimetry Assessment Tool.

The medical management of patients with acute, moderate to severe radiation exposure (effective whole body dose greater than 3 Gy) should emphasize the rapid administration of granulocyte colony stimulating factor (G-CSF).⁴⁵ These compounds appear to decrease the duration of radiation-induced neutropenia and to stimulate neutrophil recovery in patients who have received myelotoxic insult. For those patients developing febrile radiation-induced neutropenia, adherence to the current Infectious Diseases Society of America guidelines for high-risk neutropenia is recommended (<http://www.idsociety.org/>).

CLINICAL MANIFESTATIONS OF HIGH-LEVEL EXTERNAL EXPOSURE

Radiation damage results from the inherent sensitivity of certain cell types to radiation, with mitotically active cells most sensitive to acute effects. The inherent sensitivity of these cells results in a constellation of clinical syndromes (ARS) that occur within a predictable range of dose (greater than 2 Gy) after whole body irradiation delivered at a relatively high dose rate. The clinical components of ARS include hematopoietic, GI, and cerebrovascular syndromes and are reviewed elsewhere.^{14,43-45}

Symptoms of acute, high dose radiation are dependent on the absorbed dose and may appear within hours to days and follow a somewhat predictable course. Individuals suffering from a lethal dose of radiation may experience a compression of these phases over a period of hours, resulting in early death. Because of the rapid cell turnover of the lymphohematopoietic elements, these cells are among the most radiation-sensitive tissue in mammals. As such, irradiation of bone marrow stem and progenitor cells results in exponential death.

The onset of cytopenia is variable and dose dependent. In particular, the duration of neutropenia may be prolonged, requiring prolonged administration of hematopoietic growth factors, blood product support, and antibiotics. The primary goal of medical therapy is to shift the survival curve to the right by about 2 Gy. Many casualties in a terrorist-initiated weapon event (IND) whose dose exceeds 6 to 8 Gy will also have significant blast and thermal injuries that will preclude survival when combined with their radiation insult

The medical management of patients with acute, moderate to severe radiation exposure (effective whole body dose greater than 3 Gy) should emphasize early initiation of G-CSF, transfusion support as needed, antibiotic prophylaxis, and treatment of febrile neutropenia, which is discussed in more detail below. Additional supportive medications may include antiemetics, anti-diarrheals, fluid and electrolytes replacement, and topical burn creams. In the case of coexisting trauma (combined injury), wound closure should be performed within 24 to 36 hours. In non-neutropenic patients, antibiotics should be directed toward the foci of infection and the most likely pathogens. For those who experience significant neutropenia (absolute neutrophil count [ANC] less than 500 cells/mm³), broad-spectrum prophylactic antimicrobials should be given during the potentially long duration of neutropenia. Prophylaxis should include a fluoroquinolone, an antiviral agent (if indicated), and an antifungal agent.⁴³⁻⁴⁵

These antimicrobials should be continued until either the patient experiences a neutropenic fever and requires alternate coverage or experiences neutrophil recovery (ANC greater than 500 cells/mm³). In patients who experience first fever, traditionally therapy is directed at gram-negative bacteria (in particular, *Pseudomonas aeruginosa*), because infections of this type may be rapidly lethal. Any focus of infection that develops during the neutropenic period will require a full course of therapy.

DELAYED EFFECTS OF RADIATION EXPOSURE

It is common to distinguish late organ effects from the acute effects of radiation exposure. Deterministic effects typically show a sigmoid dose-response curve above an appropriate threshold, and the severity of the harm from radiation exposure increases with dose. Effects are non-neoplastic and are expressed in the exposed individual. In contrast, stochastic effects represent a probabilistic tissue response to radiation exposure. Stochastic effects

are nonthreshold and expressed in the exposed population. Damage in reproductive cells may give rise to inheritable genetic mutations, while damage in somatic cells may increase the chance of neoplasia. Leukemias and bone cancers have a minimum latency time of 2 to 5 years, while solid tumors have a minimum latency time of approximately 10 years. For carcinomas of normal adult onset, current evidence suggests that the latency period may be greater than 10 years.

From the adult atomic bomb data,⁴⁶ there is statistically significant evidence for all radiation-induced leukemia (except chronic lymphocytic leukemia [CLL]), as well as for breast, thyroid, colon, stomach, lung, and ovarian carcinoma, and borderline or inconsistent results for radiation-induced carcinoma of the esophagus, liver, skin, bladder, and central nervous system (CNS), as well as multiple myeloma and lymphoma. Regarding non-neoplastic disease,⁴⁶ there is strong evidence for radiation-induced cataracts, hyperparathyroidism, a decrease in the T cell-mediated and humoral immune response, and chromosomal aberrations in lymphocytes.

The International Agency for Research on Cancer Study Group⁴⁷ recently studied combined mortality data for 96,000 nuclear industry workers in the United States, Canada, and the United Kingdom. The exposure was primarily to low-level gamma radiation and the risk analysis was based on a constant linear relative risk model, excess relative risk (ERR) = 1 + b(dose). In this study, the ERR was found to be 2.2 per sievert for leukemia, with ERR for all other cancers, excluding leukemia, being essentially zero. Additional risk estimates for carcinoma from large epidemiologic studies have been published recently.^{48,49}

The Biological Effects of Ionizing Radiation (BEIR) V⁵⁰ excess cancer mortality estimates are widely quoted in the radiation medicine literature. Consider, for example, the hypothetical risk for a single occupational or terrorist exposure to 10 rem (0.1 Sv). Risk is traditionally expressed as lifetime risk per 100,000 exposed persons. Approximately 20,000 cancer deaths would occur in the absence of radiation exposure. For the hypothetical acute dose of 0.1 Sv, 770 excess cancers (660 nonleukemia and 110 leukemia) would be expected in the male cohort and 810 excess cancers (730 nonleukemia and 80 leukemia) expected in the female cohort. The risk model as a function of dose D is of the form:

$$\text{risk}(D) = \text{risk}(0)[1 + f(D)g(\text{age,sex,...})]$$

BEIR V also estimated the genetic effects of 1 rem (0.01 Sv) per generation. The autosomal-dominant natural incidence is approximately 10,000 cases per million. For an additional dose of 1 rem above natural background, one would expect an additional 5 to 20 cases in the first generation and 25 cases at genetic equilibrium. Most cases would be clinically mild in a 3:1 mild:severe ratio. The natural incidence of X-linked disease is estimated in BEIR V at 400 cases per million. For a dose of 1 rem we expect less than one additional case in the first generation and fewer than five cases at equilibrium. Regarding translocations/trisomies, the

natural incidence is approximately 600 translocations and 3800 trisomies per million. At 1 rem, we would expect fewer than an additional five translocations in the first generation and less than one additional trisomy.

If we consider congenital abnormalities as an entire entity, the current incidence is approximately 20,000 to 30,000 per million. Given 1 rem whole body dose-equivalent, it is expected that an additional 10 would occur in the first generation and 10 to 100 at equilibrium. In all of these calculations, BEIR V assumes a doubling dose of 100 rem (1 Sv). Risk analysis from radiation exposure is a complicated and controversial science.

PRENATAL AND PEDIATRIC ISSUES

Differential cell sensitivity to radiation damage is simply expressed by the law of Bergonie and Tribondeau (1906)⁵¹ as follows: Cells are generally radiosensitive if they have a high mitotic rate, have a long mitotic future, and are of a primitive type. The developing embryo and fetus fit within these conditions. Pregnancy dating as taught in medical school is the gestational age calculated from beginning of the last menstrual period so that the average length of pregnancy is 280 days or 40 weeks (95% confidence interval [CI] 2 weeks), split into three trimesters. During the first 2 weeks following ovulation, successive developmental phases are fertilization of the ovum, formation of the free blastocyst, and implantation of the blastocyst into the uterus.⁵²

Prior to comparing the effects of radiation on the fetus, it is interesting to compare risks that normally occur during pregnancy. For example, if the patient contracts maternal rubella in the first trimester, approximately 80% of cases will have a fetus with congenital infection. If infection occurs early in the second trimester, there is approximately a 54% incidence of congenital infection. By infection in the third trimester, approximately 25% of fetuses will be born with congenital syndrome. Additionally, if maternal alcohol consumption⁵² is considered, two to three drinks per day will cause a risk of approximately 10% incidence of fetal alcohol syndrome (FAS). Heavy maternal drinking in pregnancy (more than five drinks per day) will also cause approximately a 30% incidence of FAS. The issue of maternal smoking is particularly important in the incidence of fetal growth retardation, and many experts consider intrauterine growth retardation directly proportional to number of cigarettes smoked.⁵²

Deterministic effects⁵²⁻⁵⁵ of radiation exposure to the embryo/fetus may be considered in stages. Preconception, generally no statistically significant effects are noted at low to moderate radiation doses. When the fetus receives a moderate dose in the preimplantation phase, generally an "all or none" effect is noted. If implantation succeeds, the pregnancy is often successful. At a threshold of 10 to 20 rad, transient growth retardation has been noted shortly after implantation. During the period of organogenesis (7 to 13 weeks' gestation), the embryo is sensitive to the lethal, teratogenic, and growth-retarding effects of radiation because of the

criticality of cellular activities and the high proportion of radiosensitive cells. Growth retardation, gross congenital malformations, microcephaly, and mental retardation are the predominant effects for a uterine dose of greater than 50 rad (0.5 Gy). For survivors of in utero exposure, important clinical sequelae are microcephaly, mental retardation, growth and development delay, and lower IQ and poorer school performance. The highest risk for mental retardation occurs during major neuronal migration in the 8- to 15-week period of time. There is no report of external irradiation inducing morphologic malformation in humans unless the individual also had growth retardation or a CNS anomaly.

Generally, there exist specific windows of opportunity for radiation damage in certain organs during fetal development:

- Cataracts: 0 to 6 days (gestational)
- Exencephaly: 0 to 37 days
- Embryonic death: 4 to 11 days
- Anencephaly or microcephaly: 9 to 90 days
- Anophthalmia: 16 to 32 days
- Cleft palate: 20 to 37 days
- Skeletal dyscrasias: 25 to 85 days
- Growth retardation: 50+ days

Occasionally the question arises regarding a clinical decision to terminate a pregnancy because of first trimester radiation exposure to the fetus. It is important in this regard to consider that the normal rate of first trimester preclinical loss is greater than 30%. For a fetal exposure of 0.1 Gy (10 rad), this risk is increased by less than 1%. A useful number to consider is that the lifetime risk for induction of childhood tumors is approximately 1 in 2000 per rad or 5% per sievert. Consider a case where a fetus received a 5-rad whole body dose in a nuclear medicine procedure where the mother was not known to be pregnant. At 5 rad, the maximal risk for childhood leukemia is 1 in 400. Conversely, the probability of not having a childhood cancer is greater than 99%. If the fetal absorbed dose is greater than 50 rad in the 7- to 13-week window, then there is a substantial risk for growth retardation and CNS damage. It is relatively unusual to have a fetal dose in the range of 25 to 50 rad during the organogenesis period of 7 to 13 weeks. However, if pregnancy termination is at issue for any fetal dose, it is important to have parental value input as well as scientific and clinical input from the physician of record. However, the ultimate decision belongs with the patient.

Childhood irradiation problems are of particular concern for the primary care physician. From the atomic bomb data, the doubling dose for childhood abnormalities is at least 1.7 to 2.2 Sv (170 to 220 rem), but these data reflect both a high dose and a high dose rate. According to the BEIR V report, the minimal doubling dose in humans for chronic exposure is at least 4 Sv (400 rem) and greater than 20 rad for children. In cases of childhood irradiation therapy for CNS tumors, depression and somnolence have been noted clinically as well as late development of cognitive dysfunction. For a tumor dose of 40 to 65 Gy, at long-term follow-up, mental

retardation was found in 17% of patients, although 89% functioned at a satisfactory level. Behavioral disorders were found in 39% of this cohort. Mental retardation was greatest in those irradiated at less than 3 years of age or if the tumor was in the thalamus or hypothalamus.^{54,55}

Childhood acute lymphoblastic leukemia (ALL) is the most common childhood neoplasm. Current therapy can be expected to produce remission in greater than 95% of children, and 70% do not have a recurrence. At least 2000 new cases occur each year in children under the age of 15 years. However, treatment including radiation therapy can be potentially carcinogenic. Second neoplasms are relatively common, especially for children younger than 5 years or who have received cranial irradiation.⁵⁶⁻⁵⁸ The Children's Cancer Study Group⁵⁷ is an excellent retrospective cohort study of adverse effects from 9720 children exhibiting second neoplasms after ALL treatment. The median follow-up was 4.6 years (range 2 months to 16 years). The study results showed 43 second neoplasms, including 24 CNS neoplasms, 10 new leukemias and lymphomas, and 9 other neoplasms. These data represent a 7-fold excess of all cancers and a 22-fold increase of CNS neoplasms. All children with CNS tumors had undergone cranial irradiation with 18 to 24 Gy.

Late deaths and survival after childhood cancer were recorded in the U.K. National Register of Childhood Tumours.⁵⁷ In a retrospective cohort study, 9080 5-year survivors of childhood cancer were followed for variable periods of time. In this study, 781 deaths were recorded; 74% of these deaths were due to recurrent tumor with treatment-related effects in 15% of deaths, and a second primary tumor in 7% of cases. The important point for the primary care physician is that continued close medical monitoring of survivors of childhood cancer is very important.

Childhood thyroid cancer near Chernobyl⁵⁹ has been studied extensively after that accident. In the Gomel region of Belarus, north of Chernobyl, children are currently screened for thyroid cancer by physical examination, ultrasound imaging of the thyroid, and thyroid function tests. Prior to the accident, the thyroid cancer rate was 0.5 per million population. In the period 1991 to 1994, the corresponding rate was 96.4 per million. This represents almost a 200-fold increase.

Intracranial tumors after radium treatment for skin hemangioma during infancy have been studied through the Swedish Cancer Registry.⁶⁰ In this study, 11,805 infants treated with Ra 226 for hemangioma of the skin between 1930 and 1965 (402,958 person-years of risk) were followed through the Swedish Registry. In this relatively low-dose study, 47 intracranial tumors developed in 46 people. The standard incidence ratio was 1.89 (95% CI 1.2 to 2.83), with a mean brain dose of 7 cGy.⁴⁹

As can be seen, analysis of radiation risk is a rapidly changing and complicated issue, and current health physics references should be consulted for the latest information. In addition, Internet programs (e.g., National Institute for Occupational Safety and Health—Radio-Epidemiological Program,

irep.com/irep_niosh/) are available to calculate the probability of causation of cancer development after either an acute or a chronic dose. Appendix C gives a hypothetical calculation for a nonradiation worker (secretary) who receives 0.5 Sv over the course of 6 months due to a lost source placed in her desk.

LABORATORY AND CLINICAL HISTORY

Upon admission to the emergency department after a radiation incident, it is always appropriate to obtain a CBC with differential, either as a baseline level or as a beginning step for lymphocyte kinetic analysis. Other laboratory tests should be considered as appropriate to the presenting medical situation.

The TE, measured from the irradiating event, decreases with increasing whole body dose. For TE of greater than 1 but less than 2 hours, the effective whole body dose is likely at least 3 Gy. If TE is less than 1 hour, the whole body dose likely exceeds 4 Gy. In a mass casualty incident, patients who experience emesis less than 4 hours postaccident should be triaged to professional medical care while those with emesis greater than 4 hours can be instructed to receive delayed medical attention, either with their private physician or with a peripheral center available to deal with minimally injured patients. Patients who experience radiation-induced emesis within 1 hour after a radiation incident will require extensive and prolonged medical intervention, and an ultimately fatal outcome will occur in many instances.

CASE STUDIES IN RADIATION MEDICINE

Clinical Example: Historical Radiation Burns (U.S. Surgery Cases, 1949)

The history of medicine is replete with examples of radiation burns,⁶¹ either from incorrect implementation of a proper radiation procedure, or of improper use of radiation therapy to treat benign conditions. Viewed in a historical context, many early workers experimenting with the medical use of radiation therapy suffered burns to the hands that eventually required excision and grafting. Of interest are early radiologists performing various prolonged fluoroscopic examinations and dentists experiencing radiation burns to the fingers from holding films in the mouths of patients during exposure.

We will consider here only two cases, but many case reports are available describing the use of radiation therapy for treatment of acne, eczema, port-wine hemangiomas, plantar warts, epidermophytosis, and pruritus ani, among other benign conditions. Figure 104-1 illustrates atrophy and facial deformity following radium treatment of a hemangioma. Two operations eventually were required with excision and repair with a cross lip flap. Figure 104-2 presents a young female patient with multiple facial carcinomas throughout the nose and chin resulting from radium therapy for eczema. There was extreme involvement of the nose and chin with malignant loss of the nose. Repair (requiring four operations) was accomplished by complete excision and immediate free grafting with application of a prosthetic acrylic nose.

Residential Radiation Accident Case Study (Estonia, 1994)

On October 21, 1994, an Estonian citizen, RIH, along with his two brothers, visit a radioactive waste facility to scavenge for scrap metal, overriding the electrical alarm system and cutting various padlocks.⁶² RIH climbs into one of the vaults to obtain salvageable metal and passes a large Cs-137 source to his brothers. At this time, none of the brothers realize that this metallic object is highly radioactive. During the theft, RIH injures his leg slightly when an aluminum drum falls against it. Shortly after entry into the repository, RIH begins to feel ill and goes home. Other occupants of the house are the man's stepson (RT), the boy's mother, and the boy's great-grandmother. The cesium source is initially placed in the man's coat pocket that hangs in the hall. It eventually is placed in the kitchen drawer along with various tools.

RIH is hospitalized soon thereafter with severe injury to his leg. During the intake medical history, he claims that he received the injury while working in the nearby forest and he is therefore treated for crush injury. On November 2, 1994, RIH dies and medical authorities have no suspicion of radiation exposure as the etiology of the medical condition.

By November 9, 1994, it is clear that the stepson RT has come in contact with the source multiple times while living in the house and while working on his bicycle. Shortly thereafter, the 4-month-old pet dog dies. The dog had slept much of the time in the kitchen near the cesium source. RT is also eventually admitted to the hospital with severe hand burns, which physicians diagnose as radiation burns and the police are notified. A Russian medical delegation also arrives soon thereafter to provide medical and health physics consultation.

After an extensive radiation dose reconstruction, the deceased father, RIH, is thought to have received

approximately 1830 Gy local dose to his thigh and approximately 4 Gy whole body. Clinically, RIH experienced many of the effects of the hematopoietic subset of ARS along with severe, extensive local injury to his thigh (dose rate estimated to be 2000 to 3000 Gy/hr) (see Figure 104-3 for cell responses to irradiation). He died on day 12 postaccident from neutropenic sepsis and in acute renal failure. An autopsy showed acute radiation necrosis of the right thigh and hip, along with hemorrhage and intestinal thinning of the GI wall. The cause of death was ARS with both hematopoietic and GI components, along with severe local radiation necrosis.

The stepson, RT, is estimated to have received doses of 20 to 30 Gy to his left hand, 8 to 10 Gy to his right hand, and approximately 2.5 Gy whole body during various episodes of bicycle maintenance. Other family members received hand doses in the range 8 to 20 Gy and whole body doses in the range of 1 to 2.5 Gy. The cumulative dose was based on each individual's recollection of the degree of occupancy of various locations in the house. In addition, spatial computer analysis, chromosome aberration analysis, and other specialized assays were employed.

U.S. Fatal Criticality Accidents (Neutron-Gamma Exposures)

Two early criticality (weapons research) events occurred with a 6.2-kg plutonium sphere at Los Alamos National Laboratory.⁶³⁻⁶⁶ The first incident occurred on August 21, 1945, when a worker was preparing a critical assembly by stacking tungsten carbide bricks around the plutonium core as a reflector. He moved the final block over the assembly but, noting that this block would make the assembly supercritical, he withdrew it. The brick fell onto the center of the assembly, resulting in a super-prompt critical state of approximately $6 \times E+15$ fissions. The worker sustained an average whole body dose of

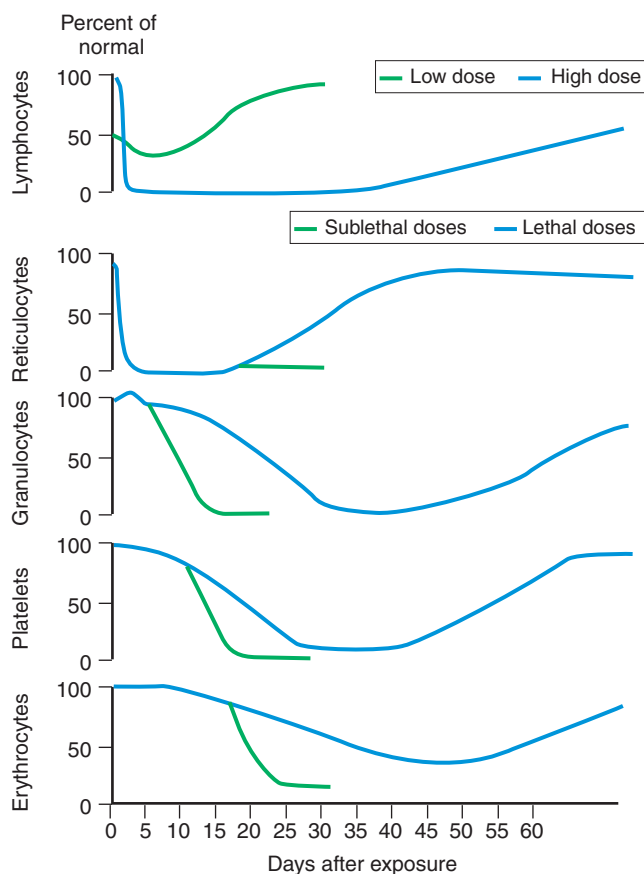

FIGURE 104-3 Hematopoietic response of various cell lines to an acute irradiation incident. The threshold is approximately 50 to 100 cGy.

approximately 5.1 Gy and a dose to the right hand of approximately 100 to 400 Gy.

Within 36 hours postaccident, blisters were noted on the volar aspect of the right third finger, and within 24 hours thereafter, extensive erythema and eventual blistering was noted on both palmar and volar surfaces of the hand. By the third week, the right hand had progressed to a dry gangrene. Desquamation of the epidermis involved almost all of the skin of the dorsum of the forearm and hand. In addition, epilation was almost complete at the time of death. The patient died of sepsis 28 days postaccident.

At autopsy, severe skin necrosis was observed as well as overt dry gangrene. The cardiorespiratory system was significant for pericarditis, cardiac hypertrophy, pulmonary edema, and alveolar hemorrhage. The spleen was noted to have no germinal centers, and the mucosa of the large bowel was ulcerated, as was the buccal mucosa. The bone marrow was noted to be hypoplastic, and lymph nodes also showed significant lymphocyte depletion. A solitary ulcer was noted in the large colon, as was a right renal infarct. This case is an excellent example of the hematopoietic component of ARS with perhaps the beginning of the GI component.

The second criticality accident occurred in 1946 during an approach to criticality demonstration at which several observers were present. The operator used a

screwdriver as a lever to lower a hemispherical beryllium shell reflector into place. While holding the top shell with his left thumb, the screwdriver slipped and caused a critical configuration. The fission yield in this accident was estimated at $3 \times E+15$ fissions. The operator received an estimated acute whole body dose of approximately 21 Gy, with a dose to the left hand of approximately 150 Gy and somewhat less to the right hand. Clinically, the patient complained of nausea in the hour prior to admission and vomited once in the first hour post-accident. On the fifth day post-accident there was a precipitous drop in his neutrophil count, and his condition began to decline rapidly. The patient rapidly lost weight, became mentally confused on day 7 post-event, became comatose, and died quietly on the ninth day in cardiovascular shock (GI and CNS syndrome). At the time of death, both hands showed extensive radiation damage.

At autopsy, the cardiorespiratory system was remarkable for cardiac hemorrhage and myocardial edema, and the terminal bronchi showed features of aspiration pneumonia. In addition, most of the GI tract showed sloughing, most pronounced in the jejunum and ileum. Widespread hyaline changes were also noted in the renal tubular epithelium.

The third major U.S. criticality accident occurred on December 30, 1958, during purification and concentration of plutonium. In the process, unexpected plutonium-rich solids were washed from two vessels into a single large vessel that contained layered, dilute aqueous and organic solutions. Accident analysis shows that the aqueous layer initially was slightly below delayed critical (approximately 203 mm thick, critical thickness 210 mm). When the stirrer was started, the central portion of the liquid system was thickened, changing system reactivity to super-prompt critical. The excursion yield was approximately $1.5 \times E+17$ fissions. Bubble generation was the negative feedback mechanism for terminating the neutron spike. The dose to the patient's upper extremity was estimated to be $120 \text{ Gy} \pm 50\%$.

The clinical course of this case has traditionally been divided into four separate phases of varying duration:

- Phase 1 (20 to 30 minutes postevent): immediate physical collapse and mental incapacitation, progressing eventually into semiconsciousness
- Phase 2 (90 minutes): signs and symptoms of cardiovascular shock accompanied by severe abdominal pain
- Phase 3 (28 hours): subjective minimal clinical improvement
- Phase 4 (2 hours): rapidly appearing irritability and mania, progressing to coma and death

The clinical course was remarkable for continuing, profound hypotension, tachycardia, and intense dermal and conjunctival hyperemia. The patient died 35 hours postexposure of the cardiovascular-CNS syndrome.

On autopsy, examination of the heart showed acute myocarditis, myocardial edema, cardiac hypertrophy, and a fibrinous pericarditis. Examination of the brain demonstrated cerebral edema, diffuse vasculitis, and

cerebral hemorrhage. The GI system showed necrosis of the anterior gastric wall parietal cells, acute upper jejunal distention, mitotic suppression throughout the entire GI tract, and acute jejunal and ileal enteritis.

The fourth fatal U.S. criticality accident occurred on July 24, 1964, at the United Nuclear Fuels Recovery Plant, Wood River Junction, Rhode Island. A chemical processing plant was designed to recover highly enriched uranium from scrap material left over from the production of fuel rods. The critical excursion occurred when nearly all of the uranium had been transferred, resulting in approximately 1.0 to $1.1 \times E+17$ fissions. The acute dose to the operator was estimated to be 100 Gy. Approximately 4 hours postaccident, the patient experienced transient difficulty in speaking, hypotension, and tachycardia. A portable chest x-ray 16 hours post-admission showed hilar congestion. On day 2, the patient became very disoriented, hypotensive, and anuric and died 49 hours postaccident in cardiovascular shock.

At autopsy, examination of the heart, lungs, and abdominal cavity revealed acute pulmonary edema, bilateral hydrothorax, hydropericardium, abdominal ascites, acute pericarditis, interstitial myocarditis, and inflammation of the ascending aorta. Examination of the GI tract showed severe subserosal edema of the stomach and of the transverse and descending colon.

Industrial Radiography Accident at the Yanango Hydroelectric Power Plant (1999)

Prior to hydrostatic testing of a pipe under repair at the Yanango hydroelectric power plant in the San Ramon District in Peru (300 km east of Lima, Peru), Ir 192 radiography was required to check welded repairs for defects. At 11:30 A.M. on February 20, 1999, an industrial radiographer and his assistant took their equipment to the area of a large, 2-m diameter pipe where repairs were underway. Their radiography equipment, a projection type camera designed to use a cable to drive a radiation source in and out through a guide tube, was reported to contain a 1.37 TBq (37 Ci) Ir 192 source. The welders had not yet completed their repairs, so the radiographer and his assistant left their locked camera (with the drive cable attached, but the guide tube not connected) in order to proceed with other tasks. They returned later that night to perform the radiography. On development of their x-ray films, the radiographer discovered that the film had not been exposed. He checked his radiography equipment around midnight and discovered that the iridium source was missing. A search was initiated, and at 1 A.M. on February 21 the radiographer recovered the source at the home of the welder.

The welder reported he had found the source in the pipe, had picked it up with his right hand, and put it into the right rear pocket of his loose fitting denim trousers. The welder then took a minibus and arrived home after a 30-minute ride. He experienced slight nausea earlier that evening and also noted some discomfort in his right thigh. On arrival home, he asked his wife to check a painful area on the back of his right thigh and she noted

the area was reddened. A local physician was consulted and gave a diagnosis of “insect bite” and was told to use hot compresses on the inflamed area. Once aware of the accident, the company promptly notified the national authority for radiation safety and regulation, the Instituto Peruano de Energia Nuclear (IPEN).⁶⁷

IPEN personnel then notified the head of the radiotherapy department of the Instituto de Enfermedades Neoplasicas (INEN) in Lima, where arrangements had previously been made for treatment of persons with radiation injury. Subsequently, IPEN personnel gathered information about the incident and arranged medical examinations for all potentially exposed persons, including the welder’s three children (ages 10 and 7 years and 18 months), his wife, and his assistant. Arrangements were then made to facilitate transport of the welder and his family to INEN in Lima. The welder was admitted to the hospital on February 21, 1999, approximately 20 hours after the discovery of the accident. Extensive clinical and dosimetric details of this accident have been published elsewhere.^{68,69}

Physical examination of the patient on admission revealed a 37-year-old, well-built Peruvian man weighing approximately 78 kg. A painful, erythematous area was noted on the right upper posterior thigh. Over the next few days, a very painful, bullous lesion surrounded by a large inflammatory halo developed, reaching 4 cm² in size by day 3. The right hip, buttock, and thigh became quite swollen over several days, and a computed tomography scan performed on February 26 showed generalized, marked edema involving all muscle groups in the right posterior thigh as well as in subcutaneous tissue. Swelling in the area diminished several days later, but extension, denudation, and necrosis of the lesion progressed rapidly.

By March 19, 1 month after the accident, the patient’s deteriorating health was evident. He had lost 7 kg in weight and was in intense pain with clinical pain control increasingly difficult, and his lesion now involved an area of more than 10 × 12 cm. The lesion at this time had dark, firm necrotic edges, was partially covered with a fibrin crust, and appeared superficially infected. The wound later progressed to approximately 2 cm in depth, with necrosis of underlying fat and involvement down to the semitendinosus and biceps femoralis muscles. Nerve involvement was suspected and subsequently diagnosed using nerve conduction studies.

A team of experts, at the request of the IAEA, arrived on March 19 to consult with the Peruvian physicians regarding details of the accident, treatment protocols, lessons learned, and so forth. The team noted slightly depressed white blood cell counts indicating low-level whole body irradiation, estimated to be between 1 and 3 Gy. The team at this time discussed the potential need for a right hemipelvectomy. Also, in this time period, the source was calibrated and found to be somewhat less than the 1.37 TBq originally reported. Measurements indicated its activity was approximately 0.962 TBq (26 Ci). By the end of March, the thigh lesion had now extended to 20 × 15 cm, with a large area of central necrosis and a surrounding fibrotic rim. Electromy-

ography at this time confirmed signs of denervation of the sciatic nerve. Histologic studies of the necrotic lesions revealed microscopic hemorrhages, extensive areas of coagulation necrosis, edema, severe inflammation, and destruction of vascular structures. In addition, walls of small and moderate-sized arteries showed a distinct postradiation necrotizing vasculitis.

Subsequent surgical exploration and débridement of the area revealed that the lesion had extended to the femur and to the sciatic nerve. On August 16, the right hip was disarticulated and a left iliac colostomy was performed. The patient left the burn center on day 205 postaccident for transfer to a rehabilitation center. By late September, the radionecrosis and superficial infection was noted to extend to the perineum, including the anal sphincter and scrotum. In May 2000, the patient was transferred from Lima to an intensive care unit in a hospital near his home town. Because of severe psychological issues, close family contact proved to be of significant therapeutic value. At the last physical examination, the patient had some closure of the necrotic perineal area, with formation of granulation tissue and progressive fibrosis. The urethral fistula was still present and requires plastic reconstruction.

CONCLUSION

In evaluation of the magnitude of a radiation event (either an industrial accident or terrorist event), it is important for the health physicist, physician, and radiobiologist to work closely together and to evaluate many variables, particularly the initial patient medical history and physical examination and the timing of prodromal signs and symptoms (nausea, vomiting, diarrhea, transient incapacitation, hypotension), and other signs and symptoms suggestive of high-level exposure. The diagnosing physician charged with medical care of patients following a radiation accident is therefore likely to see at least two distinct patient presentations: (1) a normal-appearing patient with few signs or symptoms, or perhaps offering symptoms of unexplained nausea and vomiting, or of unexplained skin lesions, or (2) a very ill patient with stigmata of the acute radiation syndrome and/or local radiation injury. The astute diagnostician must be aware of these different presentations.

APPENDIX A. A BRIEF INTRODUCTION TO RADIATION PHYSICS AND TO RADIOLOGICAL UNITS

In order for the toxicologist or emergency medicine specialist to provide initial treatment and advice to the nuclear accident victim, it is necessary to consider only a few basic ideas from radiation physics. Radioactive materials are materials that emit ionizing radiation. They emit various types of energetic particles to reach a more stable quantum ground state. These radioisotopes are chemically and physically identical to their nonradioactive counterparts and behave metabolically in the human body only according to their chemical properties.

The fact that an isotope is radioactive does, however, determine the effective half-life in the body. As is well known in toxicology, the radioactive half-life is the time required for a radioactive substance to lose half of its radioactivity. Each radionuclide has a unique half-life. Half-lives range from extremely short fractions of a second to billions of years. A long half-life implies a low specific activity (activity per unit mass) and a short half-life implies a high specific activity. If TB is the biological half-life of the stable element as degraded via normal metabolic pathways and TR is the radioactive half-life, then the effective half-life T(eff) is the parallel combination:

$$1/T(\text{eff}) = 1/TB + 1/TR$$

From Equation 1, we can see, if the radioisotope is long-lived ($TR \gg TB$), then the effective half-life is essentially the biologic or metabolic half-life TB. Conversely, if the isotope is short-lived ($TB \gg TR$), the effective half-life is dominated by the radioactive half-life.

Ionizing radiation refers to radiation (alpha, beta, photons, and neutrons) whose energy is sufficient to strip electrons from atoms or molecules. Essentially all types of radiation from the atomic nucleus are ionizing. Nonionizing radiation includes visible light, microwaves, radio waves, ultrasound, and so forth and are not included for consideration here.

Alpha particles (energetic helium nuclei) generally do not pass through the keratinizing layer of skin and therefore are primarily of interest in situations involving inhalation or ingestion of radioactive material. Generally, alpha particles are emitted only from the very heavy nuclei. Beta particles (energetic electrons) have a greater range in air and in tissue. Beta particles therefore are of interest in estimation of skin dose and in situations involving internal deposition. Gamma rays are photons emitted from the nucleus that generally penetrate the skin, soft tissue, and bone. Gamma rays are involved in the vast majority of radiation accidents involving external irradiation. X-rays are relatively lower-energy photons arising from transitions between atomic energy levels and are occasionally involved in radiation accidents arising from improper use of industrial or medical equipment.

Generally, most of the lighter radioisotopes emit both beta and gamma rays while the very heavy elements typically emit alpha particles along with relatively low energy photons. However, given the large number of isotopes, it is difficult to generalize, and many isotopes have a large number of emissions.

Atomic nomenclature shows the abbreviation of the element and atomic number A (number of protons + neutrons) as shown:

$${}^A(\text{element}) \text{ or } (\text{element})\text{-}A$$

Examples are ${}^{60}\text{Co}$ or Co 60 and ${}^{137}\text{Cs}$ or Cs 137 (see Box 104-1). Radiation energies are typically measured in electron-volts (eV), kilo-electron volts (KeV) or million-electron volts (MeV). For example, the main gamma ray of interest in Cs 137 is 661 KeV or 0.661 MeV. Co 60 emits

BOX104-1 RADIOISOTOPES OFTEN INVOLVED IN VARIOUS COMMERCIAL SECTORS

The University "Seven"	The Industrial "Four"
H 3	Ir 192
C 14	Co 60
P 32	Cs 137
Co 60	Sr 90
I 125/I 131	
Cf 252	The Military "Three"
	U 235
	Pu 239
	Am 241

two very penetrating gamma rays of energy, 1.17 MeV and 1.33 MeV.

Ir 192 (iridium) is widely used throughout the world in industrial radiography, and this radioisotope is probably the most significant isotope involved in localized radiation injury. In the United States, over a million high-level Ir 192 sources exist, and a few are unaccounted for at any point in time. It is an interesting phenomenon that specific isotopes tend to be involved in radiation accidents in certain industries. For example, only seven isotopes tend to appear in most university accidents as noted above, generally four isotopes in most accidents in the industrial sector, and essentially three in the military environment. The above list is somewhat of a generalization and there is certainly crossover between sectors, but this short list probably accounts for 90% of accidents in their respective sectors.

In radiation physics, "exposure" relates to the amount of ionization produced by x-rays or gamma rays in air under standard conditions. Exposure R is the quotient Q/m , where Q is the sum of the electrical charges on all the ions of one sign produced in air when electrons and positrons liberated by photons in a volume element of air whose mass is m, are completely stopped. The traditional unit of exposure is the roentgen (R) defined by $1 R = 2.58 \times 10^4 C/kg$. The SI unit of exposure is the C/kg.

Dose refers to the absorption of radiation energy per unit mass of absorber (e.g., soft tissue, lung, bone, etc.). The conventional unit of radiation dose is the rad (1 rad = 100 ergs/g of absorbed energy). The SI unit of dose is the gray (Gy), equal to 100 rad, and also equal to 1 joule/kg. Dose may refer either to whole body dose, partial body dose, or to organ dose. Dose equivalent is dose multiplied by a factor to account for the varying effectiveness of various types of radiation. The traditional unit of dose equivalent is the rem, while the SI unit is the sievert (Sv), equal to 100 rem. Generally, it is not necessary to consider dose equivalent in the initial evaluation of the patient involved in a radiation accident. For soft tissue, it is quite acceptable medically to assume that 1 R is approximately numerically equal to 1 rad, which is approximately equal to 1 rem. This is not true for other organs such as bone or lung. However, such approximations are quite adequate in a mass casualty radiation event.

Activity is the number of disintegrations or nuclear transformations per unit of time occurring in radioactive material. The conventional unit of activity is the curie (Ci; $1 Ci = 3.7 \times 10^{10}$ disintegrations per second). The SI unit of activity is the becquerel (Bq) equal to one disintegration per second. Therefore $1 Ci = 3.7 \times 10^{10} Bq$. The activity per unit mass (specific activity, SA) is another useful quantity defined as Ci/g or Bq/kg. SA is defined by $Ci/g = (1.3 \times 10^8) / (\text{half-life in days} \times \text{atomic mass})$.

Example 1. Internal Dose from a Cardiac Scan

A patient is given 20 mCi technetium-99m as part of a cardiac stress test performed in a university teaching hospital. First, express this activity in SI units. We therefore have $20 \times E-3 Ci \times 3.7 E+10 Bq/Ci = 740 MBq$. What is the patient dose from this medical procedure?

From the Radiation Internal Dose Information Center (RIDIC) and from CDC Dosimetry Services (<http://www.internaldosimetry.com/linkedpages/doseestimates.html>), we have a DCF (dose per unit input; $1.3 E-2 mSv/MBq$ for ^{99m}Tc). The effective dose equivalent is therefore $740 MBq \times (1.3 E-2 mSv/MBq) = 9.6 mSv = 0.96 rad$. Our patient has therefore received an effective dose of about 1 rad during the cardiac stress test. The key to effective and efficient internal dose calculations is proper determination of the DCF. Another very useful compilation of DCF data and health physics information in general is the Radiation Dose Assessment Resource, RADAR (<http://www.ieo.it/radar/>).

Assume that ^{99m}Tc has an effective half-life of 6 hours. After one half-life (6 hours), there is 10 mCi remaining, after two half-lives (12 hours), there is 5 mCi remaining, and so forth.

Example 2. Regulatory Limits

What are the current regulatory limits to the public and to occupational workers (Table 104-1)?

Example 3. Illustrations of Commonly Used Radioisotopes

Give some illustrations of commonly used radioisotopes and their uses (Table 104-2).

TABLE 104-1 Regulatory Limits

Members of the Public	Limit
Occupational Limits	100 mrem
Total effective dose equivalent	5 rem
Lens of the eye	15 rem
Single organ dose equivalent	50 rem
Skin dose equivalent	50 rem
Extremity dose equivalent	50 rem

TABLE 104-2 Commonly Used Radioisotopes and Their Use

NUCLIDE	HALF-LIFE	SpA (Ci/g)	EMITS	USE
H-3	12.3 yr	9640	Beta	Luminous signs
Co-60	5.3 yr	1130	Beta, gamma	Medical therapy
I-131	8.05 days	1.23×10^5	Beta, gamma	Medical therapy
Cs-137	30 yr	87	Beta, gamma	Medical therapy
Ir-192	84 days	9170	Beta, gamma	Industrial radiography
Ra-226	1620 yr	0.99	Alpha, gamma	Medical therapy
U-235	7×10^8 yr	2.1×10^6	Alpha, beta, gamma	Reactors/weapons
Pu-238	87 yr	17.2	Alpha	Thermoelectric generation
Pu-239	24,400 yr	0.061	Alpha	Reactors/Weapons
Pu-241	13.2 yr	112	Beta	Waste product
Am-241	458 yr	3.2	Alpha, gamma	Smoke detectors

SpA, specific activity.

Example 4. Typical Radiation Dose in Life Activities and in Common Medical Procedures

Provide some illustrative dose estimates for common life and medical activities (approximate doses) (Table 104-3).

Example 5. Common Industrial Applications of Radioactive Materials

Describe various common applications where radioactivity is used, and therefore where the possibility of an accident exists (not comprehensive).

IONIZING RADIATION: MEDICAL, INDUSTRIAL, AND CONSUMER PRODUCT APPLICATIONS

- Radiography, analytical, and irradiation techniques (e.g., irradiation of food products)
- Instrument calibration techniques using unsealed radioactive sources
- Industrial gamma and x-ray industrial radiography (nondestructive testing)
- Medical diagnostic radiography

Industrial beta and neutron radiography; x-ray fluorescence gauges such as instrumentation to detect residential lead levels

Photon switching gauges (level gauges)

Medical therapy: radiation beam therapy and brachytherapy for cancer treatment

High-level radiation sources for sterilization of food and medical products, food preservation, and cross-linking, curing, and grafting

Radioisotope tracer techniques in research and the therapeutic use of radiopharmaceuticals

Use of radioisotopes for self-luminous dials and devices

Radioisotopes for enhancement of electrical discharge, static elimination, and commercial and residential smoke (approximately $0.9 \mu\text{Ci}$ of ^{241}Am in each residential smoke detector).

Use of radioisotopes for nuclear batteries, such as those used in spacecraft and in remote areas of the earth for instrumentation

APPENDIX B. ASSETS AVAILABLE TO ASSIST IN THE MEDICAL MANAGEMENT OF RADIATION ACCIDENTS

Two major U.S. organizations are available to assist the toxicologist in the initial medical management of the radiation victim. These are the Radiation Emergency Assistance Center/Training Site (REAC/TS; www.orau.gov/reacts/), a Department of Energy medical asset located in Oak Ridge, Tennessee, and the Armed Forces Radiobiology Research Institute (AFRRI) located in Bethesda, Maryland.

Since its formation in 1976, REAC/TS has provided medical support and advice in the medical management of many radiation accidents. A 24-hour emergency response team is available through the U.S. Department of Energy 24-hour number in Oak Ridge, Tennessee (865-576-1005). The Center's team of physicians, nurses, health physicists, radiobiologists, and emergency coordinators is prepared around the clock to provide medical and health physics assistance at the local, national, or international level.

TABLE 104-3 Dose Estimates for Common Life and Medical Activities

ACTIVITY	DOSE ESTIMATE
Natural background and manmade radiation (annual average dose equivalent, including radon)	360 mrem
Diagnostic chest x-ray	6–10 mrem
Flight from Los Angeles to Paris	5 mrem
Barium enema	800 mrem
Smoking 1.5 packs per day for 1 year	16,000 mrem = 16 rem
Heart catheterization	45,000 mrad = 45 rad = 0.45 Gy
Mild acute radiation syndrome	200 rad = 2 Gy
LD ₅₀ for acute whole body irradiation	450 rad = 4.5 Gy
Occupational limit for a radiation worker	5 rem = 0.05 Sv
Limit of a member of the public	0.1 rem = 0.001 Sv = 1 mSv

The AFRRI is a tri-service laboratory chartered in 1961 to conduct research in the field of radiobiology and related matters essential to the operational and medical support of the U.S. Department of Defense and the military services. The institute collaborates with other governmental facilities, academic institutions, and civilian laboratories in the United States and other countries. Its research findings have had broad military and civilian applications. The AFRRI Biodosimetry Team may be reached at 301-295-0484 and the Medical Radiobiology Advisory Team (MRAT) physician may be reached at 301-295-0530.

In particular, the Biodosimetry Assessment Tool (BAT) is a comprehensive software application developed by the AFRRI for recording diagnostic information in suspected radiologic exposures. The application, for use on the Microsoft Windows operating system, is available at www.afri.usuhs.mil. A companion program, the First-responder Radiological Assessment Triage (FRAT) software application, is a complementary product under development for use on hand-held PDAs. It is being designed as templates into which first responders record clinical signs and symptoms, lymphocyte counts, physical dosimetry, radioactivity, and location-relevant dose estimates.

The FRAT and BAT applications compare collected data with known radiation dose response to provide triage and multiparameter dose assessment. The software allows the entry of exposure information based on multiple parameters (physical dosimetry, prodromal symptoms, hematology, radiation cytogenetics, etc.). Templates are available for recording exposure information based, for example, on physical dosimetry (e.g., personnel dosimeters) or contamination (e.g., radioactivity bioassay counting). An integrated, interactive human body map permits convenient documentation of the location of a personnel dosimeter, radiation-induced erythema, and radioactivity detected by an appropriate radiation detection device.

APPENDIX C. RADIATION RISK EXAMPLE

A 25-year-old secretary, while on vacation, is notified that an old radium source was found in the back of a desk drawer in her office. The source is traced to a hospital decommissioned some 20 years ago. A time and motion health physics analysis indicates that she may have received, at most, 50 rem (0.5 Sv) over the course of 6 months. The risk analysis was performed using the SURVRAD software,⁷⁰ which generally uses state of the art radiation epidemiology risk models. The SURVRAD computer output follows:

Run date	March 6, 2005
Title	25 year-old secretary with source in her desk
Sex	Female
Race	All races
Type vital statistic	Period-specific
Life table used	1990
Truncate last plateau	No
Risk coefficients	From Thompson et al (1994) and Preston et al (1994)
Type lifetime risks:	Incidence
Leukemia	
Minimal latency (yr)	2
Plateau (yr)	40
Solid cancers	
Minimal latency (yr)	10
Plateau (yr)	100
Leukemia plateau	
Beginning (age)	27
End (age)	67
Solid cancer plateau	
Beginning (age)	35
End (age)	100
DRREF	2.0
Age at first exposure	25
Age at last exposure	25
Total dose equivalent (SV)	0.5000000

MODEL	SITE	RADIATION-INDUCED CANCERS		BASELINE CANCERS	
		PER 10 ⁵	90.0% CI	PER 10 ⁵	PC (90.0% CI)
RR	Oral cavity	121	(52, 280)	826	0.13 (0.05, 0.30)
RR	Digestive	1653	(715, 3817)	11073	0.13 (0.06, 0.30)
RR	Esophagus	107	(46, 248)	245	0.30 (0.09, 1.00)

RR	CNS	23	(10, 54)	483	0.05 (0.02, 0.11)
RR	Thyroid	43	(18, 100)	492	0.08 (0.03, 0.19)
RR	Nonleukemia	7195	(3116, 16617)	47011	0.13 (0.06, 0.31)
AR	Leukemia	157	(67, 362)	203	0.44 (0.11, 1.00)
AR	ALL	40	(17, 93)	22	0.64 (0.00, 1.00)
AR	AML	48	(21, 112)	86	0.36 (0.07, 1.00)
AR	CML	52	(22, 120)	54	0.49 (0.04, 1.00)

Probabilities of causation (PCs) represent the likelihood that either a cancer (for incidence) or cancer death (for mortality) is attributable to radiation exposure. PCs are based on the end of the plateau period for the last age at exposure. The probability of causation PC is defined as the $(RR-1)/RR$, where RR is the relative risk. As noted above, PC is only significant in this case for those cancers of hematopoietic origin (ALL, acute myeloid leukemia [AML], chronic myelogenous leukemia [CML]), although with large uncertainty. CLL is thought by most investigators not to be radiation-related.

A Nerve Agents

EDWARD W. CETARUK, MD

At a Glance...

- Nerve agents are highly toxic organophosphate compounds that inhibit the enzyme acetylcholinesterase as their mechanism of action.
- Their mechanism of action is identical to that of organophosphate pesticides, although they are more highly toxic.
- Historically, they have been manufactured and used by the military. However, more recently, they have been manufactured and used by nongovernmental terrorist groups as well.
- Nerve agents can be absorbed by multiple routes: inhalational, dermal, and ingestion.
- Patients present with a cholinergic syndrome that may include excessive salivation, lacrimation, incontinence of bowel and bladder, abdominal cramping, respiratory distress including wheezing and dyspnea, vomiting, miosis, muscular weakness, fasciculations, and paralysis, coma, and seizures.
- Antidotes for nerve agent poisoning include atropine (to block the effect of excess acetylcholine at muscarinic receptors), an oxime (to reactivate acetylcholinesterase), and a benzodiazepine (e.g., diazepam) for treatment of nerve agent-induced seizures.
- Early administration of antidotes and aggressive advanced life support measures can result in survival for even severely poisoned patients.
- Decontamination is extremely important in the treatment of nerve agent casualties.
- Nerve agents can be detected by a wide range of chemical detection equipment.
- Proper personal protection equipment is essential for those responding to a nerve agent release.

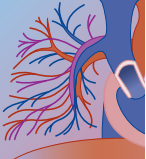

RELEVANT HISTORY

Nerve agents are extremely toxic organophosphate compounds that were initially developed by the German chemist Gerhard Schrader, who synthesized tabun in 1937 (GA) while researching new insecticides. Tabun was followed by the development of sarin (GB) in 1938, soman (GD) in 1944, and then VX (developed by Ghosh in England) in 1952. Although stockpiled in great quantities during both World War I and World War II, nerve agents were not employed in warfare until the Iran-Iraq War during the 1980s. Many additional nerve agents have been developed since the G agents, including derivatives of the G and V agents, newer binary agents, and others not described in the open scientific

literature. However, resources are readily available that provide detailed information regarding the preparation of nerve agents, as well as other chemical weapons.¹

The government of Iraq was responsible for the first large-scale use of nerve agents in warfare as well as against civilians. The Iraqi army use of tabun in a 1984 attack on Iranians near al-Basrah is the first documented use of a nerve agent in warfare. During the 1980s, Iraqi military forces also undertook an attempt to eradicate, relocate, and otherwise commit genocide against the Kurdish population of northern Iraq. The Kurds sought self rule for the ethnic region of Kurdistan, which encompasses geographic portions of northern Iraq, southeastern Turkey, and western Iran. During this war, they often allied themselves with the Iranians and were considered traitors and saboteurs by the Iraqi regime. *al-Anfal* was the name given to a series of eight military offensives, conducted in six geographic areas between February and September 1988. However, their first use of chemical weapons is reported to have occurred almost 1 year earlier, with the bombing of Sheikh Wasan and the Balisan Valley on April 16, 1987. Based on reports from survivors and medical care providers, both mustard and nerve agents were used. The operation was under the command of Saddam Hussein's cousin, Ali Hassan al-Majid, also known as "Chemical Ali," and officially began in February 1988 with conventional and chemical weapon attacks on 25 to 30 villages in the Jafati valley, including Sergalou, Bergalou, and Halabja, a town just a few miles from the Iranian border. The eighth and final Anfal operation was against the 300 to 400 Kurdish villages of Badinan, a 4000 square-mile area of the Zagros Mountains bounded to the east by the Greater Zab River and to the north by Turkey. The actual number of people killed during this genocide may never be known but has been estimated to be in the hundreds of thousands.

To date, the most significant uses of nerve agents against civilians by a terrorist group have been by the Aum Shinrikyo cult of Japan. This cult, led by Chizuo Matsumoto, who later took the name Shoko Asahara ("Bright Light") to attract followers, was well financed with assets estimated in the hundreds of millions of dollars. It subscribed to Asahara's "doomsday" philosophy that included causing catastrophic anarchy in Japan so that he could take power in the aftermath. The Aum chemical weapons program was able to produce significant quantities of VX and sarin, and lesser amounts of other nerve agents, mustard agent, phosgene, and cyanide. Nerve agents were used in a number of

assassinations of cult “enemies,”^{2,3} as well as two large-scale attacks.^{4,7} The first was in Matsumoto, Japan on June 27, 1994, when the cult released about 20 kg of sarin vapor from a specially equipped van in an effort to assassinate three district court judges hearing a civil suit brought against the cult. This attack killed seven people and sent several hundred more to local hospitals, with 58 being admitted for treatment. The Aum subsequently perpetrated another, larger-scale nerve agent attack in Tokyo on March 20, 1995. In this attack, about 159 ounces of sarin was released from eight nylon-polyethylene bags (three additional bags were recovered intact) that were punctured by *Aum* cult members between 7:46 AM and 8:01 AM on five of Tokyo’s main subway lines, causing 12 deaths. Ultimately, Tokyo hospitals and clinics saw 5510 patients: 17 critical, 37 severe, and 984 moderately ill. More than 70% of those presenting for treatment had no objective signs of nerve agent poisoning. Additional aspects of this event are addressed later under Management of Mass Casualties.

All nerve agents are organic ester derivatives of phosphoric acid, with varied chemical functional groups replacing the hydroxyl radical group of the basic phosphate structure. All are volatile liquids at room temperature, colorless, tasteless, and odorless. However, several of the G agents have been reported to have a fruity or sweet smell.⁸ Their vapors are all heavier than air; hence, they tend to remain close to the ground, traveling downwind, downhill, and into geographic depressions. These physical characteristics make them ideal for controlled deployment and dissemination by either military forces or terrorists, although weather conditions can unpredictably disperse chemical agent releases, resulting in exposure to the terrorists who released the agent.⁶

The physicochemical properties affect their use as chemical weapons. Volatility and vapor pressure determine the likelihood that a chemical agent will be an inhalational threat. At room temperature, nerve agents exist as liquids and therefore must be aerosolized or evaporated to become inhalational threats. In traditional military munitions, nerve agents are disseminated by artillery shells or rockets using low-order bursting charges to disperse the agent on impact, or can be sprayed from aircraft. Binary and trinary nerve agents, whereby multiple separate chemical components combine during the flight of a projectile (e.g., partitioned 155-mm artillery shell, GB-2, M687) to deliver active agent on impact, have also been developed. In their attack on the Tokyo subway system, the Aum Shinrikyo simply allowed sarin that leaked from punctured nylon-polyethylene bags to evaporate. Because this dissemination method was relatively inefficient, affecting primarily nearby people, it caused only 12 fatalities out of potentially hundreds or thousands.

Another important characteristic of nerve agents is persistence: the ability to remain present and active in the environment after dissemination. Although nerve agents with high volatility pose significant inhalation hazard, they soon evaporate and dissipate, limiting their persistency. Agents with low volatility and vapor pressure,

such as the V agents, do not readily evaporate and therefore do not pose an inhalational threat, but they are persistent. Ambient temperature directly correlates with an agent’s rate of evaporation and inversely correlates with its persistence. Generally speaking, sarin evaporates about as fast as water, cyclosarin about 20 times slower, and VX about 1500 times slower.¹ Heavily splashed tabun, soman, or cyclosarin (GF) will persist for 1 or 2 days and V agents for weeks to months.¹ As a result of their environmental persistence (creating a prolonged contact threat), the V agents have often been weaponized and deployed (e.g., land mines) to deny territory or the use of equipment to an enemy on the battlefield. Also, some of the G agents (e.g., soman) have been “thickened” to decrease their volatility and make them more persistent. Additional factors that affect an agent’s persistence in the environment include hydrolysis (all agents undergo spontaneous hydrolysis) and density (higher-density liquids and aerosols remain in the environment longer).

PATHOPHYSIOLOGY OF INJURY

Nerve agents exert their primary toxicity at cholinergic synapses of the central and peripheral nervous systems and at neuromuscular junctions that use acetylcholine (ACh) as their neurotransmitter. It is released from presynaptic postganglionic parasympathetic nerve fibers (innervating exocrine glands and smooth muscle), somatic motor nerve endings (i.e., the neuromuscular junction), and both parasympathetic and sympathetic preganglionic nerve fibers, and at synapses within the central nervous system (CNS). Under normal physiologic conditions, ACh binds to specific receptors (AChRs) on the postsynaptic membrane of the cholinergic synapse. AChRs are divided into two major types: nicotinic (found at cholinergic synapses in the CNS, at parasympathetic and sympathetic autonomic ganglia, and at the neuromuscular junction) and muscarinic (found at cholinergic synapses in the CNS, at postganglionic parasympathetic nerve termini, and at the postganglionic sympathetic fibers that release acetylcholine rather than norepinephrine) of sweat glands. Binding of ACh to a nicotinic receptor results in opening of membrane sodium channels and depolarization of the postsynaptic neuron or skeletal muscle cell. Muscarinic AChRs modulate their effects through the G-protein secondary messenger system and are found on smooth muscle and exocrine glands and in the CNS.

The enzyme acetylcholinesterase (AChE, E.C. 3.1.1.7) is located on the postsynaptic membrane of all cholinergic synapses and the neuromuscular junction where it terminates or regulates cholinergic activity by hydrolyzing ACh within the synapse. AChE is a serine esterase that contains an active site composed of neighboring esteratic and anionic active sites that cooperate to catalyze the hydrolysis of acetylcholine. The choline quaternary nitrogen of ACh forms an electrostatic bond with a glutamate amino acid residue in the anionic site, essentially positioning the acetyl moiety of ACh in the esteratic active site. The carbonyl carbon of ACh binds to

the hydroxyl group of serine-203 residue of the enzyme's esteratic site, forming an unstable tetrahedral enzyme-substrate intermediate (which is also stabilized by hydrogen bonding with other amino acid residue moieties within the esteratic site), which spontaneously collapses, releasing the choline moiety and leaving the acetyl group bound to the esteratic site. The acetyl-AChE bond is then quickly and spontaneously hydrolyzed by weakly nucleophilic H_2O , releasing acetic acid and regenerating AChE to its active form. Hydrolysis of ACh decreases its concentration in the synapse and at postsynaptic AChRs, terminating cholinergic stimulation of the postsynaptic cell.

Nerve agents are derivatives of phosphoric acid whose relative toxicity, as well as their toxicokinetics, is largely determined by the molecular substitutions on the organophosphate skeleton. Their primary mechanism of toxicity is the inhibition of AChE by acting as pseudosubstrates, occupying AChE's esteratic active site and inhibiting its hydrolysis of ACh in the synapse. The nucleophilic hydroxyl group of serine-203 (activated by the adjacent imidazole nitrogen of histidine) attacks this electrophilic phosphorous atom of the nerve agent (activated by the presence of an adjacent alkyl moiety, also called a "leaving group"), forming a stable covalent bond and phosphorylating the AChE serine residue. In contrast to the relatively unstable tetrahedral ACh-AChE intermediate, the nerve agent-AChE intermediate is extremely slow to spontaneously hydrolyze. This results in noncompetitive inhibition of AChE, leading to increased synaptic concentrations of ACh and continual stimulation of the postsynaptic acetylcholine receptors, producing a clinical cholinergic toxidrome.

Similar to the loss of acetylcholine's choline moiety, nerve agents bonded to AChE undergo dealkylation to release a functional group in a process referred to as "aging."^{9,10} However, unlike acetylcholine, the loss of this leaving group results in an irreversible nerve agent-AChE bond that permanently inactivates AChE. Amino acid mutation studies have shown that the configuration and type of amino acids within the catalytic gorge of AChE containing the anionic and esteratic active sites is thought to have significant impact on AChE's interaction with each anticholinesterase compound, especially the alkyl functional (leaving) group.¹⁰⁻¹³ This may explain why this aging can occur within minutes for some nerve agents (e.g., soman) or over many hours for others (e.g., VX).⁹ In vitro studies have shown that soman irreversibly phosphorylates AChE within minutes (half-life of 2.2 ± 0.3 minutes).¹⁰ Once aged, AChE cannot be reactivated by spontaneous hydrolysis or by an oxime antidote (see later).

Nerve agents inhibit a number of serine esterases, including acetylcholinesterase (red blood cell cholinesterase or true cholinesterase, E.C. 3.1.1.7), butyrylcholinesterase (plasma cholinesterase or pseudocholinesterase, E.C. 3.1.1.8), carboxylesterase (EC 3.1.1.1), and neurotoxic esterase (NTE).¹⁴ Nerve agents are also thought to exert toxic effects by inhibiting other noncholinesterase targets.^{15,16} These include serine proteases, a large family of enzymes that also use a serine hydroxyl group in their

esteratic active site. These proteases are important in the formation, as well as breakdown, of many biologically active peptides (e.g., enkephalin, endorphin, substance P), that, in turn, modulate the activity of neurotransmitters. For example, substance P acts to modulate the nicotinic acetylcholine response. These noncholinesterase effects of anticholinesterase compounds may explain the clinical manifestations of nerve agent exposure not explained by acetylcholinesterase inhibition alone.¹⁶ Van Meter and colleagues showed that sarin could induce seizures in rabbits, even though their AChE had already been profoundly inhibited by a prior dose of sarin (administered with atropine to prevent seizures).¹⁷

CLINICAL PRESENTATION

Nerve agents exert their toxic effects at peripheral muscarinic and nicotinic nerves by inhibiting acetylcholinesterase, resulting in excess acetylcholine at the postsynaptic acetylcholine receptors, and by multiple, and not completely understood, CNS effects (Table 105A-1). The clinical manifestations can be described in terms of organ systems, acetylcholine receptor distribution, routes of nerve agent exposure, and severity of exposure.

The characteristic clinical toxicity of nerve agents is a cholinergic toxidrome, which is a direct result of excess acetylcholine binding to nicotinic and muscarinic acetylcholine receptors in the CNS, the autonomic nervous system, and the neuromuscular junction. Muscarinic manifestations of nerve agent poisoning include excess exocrine secretions and smooth muscle contraction. These effects are often summarized in the mnemonics SLUDGE or DUMBELS, which include salivation, lacrimation, urination, gastrointestinal distress, defecation or diarrhea, emesis, bronchoconstriction and bronchorrhea, and miosis. The most clinically significant of these are the respiratory effects, bronchorrhea and bronchoconstriction, and should be the initial focus of clinical assessment, treatment, and antidote administration. Nicotinic manifestations of nerve agent poisoning are primarily the result of excess acetylcholine at the neuromuscular junction causing skeletal muscle fasciculations, weakness, and eventually, paralysis. Paralysis of the skeletal muscles involved in respiration, including the diaphragm, adds to muscarinic-mediated respiratory distress and can rapidly lead to respiratory failure or apnea. Excessive acetylcholine at autonomic ganglia may cause increased heart rate and hypertension. However, these manifestations are not typically clinically significant in the overall picture of nerve agent poisoning. Diaphoresis is also seen as a result of excessive cholinergic tone at the autonomic ganglia of sweat glands (Table 105A-2).

As mentioned previously, the respiratory system is the site of the most serious acute clinical manifestations of nerve agent poisoning. The direct effects of the nerve agent on the respiratory tract (bronchorrhea and bronchoconstriction), inhibition of the CNS medullary respiratory center, and paralysis of the diaphragm and

TABLE 105A-2 Signs and Symptoms Following Short-Term Nerve Agent Exposure

SITE OF ACTION	SIGNS AND SYMPTOMS
Ciliary body	Frontal headache, eye pain on focusing, blurred vision
Conjunctivae	Hyperemia
Nasal mucous membranes	Rhinorrhea, hyperemia, but this may also be present after systemic absorption
Bronchial tree	Following systemic absorption of liquid and prolonged vapor exposure Tightness in chest sometimes with prolonged wheezing, expiration suggestive of bronchoconstriction or increased secretion, dyspnea, slight pain in chest, increased bronchial secretion, cough, pulmonary edema, cyanosis
Gastrointestinal system	Anorexia, nausea, vomiting, abdominal cramps, epigastric and substernal tightness (cardiospasm) with "heartburn" and eructation, diarrhea, tenesmus, involuntary defecation
Sweat glands	Increased sweating
Salivary glands	Increased salivation
Lachrymal glands	Increased lachrymation
Heart	Bradycardia
Pupils	Slight miosis, sometimes unequal, later maximal miosis (pinpoint pupils); sometimes mydriasis is observed
Bladder	Frequent, involuntary microuination
Striated muscle	Easy fatigue, mild weakness, muscular twitching, fasciculation cramps, generalized weakness including muscles of respiration with dyspnea and cyanosis
Sympathetic ganglia	Pallor, occasional elevation of blood pressure
Central nervous system	Ataxia, generalized weakness, coma with absence of reflexes, Cheyne-Stokes respiration, convulsions, depression of respiratory and circulatory centers resulting in dyspnea and fall in blood pressure; emotional effects very often occur

From Grob D: Manifestations and treatment of nerve gas poisoning in man. US Armed Forces Med J 1956;7(6):781–789. Used with permission.

skeletal muscles associated with respiration^{18,19} combine to cause respiratory failure. Neurologic symptoms include seizures, coma, muscular weakness and paralysis, and delayed neuropsychiatric effects, including depression and anxiety. Gastrointestinal symptoms include vomiting, abdominal cramping, and diarrhea. Respiratory

failure is the ultimate cause of death after nerve agent poisoning.

The severity (i.e., acuity and dose) and route of exposure are also significant factors in determining the clinical presentation of nerve agent poisoning. Nerve agents are well absorbed by all routes (e.g., inhalation,

ingestion, and dermal route). Nerve agents absorbed through the inhalation route cause symptoms within seconds to minutes of exposure, whereas absorption by the dermal route may result in a delay in onset of symptoms because of the time required for the agent to be systemically absorbed. Victims of a vapor or aerosol nerve agent exposure may initially complain of eye pain exacerbated by accommodation, loss of dark adaptation, dim or blurred vision, conjunctival irritation, lacrimation, and miosis. These effects are thought to result both from direct exposure of the eye to the nerve agent vapor and CNS effects.²⁰⁻²² Upper respiratory tract symptoms (e.g., rhinorrhea and nasal congestion) are followed by progressive respiratory complaints, including chest tightness, dyspnea, wheezing, shortness of breath, cough, and increased bronchial secretions. If the exposure is significant or prolonged, other signs of respiratory toxicity rapidly develop, including severe bronchoconstriction, wheezing, bronchorrhea, respiratory distress, and apnea. Inhalational exposure to nerve agents results in the most rapid onset of symptoms because of rapid absorption of nerve agent through the large surface area of the pulmonary bed. Studies have shown that a high percentage of inhaled nerve agent is retained in the lungs, and the systemically absorbed dose is a factor of minute ventilation and the nerve agent vapor concentration.²³ Also, if the concentration of the inhaled nerve agent vapor is high, patients may not develop symptoms in a typical “respiratory route pattern,” with dyspnea, wheezing, and bronchorrhea, but may rapidly

lose consciousness, become apneic, and have seizures due to the rapid absorption of the agent into the CNS (Table 105A-3).

Dermally absorbed nerve agent will initially cause localized symptoms at the site of exposure (e.g., fasciculations, diaphoresis). The rate of dermal absorption of nerve agent is dependent on the physical characteristics of the agent, environmental temperature, type, and condition of the skin exposed.^{24,25} Absorption increases on damaged skin and varies with anatomic location.²⁶ As agent is systemically absorbed, victims develop other cholinergic symptoms, such as bronchorrhea and bronchoconstriction, gastrointestinal symptoms, muscle weakness, and seizures. Development of miosis is delayed³ and is often absent following dermal absorption. It is important to note that dermal exposure to nerve agents may result in latent or progressive intoxication, even after appropriate skin decontamination, owing to deposition of the nerve agents in the skin and delayed systemic absorption.^{24,25} Therefore, victims of dermal nerve agent exposure must be observed for a minimum of 18 hours after decontamination for the delayed development of toxicity.

Sidell reported a case in which a 33-year-old man was splashed in the face and mouth with about 1 mL of a 25% (v/v) soman solution.²⁷ He immediately rinsed his face and mouth with water and was asymptomatic until collapsing about 10 minutes after the exposure. He was immediately treated with atropine (4 mg intravenously, 8 mg intramuscularly) and 2-PAM (2 g intravenously over

30 minutes). Endotracheal intubation was unsuccessful due to trismus. Signs and symptoms included miosis, coma, markedly injected conjunctiva, marked oral and nasal secretions, prominent muscular fasciculations, tachycardia, cyanosis, bronchoconstriction, and decreased respiratory rate and amplitude. He began to awaken after 30 minutes but continued to have fasciculations, tremor, nausea, vomiting, abdominal pain, and restlessness over the next 36 hours. Red blood cell cholinesterase activity was undetectable until 10 days after the exposure.

Sidell also reported a case of a 52-year-old man with an inhalational exposure to sarin.²⁷ Within minutes of noticing increased nasal and oral secretions and difficult breathing while wearing a protective gas mask (later determined to have been damaged), he developed seizures, respiratory distress, miosis, muscular fasciculations, cyanosis, wheezing, and copious secretions. His respirations were less labored, and cyanosis decreased within minutes of being treated with atropine (intravenously and intramuscularly), 2-PAM intravenously, and oxygen. He received a total of 14 mg of atropine, and 6 g of 2-PAM was administered over 1 hour. An electrocardiogram taken 1 hour after admission showed global ST-segment depression. Additional electrocardiograms obtained 18 and 42 hours after admission showed ST-segment elevation in leads I, aVL and V₁₋₃ and ST-segment elevation in leads I, aVL, and V₂₋₆, as well as T-wave inversion in leads I, II, aVL, and V₂₋₆. No cardiac enzymes were obtained, and the patient's electrocardiogram normalized within 4 months.²⁷

PRENATAL AND PEDIATRIC ISSUES

Because of the relatively indiscriminant nature of terrorist attacks on civilians, children will likely be among the victims. A report of the sarin attacks in Matsumoto, Japan in 1994 lists the victims' ages as 3 to 86 years.²⁸ Although information regarding pediatric nerve agent poisoning is minimal, the release of a nerve agent could disproportionately affect children by several mechanisms. If the agent were aerosolized, the higher minute ventilation of children could result in a larger relative inhalational dose compared with adults. Further, the breathing zone for the typical adult is 4 to 6 feet above the floor, compared with a child's, which is much closer to the ground depending on the child's height. Because nerve agent vapor (e.g., sarin) is likely to be at its highest concentration closer to the ground, children potentially face a greater inhalational exposure compared with adults. Also, preambulatory infants, toddlers, or young children will not be able to remove themselves from the scene of a chemical agent release. Even if they were able to walk, they may not know in which direction to escape. These factors may leave proportionately more children poisoned at a scene than adults.

Pediatric victims of nerve agent poisoning may not present with the same pattern of clinical signs and symptoms typically seen in adults. Reports of pediatric organophosphate pesticide poisoning have noted that children are less likely to manifest muscarinic-mediated

glandular hypersecretion and may present with more marked signs of central toxicity such as coma.²⁹ As is seen in other illnesses, pediatric patients often precipitously decompensate as their condition worsens, necessitating more careful assessment and closer monitoring of pediatric nerve agent victims compared with adults.

The more permeable skin of infants and children would also increase absorption of nerve agents because of dermal exposure. Also, because their larger surface-to-body mass ratio, children may absorb a larger relative dose of nerve agent than adults for a given exposure. Their relatively larger body surface area also increases the rate at which they will lose body heat when they undergo water decontamination. Skin decontamination with cold water, or in cold weather conditions, may result in hypothermia in children unless the decontamination water can be warmed or postdecontamination shower warming equipment is used (e.g., heating lamps, warm indoor environment). Because children have smaller bodies, they require smaller equipment (e.g., endotracheal tubes, needles and tubing, oxygen masks and ventilators). Additionally, the personal protective equipment (PPE) worn by first responders, which is essential for the safe response to a chemical terrorist event (e.g., level A), makes moving, working, and delivering care to victims much more difficult. These challenges are compounded when caring for small children, who present unique challenges of their own (e.g., obtaining intravenous access). Finally, the psychological impact that a terrorist attack will have on a child cannot be underestimated. The child will likely witness and experience events that are well beyond the child's scope of understanding and may be forced to do so without the comfort of a parent (who may indeed be a victim). Therefore, as much as is possible, provisions should be made to move children to places of safety where they can be appropriately medically observed, but spared ongoing exposure to the traumatic exposure of a terrorist incident and its aftermath. Ideally and if possible, they should also be reunited with their parents, or other family members, as soon as possible after all medical concerns have been properly attended to.

Adjustment of antidote dosing in children is also essential. In 2003, the U.S. Food and Drug Administration (FDA) approved a pediatric-dose atropine autoinjector. Although not yet widely available, it raises concerns regarding the use of adult-dose autoinjectors in children.³⁰ However, published experience with children receiving supratherapeutic doses of nerve agent antidote has not reported cases of significant poisoning.³⁰⁻³² Ideally antidotes should be administered in appropriate pediatric doses according to weight and severity of poisoning. The doses approved for use in children and adolescents with symptoms of nerve agent poisoning include 0.5 mg for children weighing between 15 and 40 lb, 1 mg for children weighing between 40 and 90 lb, and 2 mg doses for adults and children weighing more than 90 lb. These doses should be repeated and titrated according to clinical response (i.e., improvement and stabilization of respiratory function or control of seizures or other serious neurologic toxicity). A study of

accidental atropine administration using atropine autoinjectors in 268 children found that many received higher than therapeutic doses, and in 20 children, the atropine was administered by an adult. However, only 8% experienced serious signs of atropinization, and no seizures of life-threatening cardiac arrhythmias were reported.³¹ The administration of an oxime antidote is indicated for pediatric nerve agent poisoning and should be done using established pediatric doses: 25 to 50 mg/kg intravenously or intramuscularly. Benzodiazepines are also indicated for severe nerve agent poisoning and should be administered in the appropriate pediatric doses according to the benzodiazepine used. Pediatric dosing for nerve agent antidotes is summarized in Table 105A-4.

The initial assessment of any suspected nerve agent victim should include airway, breathing, and circulation. The initial assessment and triage of pediatric victims of nerve agent poisoning is also different from the approach used for adults. The clinical presentation of a child poisoned by nerve agent may differ from that of an adult. An effective response to a mass casualty incident (MCI) includes rapid assessment, triage, and treatment of victims. However, the typical parameters used for assessing adult victims of a nerve agent attack may not be appropriate for assessing the pediatric victims of the same attack.

Although there is no replacement for sharp clinical acumen in assessing and treating any patient, adult or pediatric, the Pediatric Assessment Triangle (PAT) is a tool developed for the assessment of pediatric patients that uses only visual and auditory clues to develop a first impression of the severity of the child's condition and to identify physiologic instability. It offers a quick (30–60 seconds) standardized approach to triage, resuscitation, treatment, and transport. The PAT includes assessment of appearance, work of breathing, and circulation to

the skin. Appearance is assessed by generally observing the child (e.g., alertness, age-appropriate speech and behavior). Work of breathing is assessed by listening for abnormal breath sounds (e.g., wheezing) and looking for signs of increased work of breathing (e.g., grunting, retractions). Skin circulation is assessed by looking for signs of poor skin perfusion (e.g., pallor, mottling, cyanosis). The combination of all three components of the PAT should determine a child's degree of nerve agent poisoning and need for treatment.

In addition, the JumpSTART system is an adaptation of the START (Simple Triage and Rapid Treatment) algorithm developed as a more appropriate system for assessing children.³³ It should be considered another possible tool for the triage of children in a nerve agent mass casualty incident and is delineated in Figure 105A-1.

Similar to children, elderly victims with impaired mobility may find it difficult to escape from the scene of a nerve agent release. Therefore, it is theoretically possible that they may have prolonged exposure at the incident scene. Also, elderly individuals with preexisting medical conditions, especially cardiac and pulmonary disease, may have lower tolerance of the clinical manifestations of nerve agent poisoning (e.g., respiratory distress, hypoxia) or to the adverse effects of antidotes (e.g., atropine). However, the overall approach to triage and treatment of elderly victims is the same as for adults.

There are very few data regarding nerve agent poisoning in pregnancy. However, there were five pregnant women among the victims of the Tokyo sarin attack.^{4,5} All had signs and symptoms of mild exposure and were admitted for observation, but none required antidotal treatment. Although one victim reportedly underwent an elective abortion as a result of the exposure (F. R. Sidell, personal communication), follow-up questionnaires sent to victims 1 month and 1 year after the incident reported no fetal malformations.²⁸

TABLE 105A-4 Pediatric Nerve Antidote Indications and Doses

SYMPTOMS	TRIAGE LEVEL: DISPOSITION	ATROPINE*	PRALIDOXIME	BENZODIAZEPINES (E.G., DIAZEPAM, MIDAZOLAM)
Asymptomatic	Delayed: observe	None	None	None
Miosis, mind rhinorrhea	Delayed: admit or observe	None	None	None
Miosis and any other symptom	Immediate-moderate: admit	0.05 mg/kg IV or IM Repeat as needed q5–10 min until respiratory status improves	25–50 mg/kg IV or IM (may repeat q1h) Adverse effects: Muscle rigidity Hypertension Laryngospasm Tachycardia	For any neurologic effect 30 days to 5 years: 0.05 to 0.3 mg/kg IV (maximum of 5 mg/dose) May repeat q15–30 min 5 years and older: 0.05 to 0.3 mg/kg IV (maximum of 10 mg/dose) May repeat q15–30 min
Apnea, convulsions, cardiopulmonary arrest	Immediate-severe: admit critical care status	0.05–0.1 mg/kg IV, IM, per endotracheal tube No maximum Repeat q5–10 min as above	25–50 mg/kg IV or IM as above	See above

*Correct hypoxia before IV use due to increased risk for ventricular arrhythmias.

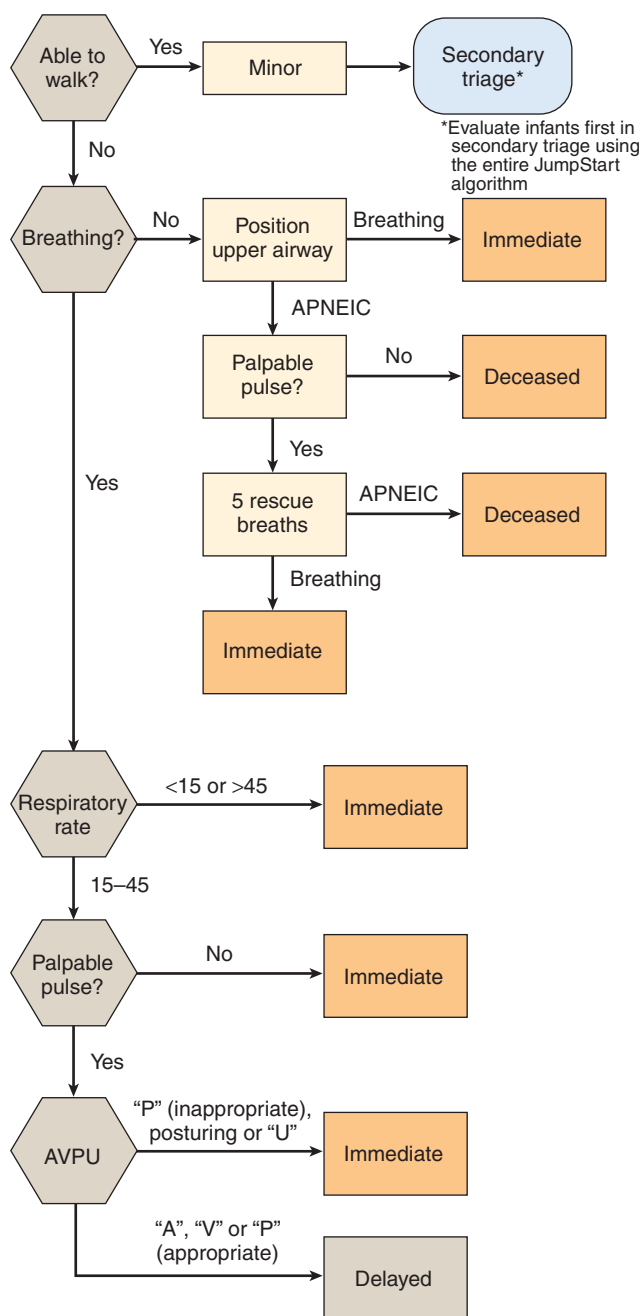

FIGURE 105A-1 JumpStart algorithm. AVPU: alert, verbal, painful, unresponsive (referring to neurologic function). (From Romig LE: Pediatric triage: a system to JumpSTART your triage of young patients at MCIs. *JEMS* 2002;27(7):52-58, 60-63. Used with permission.)

Therefore, in the absence of any additional data regarding nerve agent poisoning and its treatment during pregnancy, all therapeutic interventions recommended for adults should be used in pregnant patients as well.

ASSESSMENT

The diagnosis of nerve agent poisoning may be made on the basis of a single patient's presentation (i.e., a

cholinergic toxidrome), and on a situational basis, in which multiple patients present with similar or identical symptoms that, collectively, suggest a diagnosis of nerve agent poisoning.³⁴ Regardless of how the diagnosis is determined, because of the extreme toxicity of nerve agents, victims must be evaluated as quickly as possible to determine their need for airway management (i.e., intubation) and the administration of antidotal therapy (e.g., atropine and oxime). Therefore, the clinical assessment of a nerve agent victim is based on the severity of their cholinergic toxidrome. Although useful retrospectively, the measurement of cholinesterase activity is not practical in the acute assessment of a nerve agent victim because of the delay in obtaining results. Further, in the case of an MCI, the initial assessment of victims must be accomplished in a rapid and efficient manner so as to triage victims for treatment.

Victims of a vapor nerve agent exposure will likely present with ocular and upper respiratory symptoms as described previously. Miosis is the earliest sign of a vapor nerve agent exposure but may be absent or delayed in a dermal exposure. Patients with only miosis and upper respiratory tract symptoms can be observed without treatment. Patients with lower respiratory tract manifestations (e.g., wheezing, dyspnea), neurologic symptoms (e.g., seizures, weakness) or multiple-organ system involvement should receive antidotal therapy with atropine and an oxime (see Treatment section). The assessment of victims of dermal nerve agent exposure should also be based on the severity of their clinical cholinergic toxidrome. However, it is important to note that initial symptoms can be localized to the site of nerve agent exposure and that severe or fatal toxicity can develop up to 18 hours after exposure. All patients should be reassessed frequently for worsening, or resolution, of symptoms, the effectiveness of antidote administration, or the need for additional antidote.

TREATMENT

The most immediate concern in the treatment of acute nerve agent poisoning is to establish an airway and provide adequate ventilation and oxygenation, using advance life support techniques including intubation and ventilation with supplemental oxygen. Mouth-to-mouth resuscitation is not recommended because of the high risk for rescuer contamination and poisoning. Note that oropharyngeal intubation may be difficult owing to trismus from muscular spasm and fasciculations or seizures.^{24,27} Succinylcholine should be used with extreme caution and at lower doses because its pharmacologic half-life and duration of paralysis may be markedly prolonged as a result of nerve agent inhibition of plasma cholinesterase.³⁵ During the 1991 Persian Gulf War, military patients who had received pyridostigmine (a carbamate acetylcholinesterase inhibitor) as a nerve agent pretreatment and then underwent intubation using succinylcholine did not exhibit prolonged paralysis. However, they did have copious upper airway secretions requiring large amounts of atropine.³⁶ These

initial advanced life support measures should be accompanied by the earliest possible administration of nerve agent antidotes, including atropine, an oxime, and a benzodiazepine for the treatment of seizures. Initial ventilation may demonstrate marked airway resistance due to severe bronchoconstriction and bronchorrhea. Therefore, atropine should be administered as soon as possible by whatever route is available (e.g., intramuscular, intravenous, endotracheal) to reverse the respiratory effects of the nerve agent.

Decontamination is a critical step in the care of nerve agent victims. Continued absorption of agent will significantly undermine the effectiveness of advanced life support measures and antidotes administered to victims of nerve agent poisoning. Therefore, treatment plans and protocols should provide for decontamination taking place as early as possible. The key to successful mass casualty decontamination is to use the fastest approach that will cause the least harm and do the most good for the most people. The choice of decontamination methods depends on the route and intensity of exposure and available resources. Briefly, victims with dermal exposure require thorough decontamination, including undressing and full-body water decontamination. Large-volume, low-pressure water is the preferred method of decontamination. Soap is also recommended but has not been found to offer significant benefit over timely and adequate water decontamination. Victims with *only* vapor exposure (i.e., no possible contact with liquid agent) to nerve agent can be adequately decontaminated by removing them from the exposure and undressing them. If the exposure occurred indoors, moving the patient into outdoor fresh air and undressing them should be sufficient. If nerve agent is released outdoors in sufficient quantity to create toxic ambient concentrations, upwind evacuation from the plume of agent is necessary, as is respiratory protection for rescuers and victims if possible. See the Management of Mass Casualties section for a more complete discussion of decontamination.

Decontamination should begin with removal of the victim's clothing. It is estimated that removal of all clothing will provide about 80% of all possible decontamination after vapor exposure to a nerve agent. In addition, nerve agents from aerosols or vapors can adsorb into victims' clothing and then off-gas well after the victim has been removed from the site of exposure. Victims of the 1995 Tokyo subway sarin attack were transported from the scene of the attack without any form of decontamination. Prehospital first responders quickly became symptomatic until ambulances were ordered to keep all windows open to maximize ventilation during transport. Hospital-based care providers also became symptomatic after exposure to off-gassing victims who were brought into the hospital without decontamination.^{4,5}

Atropine is a direct-acting competitive muscarinic receptor antagonist. It binds to muscarinic AChRs, preventing ACh from binding, thereby decreasing cholinergic tone at the postsynaptic cell or organ, including smooth muscle, exocrine glands, and muscarinic synapses within the CNS. Other potent antimuscarinic

compounds have also been investigated as potentially effective organophosphate antidotes.^{27,37,38} Atropine reverses muscarinic-mediated smooth muscle contraction and exocrine hypersecretion. This clinical effect is most important in the lungs, where excessive bronchorrhea and bronchoconstriction lead to hypoxemia, decreased ventilation, respiratory failure, and death. However, note that the respiratory failure is also the result of CNS nerve agent toxicity at the medullary respiratory center. Atropine does not bind to nicotinic receptors and therefore does not have any therapeutic effect at the neuromuscular junction or ganglia. Because the AChRs found at the neuromuscular junction are nicotinic, atropine does not reverse skeletal muscle paralysis. Atropine eye drops can be used to reverse nerve agent-induced miosis and paralysis of accommodation.³⁹

Adverse effects of atropine are unlikely except if administered to a victim misdiagnosed with a cholinergic toxidrome (i.e., nerve agent or other organophosphate poisoning). These include increased heart rate, drying of secretions, mydriasis, loss of accommodation, and decreased sweating.³² The last of these adverse effects is the most significant and can lead to severe hyperthermia, especially in the setting of a warm environment or physical exertion.^{31,40} All patients who receive atropine should be monitored not only for therapeutic improvement but also for signs of anticholinergic effects.

The recommended adult dose of atropine is 2 mg, which can be administered intravenously, intramuscularly, endotracheally, or by autoinjector (e.g., Mark I kit). The autoinjector is an effective means of administering atropine expeditiously because it can quickly deliver antidote through clothing (including PPE). Animal studies have shown that atropine administered by autoinjector was absorbed at a rate intermediate between intravenous administration and intramuscular administration with a conventional syringe.^{41,42} Atropine administration should be repeated in 2-mg doses every 5 to 10 minutes based on clinical response. The most critical indicator of antidotal response is pulmonary function (i.e., drying of bronchial secretions and decreased airway resistance). This can be assessed by the patient's self-reported ease of breathing or by improved compliance if the patient is being artificially ventilated. There is no dose limit for the total amount of atropine administered, and end of therapy should be determined by clinical stabilization. Patients who require continued antidotal treatment after initial improvement should be suspected of having continued dermal nerve agent absorption and undergo repeat decontamination.

The early administration of antidotes is critical in the treatment of nerve agent poisoning. Antidotal therapy for nerve agent poisoning includes atropine, an oxime, and a benzodiazepine (each is discussed in detail later). The decision to administer an antidote is based on the severity of poisoning and route of exposure. Victims of an inhalational exposure that present with mild symptoms including miosis, eye pain, and rhinorrhea, but no other significant signs or symptoms, may be observed without the administration of antidote. Those with any complaints of respiratory distress, including

shortness of breath, complaints of chest tightness, wheezing, or dyspnea, should be treated with a initial administration of 2 mg of atropine plus pralidoxime, 600 mg through intramuscular autoinjector or 500 to 1000 mg/hour through intravenous infusion. If respiratory symptoms are significant (e.g., dyspnea, wheezing, shortness of breath), or the victim has additional symptoms such as weakness or vomiting, the initial doses of atropine and pralidoxime should be doubled to 4 mg of atropine through intramuscular or intravenous injection, and 1200 mg of pralidoxime (i.e., two 600-mg intramuscular autoinjectors). Victims with severe manifestations of nerve agent poisoning, including severe respiratory distress or apnea, seizures or coma, or significant skeletal muscle weakness, should receive initial doses of atropine and pralidoxime of 6 mg and 1800 mg, respectively, as well as a benzodiazepine to treat or prevent seizures.

OXIME ANTIDOTES

Oximes are the second important antidote in the treatment of nerve agent poisoning.⁴³ Their primary role is to reactivate AChE after it has been phosphorylated by a nerve agent by removing the nerve agent from its active site. Oximes reactivate AChE by acting as potent nucleophiles that attack the phosphorous moiety of the nerve agent, cleaving the nerve agent–serine-203 bond and displacing the nerve agent from the enzyme active site as an oxime–phosphate complex.¹⁰ Because atropine effectively antagonizes the muscarinic effects of nerve agent poisoning, oximes are clinically most important because of their ability to reactivate AChE in nicotinic synapse, restoring neuromuscular function and reversing skeletal muscle paralysis.

In the United States, 2-pralidoxime chloride (2-PAM, pyridine-2-aldoxime methochloride, Protopam) is the only oxime currently approved by the FDA for the treatment of organophosphate or nerve agent poisoning. However, other oximes, including obidoxime, pralidoxime iodide (2-PAM iodide), pralidoxime mesylate (P2S), pralidoxime methylsulfate, and trimedoxime (TMB4), are available in other countries. The differences in the oxime effectiveness are mainly due to the variation in aging rates that the nerve agent, the oxime, and the animal model, including human, used.⁴⁴⁻⁴⁷ The reactivation of AChE inhibited by VX, sarin, or GF is possible hours after the intoxication, whereas soman-inhibited AChE cannot be reactivated within minutes after intoxication because of its rapid aging of AChE.

Pralidoxime can be administered by repeat intramuscular injection (e.g., autoinjector), as described earlier, to reach the traditional therapeutic level of 4 µg/mL.^{48,49} If pralidoxime is administered intravenously, a dosing regimen consists of an intravenous bolus of 500 to 1000 mg over 30 minutes, followed by an infusion of 500 mg/hour, appears to maintain a concentration of about 13 mg/L for a 70-kg person, which is above the previously reported minimum therapeutic level (4 µg/mL)^{48,49} and below the level at which adverse effects are seen

(14 µg/mL).⁵⁰ The infusion should be continued until the patient's muscle weakness has resolved. As a general rule, any victim that receives atropine should also receive an oxime antidote.

Newer oximes under active development include the bisquaternary oxime Hagedorn agents (H oximes). HI-6 has been shown to as effective, or superior, to 2-PAM in the treatment of OP pesticide poisoning.^{47,51} HI-6 plus atropine has been reported to produce a protective ratio of 42 against VR (*O*-isobutyl *S*-[2-(diethylamino) ethyl]methylphosphonothioate, a structural isomer of VX, also known as Russian VX), whereas pralidoxime plus atropine under identical conditions produced a protective ratio of 6 (P. M. Lundy, personal communication). Interestingly, although comparable to other oximes as a reactivator of AChE in *in vitro* studies,⁴⁶ HI-6 has been shown to be a more effective antidote in studies in which AChE was permanently and irreversibly inhibited (aged).^{52,53} The newer bispyridinium oximes, including HI-6, have been found to have significant pharmacologic properties not associated with the reactivation of nerve agent-inhibited AChE.⁵²⁻⁵⁵ However, HI-6 and HLö-7 chloride salts are unstable over time in aqueous solution and must be stored as lyophilized powder, complicating their use in autoinjectors.⁵⁶ Recent research has shown the HI-6 dimethanesulphonate salt (HI-6 DMS) to be stable in aqueous solution, as well as safe and effective against nerve agents, making it more attractive for use in autoinjectors.⁵⁷ Overall, HI-6 has shown potential advantages over other oximes and may eventually emerge as the oxime of choice.^{55,58,59} Several countries, including Canada, Sweden, the former Yugoslav entities, and the Czech Republic, are investigating HI-6 as their oxime of choice for the treatment of nerve agent poisoning.

BENZODIAZEPINES

Victims with severe nerve agent poisoning are likely to also have seizures. The addition of a benzodiazepine has been shown to improve survival from nerve agent poisoning and to decrease the development of permanent brain damage.^{60,61} Diazepam is available in an autoinjector and is issued (in addition to 3 Mark I autoinjectors) to U.S. military personnel as part of their nerve agent medical countermeasure kit. It is recommended that a benzodiazepine be administered for any seizure activity as well as for any moderate to severe manifestations of nerve agent poisoning (before the development of seizures). Although diazepam is most commonly recommended, other benzodiazepines should be considered if diazepam is not available, as might be the case in an MCI.

OTHER MEDICAL COUNTERMEASURES IN DEVELOPMENT

Atropine, oximes, and benzodiazepines have been the mainstay of therapy for nerve agent poisoning for almost

as long as nerve agents have been a threat. Additional therapeutic measures in development include other anticholinergic compounds such as biperiden, scopolamine, and trihexyphenidyl. The excitatory neurotransmitter glutamate and its stimulation of the *N*-methyl-D-aspartate (NMDA) receptors, has also been found to play a role in nerve agent-induced seizures. This work has led to research in the development of NMDA receptor antagonists such as MK801 and gacyclidine (GK-11) that may find a place in nerve agent treatment in the future.^{59,62}

MANAGEMENT OF MASS CASUALTIES

Decontamination and patient management priorities at the scene of a terrorist attack using nerve agents include collection of victims at a point upwind of the chemical hazard, the establishment of a clean-dirty line between the contaminated (i.e., “hot”) and uncontaminated (i.e., “cold”) zones, and the administration of initial medical treatment if necessary (i.e., antidotes, advanced life support). Plans should include means to decontaminate both ambulatory and nonambulatory victims and provide a way for emergent medical treatment to be administered as soon as possible once the patient exits the “warm” decontamination zone (Fig. 105A-2). If adequate PPE is available for medical personnel, treatment may be started earlier (i.e., before or during decontamination).

Basic principles of mass casualty decontamination include the following: (1) decontamination should take place as soon as possible—expect the ratio of unaffected to affected to be about 5:1; (2) disrobing *is* decontamination and should be the earliest step in the process; (3) high-volume, low-pressure water showers are the best mass decontamination method; and (4) after a known dermal exposure, first responders must be decontami-

nated as soon as possible.⁶³ Terrorist attacks using nerve agents in cold weather present additional decontamination challenges. If ambient temperatures are above 18.3° C (65° F), all methods of decontamination can be done outdoors. As ambient fall below 18.3° C (65° F), heated enclosures should be made available for postdecontamination shelter. As ambient temperatures fall further, water decontamination should take place in a heated enclosure, and under extreme weather conditions (e.g., below 1.7° C [35° F]), dry decontamination methods are recommended (e.g., removal of all outer garments and dry blotting of the skin with absorbents) until victims can be transported to a heated facility for water decontamination. However, regardless of the ambient temperature, people who have been exposed to a known life-threatening level of chemical contamination should disrobe, undergo decontamination with copious amounts of high-volume, low-pressure water or an alternative decontamination method, and be sheltered as soon as possible.⁶⁴ In 2003, the FDA approved a reactive skin decontamination lotion (RSDL) for use as a decontaminating liquid for dermal nerve agent exposure. It is an oximate-based skin decontaminant developed in Canada and currently in use worldwide.⁶⁵ In the absence of a water-flushing or showering system, it represents a viable method of portable decontamination.

Ideally, all victims would undergo adequate decontamination before leaving the incident scene. Historically, however, about 70% to 80% of victims of an MCI evacuate themselves and each other from the incident scene and then self-triage to nearby health care facilities. This creates the need for decontamination plans and equipment at the receiving health care facilities. This was the case during the 1995 Tokyo sarin attack, when there was no field decontamination of victims at the incident scene. Secondary contamination occurred at the receiving hospitals, with 23% of the Saint Luke’s hospital staff developing signs and symptoms of

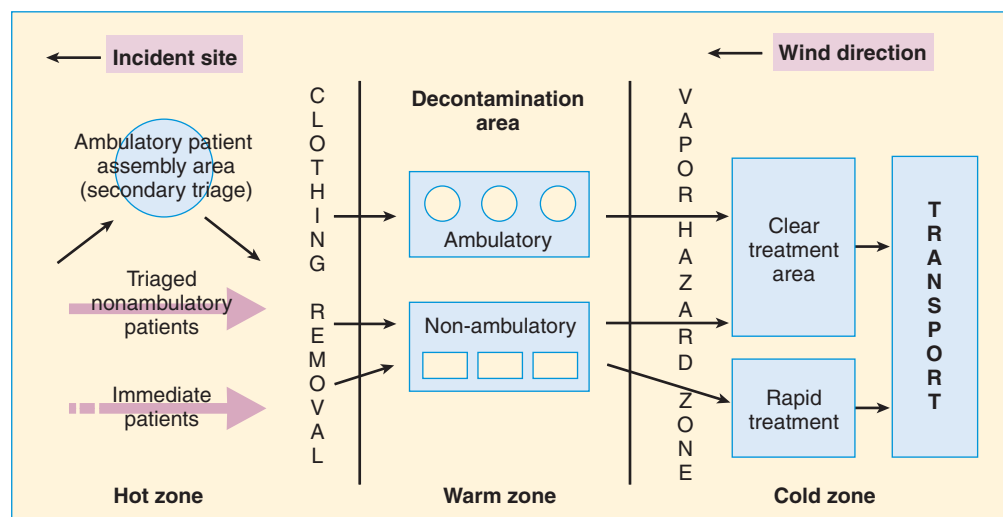

FIGURE 105A-2 The dual-corridor emergency decontamination system has two corridors for the triage, decontamination, and treatment of nerve agent victims. (From U.S. Army Soldier and Biological Chemical Command (SBCCOM): Guidelines for mass casualty decontamination during a terrorist chemical incident. Aberdeen, MD, Edgewood Chemical Biological Center, 2003.)

sarin poisoning while treating the hundreds of victims, many of whom were contaminated, who presented to the hospital. Forty-six percent of those working in a poorly ventilated hospital chapel became symptomatic. However, only one nurse was admitted, and no one required antidotal treatment.^{4,5,34,66} An inhalational exposure is likely due to the use of a nerve agent aerosol or vapor, as in the Tokyo subway attacks of 1995. Victims exposed to nerve agent vapor adsorb the agent into their clothing and off-gas the agent after they have been removed from the exposure. The risks associated with off-gassing include continued inhalational exposure for the patient and medical care providers who will be in close proximity to the patient, especially indoors and in confined spaces (e.g., ambulances). This was seen after the Matsumoto and Tokyo sarin attacks, in which prehospital care providers became symptomatic from exposure to sarin off-gassing from victims transported to hospitals by ambulance. Hospital care providers also became symptomatic as a result of off-gassing from patients brought into the hospital without decontamination.

The hospital response to a terrorist nerve agent attack should anticipate mass casualties arriving unannounced, contaminated, and in a disorganized fashion. Saint Luke's Hospital's first victim arrived on foot 30 minutes after the attack and was followed by about 500 more within the next 30 minutes. Among 640 victims who presented to Saint Luke's Hospital on the day of the attack, 15% arrived by emergency vehicle (only 10% by ambulance), 48% by foot or private vehicle, and 25% by taxi. Radio-dispatched taxis played a significant role in transporting victims from the scene and were also important in communicating information.^{4,5} Typically, because they are the most able to flee the incident scene and make their way to the hospital, most of the early presenters are less severely affected than those incapacitated at the scene.

Ten percent of first responders developed acute signs and symptoms of nerve agent poisoning (some requiring treatment) primarily as the result of sarin vapor off-gassing from the clothing of victims during ambulance transport to hospitals.⁴ In comparison, 35% of emergency responders developed signs of sarin toxicity while rescuing victims of the 1994 Matsumoto sarin attack, although most were thought to have been exposed as a result of entering the area of the sarin release without adequate respiratory protection.⁶⁷

PRINCIPLES OF PREPAREDNESS

It is a commonly accepted concept that *all disasters are local*. This is a very important reality that must be considered in all stages of disaster planning and preparedness. As much as outside assets (e.g., state, federal, nongovernmental) are mobilized as soon as any major MCI takes place, it is arguably unlikely that logistics will allow them to be involved in the initial emergency response at a significant level within 48 hours of the incident. Therefore, consumable supplies, medications, antidotes, personnel, and safe food and water should be

stockpiled in quantities to suffice for at least 3 days or more, depending on the community's accessibility.

An important step in preparing to respond to a nerve agent terrorist attack is to perform community risk assessments to identify potential targets, their degree of vulnerability to attack, and when an attack would be likely to occur. By determining the maximum number of potential victims for a "worst case scenario" attack, preparations can be made to respond. Advance planning should include identifying potential staging areas, victim collection points, sites for decontamination stations, and sites for victim and responder sheltering in extreme weather conditions for all sites (e.g., sports arenas, mass transit systems) that are deemed at high risk for a terrorist MCI based on a community vulnerability analysis. Additionally, alternatives for all sites mentioned should also be determined.

Another essential step is to take inventory of any and all resources that are *available* in your community to respond to a terrorist attack. This assessment should include decontamination equipment, personnel, hospital beds, alternative health care facilities, ambulances, antidotes, ventilators, PPE, and additional items too numerous to list here. This should be followed by an estimation of what is *needed* to respond to an MCI in your community (based on a vulnerability assessment). In the event that a community's maximal response capability could not adequately respond to a worst case scenario, emergency preparations should include planning to rapidly access, or even predeploy in the case of a scheduled event (e.g., large sporting event), outside assets to close the gap between likely emergency response needs and those locally available. Access to outside assets can be facilitated by the advanced establishment of interagency and interjurisdictional memoranda of understanding that delineate how and when assets are brought in to assist with a local MCI or major disaster. The difference between the two is the *gap* that additional planning and preparation can lessen. Emergency planners should avail themselves of the many published after-action reports and "lessons learned" developed after MCIs that have occurred as the result of both terrorist acts and natural events.^{4-7,66-71}

One of the most important and critical assets for responding to an MCI is personnel. However, it is important to include in an emergency response plan the possibility, or likelihood, that responders at all levels may also be victims of the attack, degrading the ability for the emergency and medical communities to respond. Additionally, it has become an established fact that first responders, and even health care facilities, may be targeted with secondary devices or nerve agent releases. Further, the possibility of a mixed weapon or multiple-location attacks should be considered in the allocation of resources once the incident has occurred.

Although this chapter focuses on nerve agents, an "all-hazards approach" should be used as the basis for developing a plan to respond to a terrorist nerve agent attack. By establishing robust plans and procedures for responding to any hazardous materials (Hazmat) event, additional measures (e.g., specific antidote availability,

B Vesicants

LAWRENCE STILWELL BETTS, MD, PHD ■ BRIAN CHRISTOPHER BETTS, MD

At a Glance...

- Sulfur mustard (or “mustard”) is the most significant member of the vesicant agents. It is the only vesicant with known use in combat.
- Skin lesions produced by contact with vesicant agents are nonspecific and, alone, are of little diagnostic value in identifying the etiology in early cases. History of the use of, or presence of, a vesicant agent, or prior cases with similar presentations, is of great value in approaching the differential diagnosis.
- The most important preventive measure to control exposure is avoidance of contact; the most important treatment measure to limit injury is prompt decontamination.

- Skin decontaminants available to the general public include a dilute hypochlorite solution (0.5%); military chemical agent decontaminants, such as the M291 kit, can be used as available.
- There is no specific antidote for mustard, and medical management of cases is based on treating signs and symptoms as they develop.
- Patient management ranges from very simple, for erythema or minor vesicles, to extremely complex, for immunosuppressed patients with multisystem derangements and extensive skin lesions.
- Disposition of casualties varies with intensity of exposure, delay and efficacy of decontamination, and severity of injuries.
- Repeated occupational exposures to mustard at levels that result in toxic effects are known to cause cancer of the upper airways.

RELEVANT HISTORY

A *vesicant* is a chemical that produces vesicles or blisters at the site of contact. This class of “military chemical agents,” specifically sulfur mustard (also called *H*; *HD*; CAS No. 505-60-2; *mustard gas*, *mustard*), has been a major military threat agent since its introduction in combat in World War I. The vesicants constitute a hazard to exposed skin and mucous membranes in both the vapor and liquid states. Three groups of vesicants are considered useful for tactical military weapons as “chemical agents”: the mustard agents, the arsenicals, and the halogenated oximes. The main vesicant agents and their short-hand military designations are listed in Table 105B-1.

Sulfur mustard (bis-[2-chloroethyl] sulfide) was first used as a weapon in World War I. Mustard was responsible for more battlefield casualties than caused by all of the other chemical agents. Mustard is the most important agent in the vesicant group and remains a current military threat today. Although chemical agents were not used on the battlefield in World War II, their

use by Iraq was reported during the 1980s during in the Iran–Iraq conflict. Some of the Iranian casualties were evacuated and treated in Belgium, the country where mustard was first used in warfare in 1915 and in France. An excellent discussion and color image presentation of the clinical findings and medical management of these casualties is provided by Jan L. Willems.¹ The images can also be found in the *Textbook of Military Medicine*.²

Lewisite, or dichloro-2-chlorovinylarsine, is an arsenical compound that produces toxic effects more rapidly than mustard. Lewisite has not been used in combat and has a low military threat potential. The widely known chelating agent, dimercaprol, or British Anti-Lewisite (BAL), was originally developed for use as an antidote for Lewisite. BAL currently finds therapeutic application in the treatment of some metal poisonings.

Phosgene oxime (dichloroformoxime) is the only representative of the halogenated oxime group with military application. It is not a true vesicant. Although it causes irritation and corrosion, reaction to contact results in a solid, urticaria-like lesion that is not filled with fluid. The military includes it as a vesicant agent, and a

TABLE 105B-1 Vesicant Groups*

AGENT	MILITARY SYMBOL	COMMON NAME	ONSET OF PAIN	TISSUE DAMAGE
Mustard Agents				
<i>bis</i> -(2-chloroethyl) sulfide (Impure) (C ₄ H ₈ Cl ₂ S and contaminants)	<i>H</i>	<i>Mustard</i> ; sulfur mustard; <i>Yperite</i> ; “lost”	Delayed—hours	Immediate

<i>dichloroformoxime</i> (Cl ₂ CNOH)	<i>CX</i>	<i>Phosgene oxime</i>	Immediate	Seconds

*Prototype agent in italics.

[†]Lewisite, or agent “T” (a vesicant chemically related to mustard), is added to decrease the freezing point and maintain the liquid form at lower ambient temperatures

brief discussion is included in this chapter. Phosgene oxime has not been used in combat, and there is little information regarding its use and toxicity. Although it is considered to have a low military threat potential, its rapid penetration of protective garments and rapid onset of severe effects make it of military interest.²

Because of the amount of information available on the use and effects of mustard from World War I and the Iran–Iraq conflict, and the relative lack of information on Lewisite and phosgene oxime, this chapter discusses mustard as the prototype vesicant.

EXPOSURE SCENARIOS

Mustard can contaminate environmental surfaces, including food and water supplies. During World War I, exposure to mustard resulted in a large number of casualties, but relatively few deaths. These findings underlie the reasons vesicants have military application. The potential for their use, with the accompanying fear of injury and need to avoid exposure, requires personnel to carry or wear protective equipment and to be fearful when touching anything, including food and water supplies. The need for precautions and the use of protective equipment restricts and impairs the ability to maneuver and fight. The resulting casualties decrease the strength of the fighting force, require medical assets, and further affect morale. It is easy to understand why the mere threat to use a chemical agent can be a powerful military tactic. The potential to use a vesicant against an unprotected and unknowing civilian population could be an even greater weapon in the hands of a terrorist.

The volatility of a chemical agent and its persistence in the environment are inversely related: The more volatile agents have less persistence in the environment. They simply evaporate based on their vapor pressure. However, the vapor may still present a significant hazard! Temperature is the main environmental factor affecting persistence. Other environmental factors, such as terrain, wind, and rain, also affect dispersal and persistence. All these factors have been exploited in the past to obtain a

military advantage. At temperatures below 57° F (14° C), mustard is a solid, but still biologically active, chemical. It forms a persistent, oily liquid at higher temperatures that may be detected by its garlic- or onion-like (mustard) odor. In areas such as the Middle East, where summer temperatures often exceed 100° F (38° C), evaporation into the vapor state becomes significant. Such temperatures increase the risk for exposure to mustard vapor, but they simultaneously decrease its persistence.³ The finding of more casualties with eye and lung damage during the Iran–Iraq conflict than were observed in World War I has been attributed to the higher temperatures and increased volatilization in the hotter climate. Mustard vapor is also much denser than air and forms high vapor concentrations close to the ground or in low-lying areas. When an agent evaporates off the ground after dispersal, injuries may occur low on the body or in individuals in low-lying areas. To maintain mustard in the liquid state at lower temperatures, mustard has been mixed with other chemicals (including Lewisite) to decrease its freezing point.

Chemical warfare material (CWM), composed of stockpiled agents (Table 105B-2) and “nonstockpiled” materials (such as buried items and contaminated objects from former production and storage), are currently being destroyed under federal statute and the Chemical Weapons Convention demilitarization program.⁴ Although extremely remote, there is a possibility of accidental release during storage, transportation, or destruction of the agent or its original container. Programs have been established to inform and educate adjacent communities regarding the potential risks and planned emergency response actions. In 2001, the Agency for Toxic Substances and Disease Registry released a draft toxicologic profile for “Mustard Gas” for review and comment. When officially released in 2003, the name of the profile was changed to “Sulfur Mustard.” This profile provides a comprehensive review of the environmental release and public exposure concerns.⁵

Nonmilitary “environmental” exposures have been reported in the literature.^{6,7} Often these reports involve adults or children finding undetonated shells. In some

TABLE 105B-2 Chemical Agents in the U.S. National Stockpile

AGENT	MILITARY SYMBOL/ NAME	CHEMICAL ABSTRACT SERVICE (CAS) NUMBER
bis-(2-chloroethyl) sulfide	H, HD; sulfur mustard	505-60-2

isopropyl methylphosphonofluoridate	GB; Sarin	107-44-8
O-ethyl-S-(2-diisopropylaminoethyl)-methyl phosphonothiolate	VX	50782-69-9

The Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and Their Destruction, also known as the Chemical Weapons Convention (CWC), was signed by the United States on January 13, 1993, and ratified by Congress on April 25, 1997. The CWC mandates that nonstockpile chemical warfare materials (CWM) be destroyed by 2007. Extensions to this deadline can be obtained.⁴

From National Center for Environmental Health: Final Recommendations for Protecting the Health and Safety against Potential Adverse Effects of Long-Term Exposure to Low Doses of Agents: GA, BV, VX, Mustard Agent (H, HD, V), and Lewisite (L). Public Health Service, Centers for Disease Control and Prevention. Washington DC, U.S. Department of Health and Human Services, 1988.

instances, the shells had remained under water or buried for many years before being found. The shells may leak or even detonate. Accidental exposures of this type still present possible patient scenarios that may be encountered by public service and medical personnel.

PATHOPHYSIOLOGY OF INJURY

The relationship between the toxic effects caused by mustard and the mechanism of cellular tissue injury that causes them is not well understood.⁸ The liquid and vapor states of mustard pass rapidly through intact skin. As a potent alkylating agent, mustard reacts rapidly with structural and functional molecules of the cell, forming adducts. The altered molecules include nucleic acids, proteins, lipoproteins, and peptides, which affect various cell functions and lead to the observed injuries. Because of the rapid rate of these cellular reactions, mustard is quickly “fixed” after only a few minutes in a biologic milieu. Mustard is then no longer present as the “free,” reactive agent. Blister fluid, blood, or other body fluids do not present a continuing exposure hazard to the individual or the caregiver. It must be remembered that mustard may contaminate inanimate objects (such as clothing or equipment) and remain “free” and biologically available for many days! These objects can result in a source of continued or accidental exposure to the vesicant.

As little as a 10- μ g droplet of mustard on the skin can produce vesication. The LD₅₀ from dermal contact to mustard is about 100 mg/kg. This is equivalent to about 7 g, or 5 to 8 mL, of the liquid agent for the average 70-kg person. When dispersed, this amount could cover about one fourth of the body surface with erythema or vesication.² The LD₅₀ for human oral exposure is estimated to be 0.7 mg/kg.⁹

Exposure levels for aerosols or vapors are often expressed in the inhalation and military literature as the product of the substance’s concentration (“C,” in mg/m³) and the duration of exposure (“t” in minutes)—the C · t (or Ct) value expressed as X mg · min/m³. It has been stated that equal Ct values cause equal toxic effects; that is: C × t = k (constant effect) in a relationship known as *Haber’s rule*.¹⁰ Note that in the practical application of Haber’s rule, caution must be used because departures from the rule are possible.¹¹ Table 105B-3 provides Ct values for injuries by different routes of exposure to mustard in the aerosol or vapor states. Although it is unlikely that quantitative exposure data will be available to the treating physician during the early phases of treatment, military chemical agent detectors are becoming more widely distributed. When available, these provide valuable exposure information in the assessment, treatment, and demonstration of contamination and decontamination of patients.

MANIFESTATIONS

Mustard is the only vesicant that does not cause immediate pain. The exposed individual is asymptomatic

TABLE 105B-3 Mustard Ct Values for Aerosol or Vapor Exposure and Injuries

CT VALUE (mg · min/m ³)	INJURY
>10	Eye damage (under laboratory conditions)
Estimated 12–70	Eye damage (under field conditions)
100–500	Airway damage
200–2000	Threshold for skin damage in eye- and respiratory-protected individuals
~1500	Estimated LCt ₅₀ through inhalation

From Sidell FR, Urbanetti JS, Smith WJ, Hurst CG: Vesicants. In Medical Aspects of Chemical and Biological Warfare. Textbook of Military Medicine. Washington, DC, Borden Institute, 1997; and U.S. Army Soldier and Biological Chemical Command (USASBCCOM): Distilled Mustard (HD) Material Safety Data Sheet. Aberdeen Proving Ground, MD, 1999.

until the effects become apparent after a period of delay—usually a few hours to 24 hours. Even in cases with severe (heavy) exposure, the onset of symptoms does not appear in the first hour. All body surfaces that come into contact with the liquid or vapor can be affected, but the eye is the most sensitive target organ, with effects ranging from mild conjunctivitis to severe eye damage. The warm, moist, and thin regions of the skin (such as the groin or axilla) are the most severely affected with erythema and vesicles, with the thicker sites (such as the palm or sole) being less affected. Respiratory tract injuries can range from mild irritation of the upper respiratory tract to severe bronchiolar damage with necrosis and hemorrhage of the mucosa and musculature. Acute, chronic, or delayed clinical effects can also be seen in the hematopoietic, gastrointestinal, and central nervous systems after severe exposures.¹² At very high doses, the systemic effects on the blood-forming tissues can result in leukopenia, thrombocytopenia, and anemia. After mild to moderate exposures, death from systemic effects is not anticipated.¹³

Erythema is an early, mild presentation of skin injury and may be the extent of response to a light (small or mild) exposure. The effects are delayed and do not become apparent until an hour or more after exposure; they may be delayed up to a day or more. The skin reaction resembles sunburn that may be present with itching, burning, or stinging. Frequently, small vesicles form in a linear array that may later join together into larger vesicles. The appearance of vesicles follows the erythema, and they may take several days to fully develop. Data from the early studies of mustard reveal variations in skin sensitivity between individuals with apparently the same, as well as differing, amounts of skin pigmentation. Highly pigmented individuals appear to be more resistant to the acute dermal effects.¹⁴ The nonspecific skin lesions produced by mustard resemble those following contact with plants (Rhus family—poison ivy, oak, and sumac) or other contact irritants. Although difficult to differentiate from effects of typical exposures, suspicious circumstances and a corresponding history of exposure are invaluable in making the diagnosis of vesicant exposure. Often, the initial case or cases will not

be attributed to a chemical vesicant agent. Melanoderma may develop after unroofing of the blisters, aiding in the physical diagnosis.

The latency period for ocular effects is shorter than that for the skin. Ocular effects may appear after exposure to mustard concentrations barely perceptible by odor. These levels are below those that cause effects on the skin or in the respiratory tract.¹³ As the Ct increases (with direct contact of liquid mustard being the worst case), the effects progress to severe damage to the cornea and intraocular structures. Photophobia occurs with even minimal exposures, and it may persist for weeks.

Mustard produces varying degrees of inflammation to the respiratory tract, depending on the Ct. Coughing and shortness of breath are common. The onset and severity of symptoms correspond to the degree of injury, but the injury may develop over a period of several days. Because of the rapid reaction with moist tissues, injury is often confined to the airways and adjacent tissue. Necrosis and sloughing of these tissues may occur. Death from pulmonary insufficiency, due to airway injury and infection, is seen in a small percentage of personnel who reach a medical facility. These deaths commonly occur several days or more after exposure.¹³

Mustard is classified as a known human carcinogen based on human data from manufacturing experience and combat casualties.¹⁵ The human evidence indicates a causal relationship with cancers of the respiratory tract and skin, and possibly leukemia.¹²

PRENATAL AND PEDIATRIC ISSUES

No specific information is available that directs exposure or treatment considerations different from those presented. From the clinical experience involving pediatric casualties during the Iran–Iraq conflict, the onset of symptoms in children was earlier and more severe than in adults.¹⁶ Mustard is known to be a mutagen and a carcinogen.

ASSESSMENT

There is no specific laboratory test available for evaluating exposure to mustard. Analysis of a mustard metabolite, thiodiglycol, in the urine has been developed by the U.S. Army Medical Research Institute of Chemical Defense (USAMRICD) to verify that an exposure to mustard has occurred.¹⁷ Additional methods for analyzing other mustard metabolites as exposure indicators have been developed and are undergoing evaluation.^{18,19}

The current U.S. Army “Standards and Guidelines as of March 2006” give a general population limit (GPL: maximum concentration for long-term exposure to sulfur mustard by the civilian general population) of 0.00002 milligrams per cubic meter of air (0.00002 mg/m³) and 0.0004 milligrams per cubic meter of air (0.0004 mg/m³) for civilian and Department of Defense personnel who work with sulfur mustard (WPLs).²⁰ Incorporating the

National Advisory Committee’s (NAC) acute exposure guideline levels (AEGs)^{21,22} into Army policy, the AEGs are used as guidance to protect individuals from the harmful effects of a single, short-term (8 hours or less) exposure to sulfur mustard. The three AEGL exposure levels have time durations ranging from 10 minutes to 8 hours. The effects at the three levels range from minor discomfort at the lowest concentration and exposure duration (AEG-1) to potentially life threatening at the highest and longest exposure level (AEG-3) (Table 105B-4). The U.S. Army has also adopted an immediately dangerous to life or health (IDLH) level of 0.7 mg/m³ and a short-term exposure limit (STEL) of 0.003 mg/m³ for civilian and Department of Defense workers initially published as interim recommendations by the Centers for Disease Control and Prevention (CDC).²³ On the other end of the exposure spectrum, the Agency for Toxic Substances and Disease Registry (ATSDR) has adopted “minimum risk levels” (MRL: a level below which daily human exposure is likely to be without appreciable risk of untoward non-cancer health effects over a specified duration of time). The following MRLs for sulfur mustard have been established for acute inhalation (1–14 days): 0.0007 mg/m³; intermediate duration inhalation (14–365 days): 0.00002 mg/m³; and acute oral (1–14 days): 0.0005 mg/kg/day and intermediate duration oral: 0.00007 mg/kg/day. Chronic MRLs have not been established.²⁴

TREATMENT

Decontamination involves the physical removal or chemical deactivation of the vesicant. Both fresh and sea water have been used for the mechanical removal and dissolution of solid or liquid vesicants. Although water (with or without soap) is not the ideal option, it may be the only available decontaminant, and it is a reasonable option.²⁵ However, at least one military guidance document cautions against the use of water for removing known mustard agent contamination from the skin.²⁶ Care should be taken to avoid spreading the agent during the decontamination process, and the use of absorbent powders (Fuller’s earth, talcum powder, flour) has been recommended to prevent this from occurring.²⁷ A 0.5% hypochlorite solution (diluted household bleach in water [1:9]) has been used since World War I for decontaminating the skin. A freshly made (daily) solution of alkaline (pH = 10–11) hypochlorite is currently recommended by the U.S. military as the universal decontaminating solution for all liquid and solid agents on the skin.²⁸ Either solution should be rinsed off the intact skin and hair within 4 minutes, taking care to avoid contact with wounds or the eyes.¹³ Poisindex recommends an alternate skin decontamination method of washing with water and a 2.5% sodium thiosulfate solution.²⁹ The use of a hypochlorite solution is not recommended for abdominal wounds, open chest wounds, wounds exposing nervous tissue, or the eye. These sites should be rinsed liberally with appropriate irrigation fluid (normal saline, lactated Ringer’s solution). Vapor exposures are treated by simple removal from the

TABLE 105B-4 National Research Council Acute Exposure Guideline Levels (AEGs) of Sulfur Mustard (adopted by the U.S. Army [in parts per million of air [ppm] and milligrams per cubic meter of air [mg/m³])

SINGLE, ACUTE EXPOSURE PERIOD IN MINUTES	AEGL-1		AEGL-2		AEGL-3	
	Conjunctival injection and minor discomfort; no functional decrement in humans		General conjunctivitis with irritation, edema, photophobia, and eye irritation in humans		Estimated lethal dose estimate in mice	
	ppm	mg/m ³	ppm	mg/m ³	ppm	mg/m ³
10	0.6	0.40	0.09	0.60	0.59	3.9
30	0.02	0.13	0.03	0.20	0.41	2.7
60	0.01	0.067	0.02	0.10	0.32	2.1
240	0.003	0.017	0.004	0.025	0.08	0.53
480	0.001	0.008	0.002	0.013	0.04	0.27

All of the AEGL-1 and AEGL-2 levels, and the 240 minute and 480 minute AEGL-3 levels, are at or below the odor threshold for sulfur mustard. From National Research Council of The National Academies: Acute Exposure Guideline Levels for Selected Airborne Chemicals, Vol. 3. Washington, DC, Subcommittee on Acute Exposure Guideline Levels, Committee on Toxicology, Board on Environmental Studies and Toxicology, 2003; National Advisory Council: Acute Exposure Guideline Levels (AEGs) for Sulfur Mustard (Agent HD). Final Acute Exposure Guidance Levels (AEGs). Washington, DC, National Advisory Committee on Exposure Guideline Levels for Hazardous Substances, 2001; and United States Army Center for Health Promotion and Preventive Medicine (USACHPPM): Chemical Agent Air Standards Status Table: Existing Standards and Guidelines as of March 2006. Environmental Medicine Program, 2006.

contaminated atmosphere.³⁰ There are additional skin decontaminants used by the military (M291 resin kit), which may become more generally available with increased homeland defense capabilities.

Sulfur mustard, in both the impure and pure forms (H and HD, respectively), has been a major military threat agent since its introduction in World War I. It is both a vapor and a liquid threat to all exposed skin and mucous membranes. The effects of mustard are delayed, appearing hours after exposure. This lack of early warning signs may result in a longer period of exposure before decontamination. There is no specific antidote for mustard, and management is based on symptomatic and supportive therapy for the lesions or systemic effects. (See also Chapters 2B, 9, and 15.) Immediate decontamination (within 2 minutes) prevents or maximizes the reduction of tissue damage.

BAL (2, 3-dimercapto-1-propanol; dimercaprol) was developed as an antidote for Lewisite. BAL is currently used in medicine as a chelating agent for heavy metals. There is evidence that BAL in oil, given intramuscularly, will reduce the systemic effects of Lewisite. However, caution should be taken because there are toxic effects associated with the use of BAL. BAL skin ointment and BAL ophthalmic ointment decrease the severity of skin and eye lesions when applied immediately after early decontamination. However, neither of these formulations is currently manufactured.

There is no antidote or specific treatment for phosgene oxime.

MANAGEMENT OF MASS CASUALTIES

Actual measurements of air concentrations of the liquid or vapor will not likely be available in most casualty situations. Based on history and clinical findings, prompt decontamination followed by symptomatic care is

indicated. Topical decontamination is not effective once a chemical agent has been absorbed. For mustard, the greatest efficacy of this treatment is obtained if accomplished in less than 2 minutes after contact, but it may have some value even 15 minutes later.³¹ As discussed previously, a dilute 0.5% hypochlorite solution is used by the military as the preferred decontaminating solution for removing mustard from the skin. If this solution is not available, water (with or without soap) can be used. Care should be taken during decontamination not to force a superficial chemical agent into the skin, or create a wound from a high-pressure water stream. High-volume, low-pressure water (with or without soap) should be used for decontaminating large numbers of exposed individuals. Further treatment for mustard exposure should be based on the clinical findings after decontamination.

PRINCIPLES OF PREPAREDNESS

Prevention of contact and prompt decontamination are the paramount public health measures. Individual exposures are difficult to recognize, and a high index of suspicion must be maintained by public service and medical personnel to recognize cases and avoid self-contamination. Butyl rubber provides a good barrier to mustard.²⁸ The National Institute for Occupational Safety and Health (NIOSH), the U.S. Army Soldier Biological and Chemical Command (SBCCOM), and the National Institute for Standards and Technology (NIST) are working to develop appropriate standards and test procedures for all classes of respirators that will provide respiratory protection from chemical, biological, radiological, and nuclear (CBRN) agent inhalation hazards. Further information can be obtained at <http://www.cdc.gov>. Contact with mustard does not cause immediate pain and, therefore, does not provide a

warning to decontaminate or use personal protective equipment (PPE). Contact with the other two groups of vesicants in either liquid or vapor state results in immediate irritation or pain and provides a warning to decontaminate immediately and don PPE. The immediate onset of irritation or pain may result in less severe lesions from these two groups.

Topically applied barrier and other decontamination creams, as well as decontamination powders, have been recently developed. Distribution will initially be limited to military applications.

C Choking Agents

LAWRENCE STILWELL BETTS, MD, PHD ■ BRIAN CHRISTOPHER BETTS, MD

At a Glance...

- Choking agents cause acute effects in the upper respiratory tract and lungs, including irritation, increased secretions, cough, dyspnea, chest tightness, and pulmonary edema.
- Termination of inhalation exposure by removal of the victim to fresh air (and with copious skin irrigation for liquid exposure), while maintaining the safety of the rescuer, is the initial and most important postexposure action.
- There is no specific, postexposure management for any of the choking agents.
- Depending on the severity of exposure, a period of observation is necessary to fully assess and treat potential lung damage and the delayed development of pulmonary edema.
- The development of several different chronic pulmonary sequelae is possible after acute exposure to agents in this class.
- After even a mildly significant acute event, follow-up pulmonary function testing may reveal persistent changes.

RELEVANT HISTORY

In the classification of military chemical warfare agents, choking agents are often included in the larger category of “pulmonary” or “lung-damaging” agents. Smokes, as members of the choking agents, are among the oldest of the chemical agents. The use of smoke dates back to the time when humans first exploited this by-product of fire in warfare. Industrial process chemicals, namely, chlorine (military symbol: CL) and phosgene (CG), were

used in World War I as simple, but large-scale, chemical weapons. Their use was intended to demoralize the enemy by causing widespread effects from an unseen, and unnatural, opposing force. These two chemicals are representative of the class of chemical warfare agents that cause choking and damage in the upper airways and lungs. The continuum of dose-related toxic effects is similar for all of the choking agents with differences in each agent’s properties and potency. Chloropicrin (PS), diphosgene (DP), sulfur mustard (H, HD), and Lewisite (L) are also considered by the military as choking agents, but the latter two substances are primarily classified as vesicants. The choking agents also include chemicals that are used in conventional warfare, such as zinc-containing smoke (HC), as well as chemicals associated with industrial and agricultural processes. The United States does not consider nonlethal chemicals, such as riot control agents and herbicides, as “chemical warfare agents,” which are controlled under the 1925 Geneva Convention.¹ Table 105C-1 provides data on selected choking agents and their sources. The riot control agents, such as tear gas and pepper spray, may cause choking and other temporary clinical features associated with the choking agents, but they are not discussed in this chapter.

Specific chemicals that cause choking and that are internationally classified as “chemical weapons (CW),” or feedstock, are listed under the Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on their Destruction (Chemical Weapons Convention, CWC),” which entered into force in 1997.² This international treaty prohibits

TABLE 105C-1 Select Military Choking Agents

CHEMICAL	CHEMICAL SYNONYM	CHEMICAL ABSTRACT SERVICE (CAS) NUMBER	MILITARY CHEMICAL AGENT SYMBOL	INDUSTRIAL OR AGRICULTURAL PRODUCT USES OR BY-PRODUCT
Phosgene	Carbonyl chloride	75-44-5	CG	Synthesis of drugs, plastics, adhesives, dyes, pesticides
Chlorine	Molecular chlorine	7782-50-5	CL	Chemical synthesis; bleaching agent; water/waste disinfection
Chloropicrin	Trichloronitromethane; nitrochloroform	76-06-2	PS	Fumigant; pesticide; organic synthesis; dyes
Diphosgene	Trichloromethylchloroformate	503-38-8	DP	Limited chemical synthesis
Military smoke*	HC/HC smokes, TiCl ₄ [†] , others	Mixture of chemicals; 7550-45-0 [†]	HC; FM [†]	Visualization of air movement in ventilation assessments; chemical synthesis; pigments [†]
Perfluoroisobutylene	PFIB	382-21-8	—	Pyrolysis product of organofluoride polymers
Oxides of nitrogen	Nitrogen oxides; NO _x	Numerous	—	Combustion of fuels; welding and other high-temperature operations; fermentation

*Military “HC” smoke contains a mixture of chemicals that cause choking. The military also generates smoke through the partial combustion of fuel.

[†]Titanium tetrachloride (TiCl₄).

the development, production, stockpiling, and use of chemical weapons. However, it does not prohibit production, processing, consumption, or trade of related chemicals that are verified for use in peaceful purposes. Chlorine was the first lethal choking agent used as a chemical weapon in modern warfare. Chlorine was released in Ypres, Belgium in 1915, but it is not controlled as a potential chemical weapon under the CWC. The use of chlorine as a weapon is now obsolete, but its industrial use is enormous. In addition to the chemicals that have been used, or have the potential to be used, as military weapons, perfluoroisobutylene (PFIB), or 1,1,3,3,3-pentafluoro-2-(trifluoromethyl)-1-propene—a thermal decomposition product of tetrafluoroethylene (Teflon) and other organofluoride polymers—is also a controlled chemical under the CWC. Table 105C-2 provides a list of specifically identified (“named”) chemicals that are controlled under the CWC.

The “oxides of nitrogen (NO_x)” comprise a group of compounds that are products of combustion and explosion generated from the discharge of munitions and propellants. These oxides are considered by the U.S. military as choking agents, but they are not used as chemical warfare agents. These compounds can also arise from sources unrelated to combat, including fires, internal combustion engine exhaust, food processing,

and biologic fermentation (see discussion of silo filler’s disease in Chapter 9). Military smokes are also considered choking agents because of their use in military applications. They are not directly used in chemical warfare, and like PFIB and the oxides of nitrogen, excessive exposure can damage the airways or lungs.

The clinical features that follow exposure to any of these chemicals are similar—hence their collective grouping as “choking agents.” Most important, this class contains chemicals that are associated with the development of potentially fatal pulmonary edema. The onset of this pulmonary edema may be delayed for many hours and is “permeability related,” or noncardiogenic in origin.³

EXPOSURE SCENARIOS

The historical use of trench warfare, with the massing of large numbers of troops in interconnected, low-lying positions, made the use, or even the potential for use, of a chemical that could cause choking and lung damage a tactic that could be exploited to military advantage. Denser-than-air gases could be released and follow the pathway created by the defensive earthen channels. With a wind favorable to the user, the opposing forces would be forced to abandon their positions or be required to

TABLE 105C-2 Named Chemicals and Chemical Abstract Service (CAS) Numbers Scheduled under the Chemical Weapons Convention (CWC)

Schedule 1*	Toxic chemicals: sarin (107-44-8); soman (99-64-0); tabun (77-81-6); VX (50782-69-9); sulfur mustards (various); Lewisites (various); nitrogen mustards (various); saxitoxin (50782-69-9); ricin (9009-86-3) and related congeners (57856-11-8); chlorosarin: o-isopropyl methylphosphonochloridate (1445-76-7); chlorosoman: o-pinacolyl methylphosphonochloridate (7040-57-5); and related congeners
Schedule 2[†]	Toxic chemicals: amiton: O,O-diethyl S-[2(diethylamino)ethyl] phosphorothiolate (78-53-5); PFIB: 1,1,3,3,3-pentafluoro-2-(trifluoromethyl)-1-propene (382-21-8); BZ: 3-quinuclidinyl benzilate (6581-06-2); and related congeners Precursors: methylphosphonyl dichloride(676-97-1); Dimethyl methylphosphonate (756-79-6); <i>N,N</i> -dialkyl (Me, Et, n-Pr or i-Pr) phosphoramidic dihalides (various); dialkyl (Me, Et, n-Pr or i-Pr) <i>N,N</i> -dialkyl (Me, Et, n-Pr or i-Pr)-phosphoramidates (various); arsenic trichloride (7784-34-1); 2,2-diphenyl-2-hydroxyacetic acid (76-93-7); quinuclidin-3-ol (1619-34-7); <i>N,N</i> -dialkyl (Me, Et, n-Pr or i-Pr) aminoethyl-2-chlorides (various); <i>N,N</i> -dialkyl (Me, Et, n-Pr or i-Pr) aminoethane-2-ols (various); <i>N,N</i> -dialkyl (Me, Et, n-Pr or i-Pr) aminoethane-2-thiols (various); thiodiglycol: bis(2-hydroxyethyl)sulfide (111-48-8); pinacolyl alcohol: 3,3-dimethylbutan-2-ol (464-07-3); and related congeners
Schedule 3[‡]	Toxic chemicals: phosgene (75-44-5); cyanogen chloride (506-77-4); hydrogen cyanide (74-90-8); chloropicrin (76-06-2); and related congeners Precursors: phosphorus oxychloride (10025-87-3); phosphorus trichloride (7719-12-2); phosphorus pentachloride (10026-13-8); trimethyl phosphate (121-45-9); triethyl phosphate (122-52-1); dimethyl phosphate (868-85-9); diethyl phosphate (762-04-9); sulfur monochloride (10025-67-9); sulfur dichloride (10545-99-0); thionyl chloride (7719-09-7); ethyldiethanolamine (139-87-7); methyldiethanolamine (105-59-9); triethanolamine (102-71-6); and related congeners

*Criteria considered for listing chemical in schedule 1: chemical has been developed, produced, stockpiled, or used as a chemical weapon; chemical has a high potential for use in prohibited activities due to similarities in structure and toxicity as chemicals listed in Schedule 1; chemical has significant lethality or incapacitating properties that could have application as a chemical weapon; chemical could be used as a precursor in the final stage of production of a Schedule 1 chemical; and chemical has little or no use for nonprohibited purposes.

[†]Criteria considered for listing chemical in schedule 2: chemical poses a significant risk due to its lethality or incapacitating toxicity and other properties useful in chemical weapons; chemical may be used as a precursor in the final stages of making schedule 1 or 2 chemicals; chemical may be important in the production of schedule 1 or 2 chemicals; and chemicals is not produced in large quantities for purposes that are not prohibited.

[‡]Criteria considered for listing chemical in schedule 3: chemical has been produced, stockpiled, or used as a chemical weapon; chemical poses a risk due to its lethality or incapacitating toxicity and other properties useful in chemical weapons; chemical may be important in the production of one or more chemicals listed in schedule 1 or schedule 2; and chemical may be produced in large commercial quantities for non-prohibited purposes
Data from Organisation for the Prohibition of Chemical Weapons (OPCW): Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on Their Destruction (Chemical Weapons Convention). don cumbersome protective equipment. However, even before the end of World War I, the volatile choking agents were replaced with the more persistent (and more controllable) vesicants in order to deny terrain and maneuverability, harass the opposition, cause casualties, consume resources, and create fear. Although no longer a military threat on the battlefield, chemicals that can cause choking and pulmonary damage are found in large quantities in industrial and agricultural settings. The sizeable amounts and widespread availability of this group of chemical agents create the potential for an occupational or environmental catastrophe—or an attractive weapon to a terrorist for release into an enclosed structure. These choking agents do not need to be synthesized by a terrorist; they only need to be commandeered! Concern for the use of these agents by terrorists caused the Centers for Disease Control and Prevention to issue an alert through the Health Alert Network on New Year's Eve 2003.⁴

Phosgene replaced chlorine as a chemical weapon and accounted for 80% of all chemical fatalities during World War I.⁵ Although phosgene was stockpiled in munitions for use in World War II, it was not used and is no longer stockpiled by the U.S. military.⁶ Phosgene is extensively used as a feedstock in many chemical processes. It is also formed when chlorinated compounds are heated to decomposition. This can occur when a chlorinated compound—found in solvents, degreasers, and dry cleaning agents—contacts a high temperature source, such as a welding arc or flame. Plastic materials containing chlorinated compounds produce phosgene when they burn. Phosgene is considered a potential chemical weapon,⁷ and the potential for individual or mass exposure from weaponized military use, industrial accidents, or acts of terror still presents a significant risk. The physiologic effects caused by exposure to phosgene and their medical management are representative of the general class of “choking agents.”

Military smokes, or “obscurants,” are used to conceal personnel and equipment. Exposure to obscurants may occur in training or combat situations, or the products or devices may be used by terrorists during an attack. HC smoke is produced from a reaction involving zinc oxide, hexachloroethane, and fine aluminum particles. HC smoke contains zinc chloride, as well as phosgene, carbon monoxide, and other chlorinated hydrocarbons. There are many other military obscurants, including chlorosulfonic acid (CSA); titanium tetrachloride (FM), and partially burned hydrocarbons. Although militarily useful in low concentrations, exposure to high or heavy concentrations of obscurants for extended periods can result in illness or death.^{5,8}

Choking agents can be produced from nonmilitary processes or sources. PFIB results from the pyrolysis of materials containing organofluoride polymers, such as tetrafluoroethylene (Teflon). Modern military vehicles, aircraft, and vessels use significant amounts of these polymers. Fires in vehicles, aircrafts, ships, and structures present possible situations in which PFIB can be formed and inhaled. Oxides of nitrogen (NO_x) are formed as products of combustion and of fermentation (see

Chapters 9 and 86). NO_x may be produced with carbon monoxide during combustion of a fuel in air (air is about 78% nitrogen and about 21% oxygen). In individuals with exposure to exhaust gases from internal combustion engines using various fuels, the physiologic effects of NO_x may be initially combined and masked with those caused by carbon monoxide.^{9,10} Silo filler's disease is caused by the inhalation of nitrogen dioxide (one member of the family of NO_x compounds), which is formed during fermentation of corn and other green plants.¹¹

PATHOPHYSIOLOGY OF INJURY

Choking agents can cause asphyxiation; irritation and damage to mucous membranes (affecting the airways, alveoli, or the tissues surrounding them); alteration of systemic processes; or an allergic response.¹² The toxic effects caused by exposure to a specific inhaled chemical are due to many factors, including the properties of the chemical, the chemical concentration, and the duration of exposure—the latter two factors comprise the “Ct” product discussed in Chapter 105B. Additional factors are related to the health status of the exposed individual, as well as the individual's level of activity during, and after, the exposure. Heavy activity during exposure results in deeper breathing and deeper penetration of the toxicant into the lungs. Heavy activity after exposure results in greater physiologic stress on the respiratory and circulatory systems—and perhaps a greater degree of tissue damage. The potential to cause delayed pulmonary edema through effects leading to membrane disruption at the alveolar–capillary bed is common to all the choking agents (see Chapters 8 and 9).

MANIFESTATIONS

Choking agents cause acute clinical effects in the upper respiratory tract and lungs, including irritation, increased secretions, cough, dyspnea, chest tightness, and pulmonary edema. One of the most important clinical features of agents in this class is the potential to cause pulmonary edema after a clinically unremarkable latent period. The period of time before the onset of pulmonary edema is related to the severity of the exposure (Ct) and to the prognosis. The onset of signs and symptoms of pulmonary edema within 4 hours of exposure is a sensitive indicator of a poor prognosis. Without intensive medical support, there is a high risk for death in patients with this early finding.⁶ Acute exposure to choking agents may result in chronic bronchitis, emphysema, bronchiolitis obliterans, or reactive airway dysfunction syndrome (RADS) (see Chapters 8 and 9).

PRENATAL AND PEDIATRIC ISSUES

Clinically significant exposure to choking agents can result in acute hypoxia in the mother and an associated lowered PO_2 level available to the fetus. This may result in

harm to the pregnancy or the fetus. Asthma, in any age group, may be nonspecifically initiated or exacerbated by exposure to the irritant effects of the choking agents.

ASSESSMENT

A history of exposure is essential to make and confirm an early diagnosis during the latent period. A period of observation is necessary as the dose-dependent clinical effects resulting from pulmonary damage become apparent over time. The prognosis for patients developing early pulmonary edema, cyanosis, and hypotension is poor. Survival is greater in patients developing these findings 4 to 6 hours or longer after exposure, and in those with immediate, intensive medical care.⁶

TREATMENT

The primary initial treatment consists of cessation of exposure. For inhalation exposure, moving the patient to fresh air and insuring an open airway and proper ventilation is essential, while taking precautions to prevent the rescuer or caregiver from also becoming a victim! For exposure to liquids, remove clothing and rinse liquid agents off the skin with copious soap or detergent and water irrigation. The eyes should be rinsed with running water or saline. Supplemental oxygen, intubation, suction, and mechanical ventilation are used as needed to treat respiratory distress. Based on the exposure history and clinical findings, a period of forced rest and observation is important in the medical management. The potential development of delayed, noncardiogenic pulmonary edema requires medical observation for a suitable period of time based on the severity of exposure and the clinical course. Treatment of pulmonary edema and other clinical findings, and the use of steroids and other therapeutic agents and modalities, are discussed elsewhere in this text. See Chapters 9, 86, 93, and 102.

A short latent period is a harbinger of a more severe clinical course. Patients developing pulmonary edema within 12 hours of exposure will usually require intensive pulmonary care. Based on U.S. Army triage recommendations, patients with dyspnea and no objective signs should be observed closely and reevaluated hourly. Asymptomatic patients with known exposures should be observed and reevaluated every 2 hours. If these patients remain asymptomatic for 24 hours, they may be considered for discharge. Patients with doubtful exposures, and no symptoms after 12 hours of observation, can also be considered for discharge at that time.⁶ The chest radiograph is helpful in the assessment before discharge. If not available, Borak and Diller recommend an observation period of 24 hours for asymptomatic patients after suspected phosgene inhalation.³

MANAGEMENT OF MASS CASUALTIES

The activity of patients under evaluation after inhalation of any of the choking agents should be controlled. Physical activity¹² and emotional factors³ can influence the development and severity of clinical findings.

PRINCIPLES OF PREPAREDNESS

The absence of early signs or symptoms involving mucous membrane irritation or respiratory distress, or a warning odor of a chemical, does not prove that an exposure was inconsequential. It is necessary to maintain vigilance for patients presenting with a reliable history of exposure to a choking agent, or with developing signs and symptoms consistent with such an exposure.

D Lacrimators

ANDIS GRAUDINS, MBBS (HONS), PHD

At a Glance...

- Lacrimators are also known as *irritant incapacitants*, *tear gas*, and *riot control* or *harassing agents*.
- Lacrimators are used primarily by law enforcement and military personnel for riot control.
- Lacrimators usually result in transient incapacitation with skin and mucosal membrane irritation.
- When used at high concentrations (i.e., enclosed, poorly ventilated spaces), lacrimators may produce significant respiratory and ocular effects.
- Following chronic, high concentration exposures, lacrimators may produce reactive airways dysfunction and dermatitis in sensitized individuals.
- Physical injury (i.e., cutaneous burns and trauma) may be sustained after exposure to exploding cartridges used to deploy lacrimators.
- Treatment is largely supportive; decontamination of the skin and mucosal surfaces is the mainstay of therapy.
- Medical staff should protect themselves with gloves, gowns, and eyewear and work in a well-ventilated environment to avoid secondary exposure to lacrimators from contaminated clothing.

INTRODUCTION AND RELEVANT HISTORY

Lacrimators, also known as *irritant incapacitants*, *tear gas*, and *riot control* or *harassing agents*, are aerosol-dispersed chemicals that produce near-immediate eye, skin, and upper respiratory tract irritation. Lacrimators have become widely accepted by law enforcement and military personnel as a method of controlling civilian crowds and criminal uprisings in correctional facilities. Virtually all police departments use tear gas as a nonlethal means of subduing suspected criminals. These agents are also advertised as nonlethal personal safety agents (in lieu of gun ownership). Ownership by civilians, however, is illegal in many countries. Large amounts of tear gas have been used worldwide. Tear gas has been used to suppress demonstrations and civil unrest in culturally diverse places, such as Chile, Panama, South Korea, and the Gaza strip and West Bank in Israel. The true incidence of complications associated with the use of these agents is unknown because of the difficulty in collecting epidemiologic information on victims of mass exposures to tear gas. Consequently, the overall safety of these agents has been questioned by the medical community.^{1,2}

Although the modern use of irritant incapacitants is for riot control, historically these agents were used in warfare to incapacitate enemy forces. From antiquity to the Middle Ages, oxides of sulfur were combusted upwind

of enemies with the aim of enveloping them in a cloud of smoke. Arsenical smoke was used sporadically from the 15th to 17th centuries. In the 20th century, the Paris police were the first to use chemical agents in 1912. Grenades filled with ethylbromoacetate (EBA) were deployed against “lawless gangs.” EBA was also used in the early phases of World War I by French ex-police conscripts.^{3,4} Modern tear gas agents were first used in the United States during the crime waves of the 1920s to combat gangsters and as personal protection agents.⁵ Subsequently, many harassing agents have been developed. Dispersal systems have also been refined in the ensuing years to improve delivery of these agents.

As many as 15 different irritants have been developed during the course of this century. Of these, only four lacrimator agents remain in common use worldwide: 1-chloroacetophenone (CN, Mace); 2-chlorobenzylidene malonitrile (CS); dibenz-1,4-oxazepine (CR); and capsaicin (pepper spray, “pepper Mace”).⁴

CHLOROACETOPHENONE

CN is the oldest of the currently used lacrimators. The name “Mace” originally described this agent alone.⁴ The eponym MACE was derived from a particular chemical formulation of CN: methylchloroform chloroacetophenone. CN is manufactured by chlorination of acetophenone with selenium oxychloride.^{4,5} Its chemical formula is $C_6H_5COCH_2Cl$. Under normal atmospheric conditions, chloroacetophenone exists as a white solid or powder.⁴ It can be delivered as a smoke from thermal grenades or artillery shells or as a solid or liquid aerosol. CN is heat stable, breaking down only when exposed to temperatures greater than 300° C for 15 minutes or more.⁴ CN is poorly soluble in water, even when alkalized; this characteristic predicts a moderate degree of environmental persistence and resistance to skin decontamination with soap and water.^{4,6} When used in large amounts, CN can persist in the environment for hours to days, depending on prevailing meteorologic conditions.^{4,7}

Although less potent than CS, CN is the most toxic of the currently used lacrimators.^{3,4,6} The concentration-time product ($mg \cdot min/m^3$) of CN that will incapacitate 50% of exposed individuals (ICT_{50}) is about 10 times greater than that for CS, yet the concentration-time product that will be lethal to 50% of exposed individuals (LCt_{50}) is about 6 times less than that for CS^{3,4,6} (Table 105D-1). At high concentrations, CN has produced permanent corneal epithelial damage, severe skin irritation with blistering, noncardiogenic pulmonary edema, and asphyxiation. At least five deaths have occurred from acute pulmonary injury or asphyxiation when CN grenades were used in enclosed spaces.^{3,4,6,8,9}

TABLE 105D-1 Riot Control Agents: Comparison of Potency and Toxicity

	CN	CS	CR
TC ₅₀ [eyes] (mg/m ³)	0.3	0.004	0.002
TC ₅₀ [airway] (mg/m ³)	0.4	0.023	0.002
IC ₅₀ (mg · min/m ³)	20–40	3–5	0.7
LC ₅₀ (mg · min/m ³)	7000–14,000	60,000	>100,000

TC₅₀, the concentration in air (mg/m³) that will irritate the eyes of 50% of the population exposed; IC₅₀, the concentration time product (mg · min/m³) that incapacitates 50% of the population exposed; LC₅₀, the concentration time product (mg · min/m³) that is lethal to 50% of the population exposed.

Modified from Beswick FW: Chemical agents used in riot control and warfare. Hum Toxicol 1983;2:247–256; Sidell FR: Riot control agents. In Sidell FR, Takafuji ET, Frank DR (eds): Textbook of Military Medicine. I. Warfare, Weaponry, and the Casualty: Medical Aspects of Chemical and Biological Warfare. Washington DC, Office of the Surgeon General, 1997, pp 307–324; and Blain PG: Tear gases and irritant incapacitants: 1-chloroacetophenone, 2-chlorobenzylidene malonitrile and dibenz[B,F]-1,4-oxazepine. Toxicol Rev 2003;22(2):103–110.

CHLORBENZYLIDENE MALONITRILE

CS was first produced in 1928 by Corson and Stoughton (hence the designation CS).^{4,6} Because it is more effective and less toxic than CN (see Table 105D-1), CS became the standard riot control agent used by military and law enforcement agencies in 1959.⁴ CS is still the riot control agent most commonly used worldwide today.^{4,6} Chemically, CS is a variant of an older, previously used irritant, bromobenzyl cyanide. It is a stable gas with a pepper-like odor.¹⁰ CS exists as a crystalline powder and is dispersed by aerosol blowers, hand-held devices, or bursting thermal grenades.^{4,7} The chemical formula of CS is ClC₆H₄CHCCH(CN)₂.^{4,6} Vaporization of CS can be achieved by igniting a mixture of the powder with a fuel substance, producing clouds of white smoke containing CS vapor.¹⁰ When detonated in the open, a CS grenade can produce a cloud 6 to 9 M in diameter. The concentration of CS at the center of the cloud can range from 2000 to 5000 mg/m³, rapidly declining at the periphery.² Detonation in an enclosed space, or multiple-grenade-burst detonation, has the potential for producing much higher concentrations. High-temperature dispersal (>700° C) of CS has been shown to release small amounts of hydrogen cyanide and hydrochloric acid as air contaminants.¹¹ The clinical effects of this are unknown. CS is rapidly hydrolyzed in water and even more rapidly in aqueous alkaline solutions.⁶ Unlike CN, CS is readily inactivated in soap and water.^{4,6} The U.S. military has developed hydrophobic, microencapsulated formulations of CS (CS1 and CS2) that are resistant to water degradation.⁴ These formulations have not been used by civilian authorities because of their environmental persistence.

DIBENZOXAZEPINE

CR was first synthesized in 1962.⁴ It is the most potent and least toxic lacrimator currently used^{4,6} (see Table

105D-1). CR is about 5 to 10 times more potent than CS and is effective at concentrations as low as 1 mg/m³.^{3,4,6} The lethal dose in humans is thought to be 2 times that of CS and more than 10 times that of CN.^{3,4,6} CR is more stable than CN or CS because of a lower water solubility and vapor pressure.⁶ CR is, thus, much more persistent in the environment than the other lacrimators.^{3,4,6} CR is commonly deployed as a liquid but can also be aerosolized. Because CR is usually delivered in solution, its effects tend to be localized to the skin and eyes. Pulmonary effects are rare owing to its low vapor pressure. Compared with other lacrimators, skin and eye effects are not as persistent following CR exposure. Based on animal studies, CR appears to be less toxic than CN or CS, but few data exist to support or refute these observations in humans.³

CAPSAICIN

Capsaicin (8-methyl-*N*-vanillyl-6-nonenamide) is the active ingredient largely responsible for the irritating and pungent effects of the fruits of the various species of *Capsicum*. These include the Mexican chile pepper and the Hungarian red pepper.¹² The potent topical irritant effects of capsaicin have made its use as a personal protection and immobilizing device appealing for both law enforcement agencies and the civilian population. Repeated topical capsaicin application has been used for cutaneous counterirritant effects in chronic pain and inflammatory conditions.

In 1993, more than 6 million “pepper gas” spray units were sold in the United States alone.¹³ When used as a harassing agent, capsaicin is used as a spray at close quarters. When used correctly, capsaicin can result in transient, severe skin and mucous membrane irritation, incapacitating an assailant rapidly. Improper use has resulted in significant morbidity in a small number of reported cases.

News reports in the lay press have raised the issue of deaths in custody temporally related to the use of capsaicin sprays. Extensive testing by the Federal Bureau of Investigation in the 1980s found no evidence of toxic problems with capsaicin use.¹⁴ No firm scientific data currently substantiate any casual relationship between these deaths and capsaicin exposure. In these situations, victims are often in an agitated state requiring restraint, which may be implemented in a way that unintentionally produces postural asphyxia.¹⁴ Victims are often under the influence of alcohol and drugs of abuse, which may increase aggression, mask occult trauma, and delay recognition of medical problems. In the absence of any definite link between capsaicin exposure and sudden death, law enforcement agencies currently continue to use capsaicin as a harassing agent.

EXPOSURE SCENARIOS

Riot control agents are generally dispersed as liquid or solid aerosols.^{4,6} The circumstances of an exposure (i.e.,

intended target and purpose) dictate the specific method of riot control agent delivery. Irritant smoke can be produced by combining the agent (CN or CS) with a pyrotechnic mixture containing chlorate and lactose. The igniter vaporizes the irritant, which then condenses into a cloud of solid or liquid particles 1 to 2 μm in diameter that can be easily inhaled.⁷ This method is best used in the control of large-scale riots. CS also exists as a micropulverized powder that can be dispersed by mechanical force, using a vehicle- or aircraft-mounted “smoke” generator, or from a hand-held tank using carbon dioxide as a propellant.⁷ This method does not require the use of a thermal agent to volatilize the irritant.

Most lacrimators have low water solubility, which necessitates their dissolution in a hydrocarbon organic solvent when used in pressurized, hand-held, delivery devices.⁶ For instance, Mace is a 1% solution of CN in a solvent mixture containing kerosene, 1,1,1-trichloroethane, and Freon 113.⁶ The United Kingdom police personnel carry hand-held CS spray devices that contain 5% CS in a methyl isobutyl ketone solvent.⁶ Pepper spray devices contain tetrachloroethylene, Freon, or isopropyl alcohol as the hydrocarbon vehicle.⁶ These organic solvent mixtures are irritants themselves and will potentiate lacrimator toxicity.^{3,6}

CN and CS can also be delivered by a thermal grenade or a cartridge fired from a gun. Grenades are often launched into confined spaces by law enforcement agencies to incapacitate criminals in siege situations. Thermal grenades may produce fires.⁷ There is a risk for mechanical trauma and burns to victims hit by projectiles or in close proximity to exploding grenades.^{15,16}

In general, CS and CN used as a particulate smoke tend to affect the eyes and respiratory tract to a greater degree than the skin. Aerosols and liquid sprays are likely to produce more marked effects on the skin and eyes with less effect on the respiratory tract.

PATHOPHYSIOLOGY OF INJURY

The mechanism of tissue injury from CN and CS is not fully elucidated but likely results from alkylation of key tissue enzymes and direct reactivity of their respective chloride moiety with mucosal tissue.⁶ Both CN and CS are SN_2 alkylating agents and likely produce tissue toxicity after binding and inhibiting key sulfhydryl-containing enzymes (e.g., lactic dehydrogenase and thioctic acid of the pyruvate decarboxylase complex).⁶ Alkylation of cellular proteins also increases the potential for mutagenesis.³ In addition, CS exposure has been shown to result in the production of bradykinin locally, which could produce tissue edema and inflammatory injury.^{3,17} Animal studies and postmortem human data have demonstrated intra-alveolar hemorrhage, pulmonary exudation of protein and polymorphonuclear cells, and tissue necrosis after exposure to high concentrations of CN.^{8,9} This is followed by suppressed phagocytic capability of immunocompetent cells. Increased susceptibility to infection is a potential consideration after large or repeated exposures to CN.^{18,19} The actual

risk for infection to humans after massive exposures to CN or other lacrimators is unknown. Additionally, little is known about the risk for chronic pulmonary toxicity, genotoxicity, or reproductive toxicologic effects associated with CN and CS exposure.

When animals are given lethal doses of CS by parenteral injection, CS is metabolized to cyanide, as evidenced by elevated levels of blood thiocyanate within hours.⁶ Inhalation and cutaneous exposures, however, do not produce significant amounts of free cyanide in plasma because systemic absorption of CS by these routes is extremely small.^{3,6} Thus, victims of CS poisoning do not need treatment for cyanide toxicity.⁶

The mechanism of action of capsaicin on cutaneous nerve endings has been extensively studied. Application of capsaicin to the skin or mucous membranes results in widespread excitation of cutaneous C-fiber polymodal nociceptor afferent nerve terminals. Capsaicin achieves this by nonspecifically opening nerve fiber sodium, calcium, and potassium channels and releasing substance P from nerve endings.²⁰ This produces an intense sensation of burning pain and marked hyperalgesia to skin heating and pressure. Symptoms may be exacerbated by the presence of sweat or the application of cold water. Hyperalgesia may persist for as long as 24 hours. Cutaneous vasodilation is also seen at the site of application and the surrounding skin through an axon flare reflex.²⁰

MANIFESTATIONS

All lacrimators produce near-immediate stinging and burning of the skin and mucosal surfaces, lacrimation, blepharospasm, salivation, and rhinorrhea.^{4,6,7,21} Inhalation produces a sensation of chest constriction with dyspnea, gagging, and burning of the respiratory tract.^{4,6,22} The dermal irritant effects of all agents are enhanced in the presence of moisture or sweat on the skin. Hot, humid weather can produce a similar augmentation of irritant effects.^{4,10} Sensitivity to tear gas is individual and age dependent.⁶ Children appear to be more susceptible to the toxic effects.⁶ In most instances, the effects of tear agents are transient and dissipate within 30 minutes of removal from the source of exposure.²³ More prolonged effects may be seen with higher-concentration, enclosed-space exposures. In addition, ocular effects may be prolonged. Conjunctivitis and blurred vision may persist for as long as 24 hours after exposure.²²

The eye is the most sensitive organ to tear gas agents.^{3,4,6} The threshold value for eye irritation is as low as 0.002 mg/m^3 for CR^{3,4,6} (see Table 105D-1). An effective aerosol concentration of 5 mg/m^3 results in severe burning of the eyes, with lacrimation, blepharospasm, and conjunctival injection. Ocular injuries include mild conjunctival irritation, corneal and periorbital edema, focal corneal epithelial injury, iridocyclitis, and necrotizing, coagulative keratoconjunctivitis.^{4,6,24} Permanent corneal damage has occurred from CN particles becoming embedded on the cornea, particularly after exposure to aerosolized particulates.²⁵ Epithelial recovery of the

cornea may take months, leaving permanent corneal opacities and visual loss.²⁶ Direct spraying of CN, capsaicin, and similar agents onto the face from high-pressure aerosols has the potential to produce barotrauma to the eyes.

Cutaneous injury from tear agents is more likely to occur with aerosol or liquid spray exposures; prolonged, concentrated exposures; direct contact of an agent to skin or exposure through wet clothing; or exposure to skin that is thin, moist, abraded, or has preexisting disease.^{4,6} Skin effects include simple stinging and burning, erythema, vesication, and allergic dermatitis. For instance, CN exposure has resulted in cutaneous allergic reactions and dermatitis, skin burns, and bullous eruptions from prolonged exposure or direct spraying of CN onto the skin.^{27,28} Generalized papulovesicular rashes responding to treatment with systemic steroid therapy have also been reported.²⁸ Despite initial enthusiasm for the use of CS as a less toxic alternative to CN, reports of significant toxicity of CS have appeared in the medical literature. Severe reactions to CS have resulted from its direct spraying onto cutaneous surfaces. Vesicular dermatitis with blistering, crusting, and marked facial swelling has developed from 12 hours to 3 days after either single or repeated exposures to CS.²⁹ Allergic contact dermatitis has been documented in cases of recurrent exposure to CS, with allergy subsequently confirmed by patch testing.²⁹ Skin discomfort may recur up to 48 hours after CR exposure when exposed skin contacts water.^{30,31} Cutaneous application of capsaicin over days to weeks can result in habituation to its irritant effects and hypalgesia of the skin.²⁰ In contrast, severe dermatitis, labeled *Hunan hand syndrome*, may result after skin exposure to capsaicin. This is particularly common in people who handle chile peppers with bare hands, resulting in severe pain and erythema of exposed surfaces.^{32,33} Relief from symptoms may be difficult to achieve.

Respiratory effects from lacrimators include nasal irritation, rhinorrhea, sneezing, mouth burning, sore throat, cough, chest tightness, and bronchorrhea. Effects typically resolve within 30 minutes for most exposures.^{4,6} Tidal volume and minute ventilation have been observed to decrease with experimental exposure to CS.³⁴ The reasons for this are uncertain. Inhalation of capsaicin by asthmatic and nonasthmatic volunteers resulted in coughing and transient increases in airway resistance. This is postulated to be due to stimulation of airway sensory nerves.

High-concentration, enclosed-space exposures to lacrimators have resulted in acute laryngotracheo-bronchitis, pulmonary edema, and death.⁶ Pulmonary edema is delayed in onset, occurring 6 to 8 hours after exposure.³⁵ Death is extremely rare but has occurred from pulmonary edema 12 hours after exposure to CN.^{8,36} Severe respiratory distress and bronchopneumonia were identified in a 4-month-old infant after exposure to CS for 2 to 3 hours in an enclosed space.^{37,38} Respiratory symptoms may persist for days to weeks after exposure and include cough, dyspnea, hemoptysis, and wheezing.^{2,39} Reactive airways dysfunction has been described after exposure to CS and CR.^{6,40,41} Permanent lung damage is

unlikely to occur from lacrimator exposure; long-term effects typically resolve by 12 weeks after exposure.⁶

Respiratory symptoms and signs are uncommon after exposure to capsaicin; effects are likely related to direct exposure of the respiratory tract to capsaicin. Laryngeal edema, stridor, and pulmonary edema requiring endotracheal intubation were observed in an 11-year-old boy 4 hours after the intentional inhalation of several sprays of a capsaicin in a hydrofluorocarbon vehicle. His clinical condition improved over 24 hours.⁴² A 4-week-old infant accidentally sprayed in the face with a 5% capsaicin aerosol developed respiratory failure and pulmonary edema, requiring extracorporeal membrane oxygenation.⁴² It is difficult to ascertain the degree of influence that inhaled capsaicin had in the evolution of pulmonary injury in both cases. Exposure to high concentrations of hydrocarbon propellant may have also had a role in the development of lung injury.⁴²

Nausea and vomiting may result from swallowing saliva that contains CS. Oral ingestion of CS has resulted in oropharyngeal irritation and pain, nausea, vomiting, abdominal cramping, and diarrhea.^{4,6,43} Increases in pulse and blood pressure often occur immediately after tear agent exposure. These cardiovascular responses are transient and are secondary to the anxiety and pain of exposure rather than the direct effects of tear agents.⁶

The risk for congenital anomalies, stillbirth, and spontaneous abortion was not increased in areas of heavy tear gas use in Londonderry during the late 1960s.⁴⁴ However, cytotoxic and mutagenic activity has been observed in mammalian cells in culture exposed to CS.⁴⁵ Animal studies have been unable to conclusively prove any carcinogenic or teratogenic effects after exposure to CR or CS tear gas.⁴⁶

ASSESSMENT

The diagnosis of tear agent exposure is based on a suggestive history and physical findings. The acute onset of irritant effects to the eyes, nose, and respiratory tract in one or more patients following an airborne chemical exposure suggests tear agent toxicity. Similar effects may occur after exposure to other irritant or corrosive gases (i.e., choking agents, ammonia), allergic reactions, and exacerbations of asthma or chronic obstructive disease. The history should include details of the exposure (time, duration, nature), associated trauma, treatment before arrival, and symptoms and past medical history of the victim. Of particular importance is whether the exposure occurred in an enclosed space or out in the open. The physical examination should focus on the patency of the airway and adequacy of respirations, vital signs, mental status, and ocular and skin findings. Patients with eye symptoms should have fluorescein and slit-lamp examination to determine the presence of corneal injury. Patients with respiratory symptoms must be re-evaluated frequently. Although lacrimators may be identified by gas chromatography/mass spectrometry and other techniques,⁶ laboratory identification of lacrimators is not possible or necessary at most hospitals.

TREATMENT

Most victims exposed to lacrimators develop transient symptoms and signs of skin and mucosal irritation that usually subside within 15 to 30 minutes of removal from the source of the exposure.^{4,6} Thus, medical treatment is often unnecessary. Treatment of victims after more significant exposure is supportive. The first priorities of treatment are health care provider self-protection and patient decontamination to reduce ongoing irritation. Health care personnel should protect themselves with gloves, gowns, and eyewear. Victims should be treated in a well-ventilated area to prevent atmospheric accumulation of the tearing agent. Contaminated clothing should be removed and discarded in plastic bags. Exposed skin areas should be washed with copious amounts of warm water and soap. Attempted orotracheal intubation of patients exposed to CS has resulted in severe blepharospasm and lacrimation in anesthesiologists performing the procedure owing to oropharyngeal contamination with tear gas.⁴⁷ This situation may result in difficulty or delay in airway control in a patient with otherwise normal airway anatomy.

The eyes should be irrigated for at least 30 minutes with normal saline in symptomatic patients. This should be followed by ophthalmologic assessment for ocular injury, including fluorescein and slit-lamp examination for corneal ulceration and abrasion. Particulate matter should be removed carefully with a cotton swab. Treatment with topical antibiotics, cycloplegics, and oral analgesics should be provided as necessary. Persisting symptoms and signs require formal ophthalmologic follow-up. Skin erythema alone does not usually require any treatment and usually diminishes within 24 hours. Severely affected skin areas that are denuded and oozing may be treated with wet compresses containing avena (colloidal oatmeal) or aluminum acetate (Burow solution).^{4,6} Contact dermatitis due to CN or CS has responded to topical or systemic corticosteroid therapy and antipruritics.^{4,27,48} Immersion of the hands in vinegar has been successful in providing relief if applied within 30 minutes of exposure to capsaicin.⁴⁹ Topical lidocaine gel has also been successful in relief of irritation.³² Prolonged immersion of hands in vegetable oil after exposure to chile slurry has also been found to provide better long-term relief from the pain of Hunan hand than bathing in cool tap water.⁵⁰ Milk compresses and topical antacid suspensions have also been suggested as effective analgesics measures for the relief of capsaicin-induced dermal irritation.^{51,52}

Respiratory symptoms due to CN or CS exposure are usually transient and should disappear within 15 to 30 minutes of removal from the exposure environment. Factors that may increase the risk for persisting pulmonary symptoms and development of pulmonary edema include prolonged exposure to CN or CS in an enclosed space, direct inhalation of capsaicin into the respiratory tract, or a history of asthma or other chronic lung disease. Humidified oxygen should be provided as necessary. Bronchospasm may respond to inhaled β -adrenergic agonists and oral or parenteral corticoids.

Patients with persistent symptoms or signs of respiratory distress may be at risk for delayed pulmonary edema and require observation for 12 to 24 hours. Standard supportive measures and ventilatory support are indicated for pulmonary edema. Extracorporeal membrane oxygenation has been successfully used to support an infant with pulmonary edema after exposure to capsaicin aerosol.⁴² Because reactive airways dysfunction may be a long-term consequence of patients presenting with significant acute respiratory symptoms, pulmonary specialist follow-up may be necessary for severely affected patients.

Finally, attention should also be paid to the potential for physical injury and burns to victims of harassing agents. Injury may be masked by the presence of alcohol or other drugs of abuse. Trauma may be due to the violent situations in which the individuals were involved or may be a direct consequence of ballistic trauma due to the projectiles used to propel harassing agents.

MANAGEMENT OF MASS CASUALTIES

Similar to other airborne toxicants, tear gas release can create a multiple-casualty incident. The priorities in management of mass casualties from tear gas include immediate removal of all victims from the source of exposure, decontamination of symptomatic patients, and the provision of supportive care as indicated. Fortunately, less than 1% of exposed patients require medical care because of the mild and transient nature of their symptoms.⁶ In ideal situations, prehospital, hazardous material (Hazmat) personnel provide on-scene triage, initial patient assessment, decontamination, and symptomatic treatment. Hazmat personnel only transport patients with significant or persistent effects. In circumstances in which prehospital care does not occur and multiple victims present unannounced to the hospital, symptomatic care and patient decontamination (e.g., clothing removal, eye and skin irrigation) should be delivered in a predetermined, segregated area of the emergency department (see Chapter 103). Activation of a hospital's internal disaster plan is unlikely necessary for multiple casualties from a tear gas incident but will depend on the number and experience of hospital personnel, the number of victims, and the severity of their illness.

PRINCIPLES OF PREPAREDNESS

Preparation for casualties from tear gas exposure does not require any specialized equipment that would not already be present in most emergency departments (see Chapter 103). The presence of a decontamination area that is segregated from the rest of the emergency department and can treat multiple victims simultaneously is ideal. It is recommended that you be familiar with the treatment of chemical casualties and the principles of advanced Hazmat life support in order to optimize patient care.

E Central Nervous System Disabling Agents

JEFFREY R. SUCHARD, MD

At a Glance...

- 3-Quinuclidinyl benzilate (BZ, QNB) or similar agents may disable by producing antimuscarinic effects, including visual impairment, ataxia, and delirium. Treatment consists of supportive care and the judicious use of restraints, sedation, and/or anticholinesterase agents (e.g., physostigmine) to reverse central antimuscarinic toxicity.
- Ultrapotent opioids (fentanyl derivatives) may be used as incapacitating agents, producing an opioid toxidrome with depressed mental status and respiratory drive. Treatment consists of airway management and opiate-receptor antagonists (e.g., naloxone).

RELEVANT HISTORY

Central nervous system (CNS) disabling or incapacitating agents are nonlethal compounds intended to temporarily disrupt an enemy's ability to fight. For over 2000 years, military planners have occasionally used chemical agents to alter the mental status of and temporarily incapacitate their enemy rather than cause death or permanent physical injury. In an era before aerosol dissemination of chemical agents was technically feasible, food or water contamination was the primary method used to disable the enemy; belladonna alkaloids were frequently used for this purpose. As early as 200 BCE, the Carthaginian officer Maharbal mixed wine with the antimuscarinic agent "mandragora" and then abandoned camp during a feigned retreat. Rebellious African forces discovered and drank the drugged wine and subsequently were easily taken prisoner or slaughtered when they fell into a stupor.¹

According to the U.S. military, the ideal CNS disabling agent should be potent, effective, persistent, logistically feasible, predictable, treatable, unlikely to produce permanent injuries or death when used as intended (high therapeutic index), and affordable.² From 1953 to 1973, the U.S. Army investigated many methods of incapacitation to find one suitable for standardization.¹ Nonchemical agents, such as noise, high-intensity photostimulation, microwaves, and olfactory assault, generally proved impractical, potentially physically damaging, or too easy to thwart with routine respiratory protective measures. Although several types of chemical and bio-warfare (CBW) agents (e.g., lacrimators, vomiting agents, staphylococcal enterotoxin B, mild exposures to nerve agents or vesicants) were considered for use as incapacitants by the U.S. military, the psychochemical agents—chemicals that disable by producing behavioral or direct CNS effects—were considered most suitable for study and investment.

The psychochemical agents were classified into four general categories: stimulants, depressants, psychedelics,

and deliriant. The stimulants included amphetamines, cocaine, caffeine, nicotine, strychnine, and metrazole. None of the stimulants proved effective as airborne incapacitating agents. In addition, it was feared that stimulants could enhance performance rather than hinder it following low- to moderate-dose exposures.

CNS depressant agents were either insufficiently potent or had a relatively narrow therapeutic index (TI; median lethal dose ÷ lowest median effective dose), with lethal doses in the range of 10 to 20 times the effective incapacitating dose.

From 1959 to 1965, D-lysergic acid diethylamide (LSD) was the primary psychedelic agent studied by the U.S. military. LSD had an inhaled ID₅₀ (the dose incapacitating 50% of those exposed) of only 5.6 µg/kg, but results were unpredictable, with exposed victims still occasionally capable of effective volitional activities.

The deliriant, anticholinergic drugs with prominent CNS effects, were considered most suitable for use as military incapacitating agents. Of the deliriant, 3-quinuclidinyl benzilate (U.S. military designation BZ) was considered the most ideal for use as a CNS disabling agent.¹ BZ is stable when delivered by a thermal munition, environmentally persistent, and more potent than a variety of widely recognized anticholinergic agents (e.g., atropine and scopolamine).¹ The U.S. military weaponized and stockpiled BZ as its only incapacitating agent in the 1960s. These stockpiles were subsequently destroyed. The drug, however, is still used in medical pharmacology research as a muscarinic receptor antagonist; it is designated QNB for such purposes.

Modern use of CNS disabling agents in warfare has been reported, but the veracity of such reports is not clear. In 1995, during the Balkan wars, Serbian military forces allegedly used BZ against civilians, who reported hallucinations associated with attacks by artillery shells that emitted smoke. Although BZ exposure has not been completely excluded, the hallucinations could be ascribed to exhaustion and other physical and psychological stressors.^{3,4}

In contrast, the modern use of nonlethal agents as weapons against terrorists is well documented. In October 2002, the Russian Federal Security Service used CNS disabling agents to end a standoff with terrorists in a Moscow theater. Chechen rebels held more than 800 hostages and threatened to detonate explosives unless their political demands were met. After a 3-day siege, "gas" was introduced into the theater's ventilation system and quickly subdued both the terrorists and their hostages. More than 650 of the hostages were hospitalized, and 128 died; all but five apparently died of the effects of the "gas."⁵ The identity of the agent used was not at first disclosed. Early reports suggested the use of BZ,⁶ but the clinical findings and time course of

symptom onset were not consistent. Traces of halothane, however, were detected in two of the victims that were transported to Germany.^{7,8} Several days after the incident, the Russian Health Minister stated that the agent used was a derivative of fentanyl,^{7,9} which was not expected to cause fatalities. Although expert opinion is not uniform, current consensus holds that the “knockout gas” was composed of an ultrapotent opioid aerosol (possibly carfentanil⁹ or remifentanil¹⁰) probably along with halothane. The relatively high case fatality rate could be due to multiple factors, including variability in dose, displacement of oxygen by rapid introduction of gas into the building, failure to adequately notify health care teams and supply them with antidotes, and poor physical condition of the hostages due to limited food and water and to immobility during their captivity. This use of an incapacitant by the Russian military as an antiterrorist agent has rejuvenated U.S. military interest in developing an effective nonlethal chemical weapon.⁹

EXPOSURE SCENARIOS

Like most chemical and biological agents, CNS disabling agents would be most effective if disseminated as an aerosol, vapor, or gas. Incapacitating agents could be delivered outdoors as an aerosol from low-flying aircraft (e.g., crop dusters), vehicle-mounted or hand-held spray devices, or detonation of artillery, missiles, or bombs. If the agent is used outdoors, low-wind conditions would be preferable, to minimize rapid dissipation. The Moscow theater siege illustrates the prototypical exposure environment for effective delivery of CNS disabling agents: an enclosed space, which allows for near-simultaneous respiratory exposure to all building occupants (particularly if a ventilation system is available for agent delivery). An enclosed space allows for more accurate estimation of the appropriate dose of incapacitant to achieve rapid tranquilization of multiple persons while minimizing permanent harm. The Moscow siege also illustrates the grim reality that incapacitating agents can have unpredictable and lethal effects, even when conditions a priori are presumed to be ideal.

Because the general tactical goals of war are to kill combatants and destroy material goods, conventional weapons or physically injurious chemical or biological agents would have more utility. CNS disabling agents, however, could be used in operations in which casualties were to be minimized or avoided, such as capture scenarios or when civilians are present. Terrorist use of CNS disabling agents seems less probable because conventional weapons or other chemical agents would be easier to procure and because the diminished likelihood of casualties would lessen the imperative to respond to threats.

PATHOPHYSIOLOGY OF INJURY

The CNS disabling agents discussed do not possess unique pathophysiology. Like other anticholinergic agents, 3-

quinuclidinyl benzilate is a potent competitive antagonist of both peripheral and central muscarinic receptors (see Chapter 39). A detailed review of opiate pathophysiology is found in Chapter 33 and of LSD in Chapter 45. The features distinguishing the CNS disabling agents from other members of their respective classes relate mostly to potency and time course of effects.

MANIFESTATIONS

BZ produces clinical effects similar to those of atropine, although it is more potent. The ID_{50} for BZ is 6.2 $\mu\text{g}/\text{kg}$ (approximately 0.5 mg for adults), whereas the ID_{50} for atropine is 140 $\mu\text{g}/\text{kg}$ (8 to 14 mg). Mild cognitive impairment is seen in 50% of individuals with BZ doses of approximately 2.5 $\mu\text{g}/\text{kg}$.¹

BZ has a slower onset and longer duration of action than atropine does. The effects of BZ are barely measurable 1 hour after exposure to the ID_{50} dose. Central effects are seen after about 4 hours, peak at 8 to 10 hours, and then gradually subside over 24 to 72 hours. The duration of incapacitation from an ID_{50} dose is roughly 24 hours.^{1,2} Doubling the dose increases the rate of onset of effects and produces incapacitation within 1 hour of exposure but also prolongs recovery an additional 48 hours.¹ In actual use, wide variation in dosing among exposed individuals is expected, with consequent variability in symptom onset and offset. It is estimated that the human ID_{50} is approximately 40-fold lower than the lethal dose (therapeutic index of 40).¹

Although toxicity from BZ is most likely to occur after inhalation of vapor or liquid aerosol, symptoms may also result from intravenous or intramuscular injection or, to a small degree, from skin contact with liquid. Effects may be delayed up to 24 hours after dermal absorption.

The clinical signs and symptoms of BZ exposure are the typical antimuscarinic effects. Peripheral signs include tachycardia, mydriasis, and dry skin and mucous membranes. Mild exposures cause drowsiness, lapses of attention, and difficulty in following complex instructions. Moderate exposures ($\approx 4 \mu\text{g}/\text{kg}$) cause somnolence or stupor, mumbling speech, ataxia, slowing of thought processes, and confusion. Higher exposures cause full delirium with staring, muttering, and hallucinations, with fluctuating lucid intervals.¹ Bizarre behaviors are often seen among individuals with antimuscarinic delirium, including undressing, crawling or climbing motions, and plucking or picking at the air or garments (carphology or “woolgathering”).

As mentioned above, depressant psychochemical agents were found by the U.S. military either to be insufficiently potent or to have relatively narrow therapeutic indices, where lethal doses exceeded incapacitating doses by factors of only 10 to 20. In actual use, when precise dose control is not possible, unintentional lethal dosing would not be unexpected. A recent review by Wax et al, however, illustrates that some ultrapotent fentanyl derivatives have very high therapeutic indices and might therefore be considered as potential CNS disabling

agents when aerosolized.⁹ Morphine has a therapeutic index of 70. Fentanyl is roughly 300 times as potent as morphine and has a TI of 300, sufentanil is 4500 times as potent as morphine with a TI of 25,000, remifentanyl is 220 times as potent as morphine with a TI of 33,000, and carfentanyl is 10,000 times as potent as morphine with a TI of 10,600. Such figures, however, are usually based on animal data, often from a single animal species, and do not necessarily apply to humans.⁹ Even if such agents were found to have remarkable safety margins in controlled settings, the doses required to induce rapid unconsciousness could also cause significant respiratory depression or apnea. With appropriate supportive care, such doses might be safe. Hypoxic brain injury might result, however, if exposed persons do not rapidly receive assisted ventilation or antidotal therapy; this is the likely reason for the “gas” fatalities in the Moscow theater incident. The aerosolized doses necessary to incapacitate humans and rate of onset and duration of clinical effects has not yet been elucidated. The clinical manifestations following opioid aerosolization, however, are similar to those experienced by other routes (see Chapter 33).

LSD is a difficult agent to disseminate and consequently is most likely to be used in a clandestine manner, such as food or water contamination.² An early stage of nausea is commonly seen, followed in 45 to 60 minutes by CNS effects (anxiety, euphoria, delusions, kaleidoscopic imagery, etc) and peripheral signs of sympathetic stimulation (see Chapter 45).

ASSESSMENT

The diagnosis of CNS disabling agent toxicity is based on a suggestive history coupled with toxidrome recognition on physical examination. Rapid identification of the chemical agents will not be possible by laboratory tests available at most hospitals. Diagnosis is further supported by the complete reversal of toxic effects following empiric antidotal therapy. Chemical warfare agent poisoning should be suspected when a group of patients have the acute onset of a similar constellation of signs or symptoms. Multiple casualties with altered mental status first require evaluation to rule out the more lethal chemical agents, such as nerve agents or cyanide. The presence of coma, miosis, and respiratory depression could occur with either nerve agents or opioids; the additional presence of seizures, fasciculations, and cholinergic findings suggests nerve agent toxicity. BZ will produce an anticholinergic toxidrome. Unintentional atropine overdose from nerve agent antidote autoinjectors may mimic BZ toxicity; multiple simultaneous atropine casualties may occur if a group believes it has been exposed to nerve agent, although clinical history should easily differentiate these exposures. Intoxication with LSD might be difficult to differentiate from intentional self-exposure to cannabinoids, but the treatment is similar and supportive for both. Anxiety reactions and malingering may mimic any potential CNS-disabling agent exposure, although peripheral signs of toxicity may be blunted or absent.

TREATMENT

For most CNS disabling agent casualties, only symptomatic and supportive treatment will be necessary. Victims should be rapidly removed from the exposure environment, and airway support should be provided as necessary. To avoid hyperthermia with BZ intoxication, restrictive clothing should be removed, especially in hot environments. Psychomotor agitation may respond to verbal assurance in mildly affected individuals, while restraints, nonspecific sedation (e.g., with benzodiazepines), or antidotal physostigmine may be indicated for more seriously poisoned patients. Physostigmine, a reversible carbamate acetylcholinesterase inhibitor, has been used safely to reverse antimuscarinic toxicity from BZ exposure.^{1,2} Intravenous doses of 30 $\mu\text{g}/\text{kg}$ (about 2 mg in 70- to 75-kg persons) are effective in reducing peripheral effects, but higher doses (at least 45 $\mu\text{g}/\text{kg}$) are often required to significantly reverse severe central cognitive effects. For unclear reasons, physostigmine appears to be ineffective if given during the first 4 to 6 hours after BZ exposure.^{1,2} Physostigmine is primarily indicated for the treatment of agitated delirium or to confirm diagnosis (see Chapter 39). Physostigmine has a short duration of action (20 minutes to 2 hours) and may require repeated dosing every 1 to 2 hours for recurrent agitation. Careful patient monitoring is necessary during physostigmine administration to avoid inducing excess cholinergic effects.

Patients with suspected opioid agent toxicity may require emergent airway support and administration of an opiate-receptor antagonist (e.g., naloxone; see Chapter 33). Larger than usual doses of naloxone (up to 10 mg) may be needed to completely reverse the toxic effects from potent, synthetic, opioid agents. Data from animal studies suggest that repeated administration of naloxone may be necessary for a period of 2 to 24 hours following fentanyl derivative toxicity.^{9,11,12} The high lipophilicity of fentanyl derivatives allows for their redistribution from tissues to the CNS, making recrudescence of opiate toxicity (e.g., CNS and respiratory depression) a real possibility. The treatment of LSD intoxication is entirely supportive.

Because of the possibility of prolonged and recurrent clinical effects, patients exposed to BZ and high-potency opioid derivatives require a prolonged period of hospital observation (12 to 24 hours).

MANAGEMENT OF MASS CASUALTIES

With mass casualties from BZ exposure, control and containment of delirious victims is the primary concern. These victims may be capable of injuring themselves or others, so dangerous objects (e.g., weapons, small items that may be swallowed) should be removed.² Loose restraints or tethers are preferable to allowing victims to roam freely without supervision. Separation of affected individuals into small groups, rather than a single large group, may prevent a crowd control crisis induced by a few agitated victims.¹ Intravenous physostigmine dosing

to multiple victims may not be feasible under field conditions. Intramuscular (1 to 2 mg) or oral (2 to 5 mg) dosing every 1 to 2 hours titrated as needed may help maintain victim comfort and manageability.^{1,2} Physostigmine may be mixed into juice to mask its bitter taste for oral administration.¹

Mass casualties from opioid toxicity can easily outstrip resources necessary to avoid complications from respiratory depression. Intramuscular or subcutaneous naloxone administration, as opposed to the intravenous route, should save time and minimize permanent injury or death when the number of victims greatly exceeds the number of rescuers.

PRINCIPLES OF PREPAREDNESS

CNS disabling agents appear less likely to be used than conventional weapons or other chemical warfare agents. Therefore, in preparing for chemical weapons casualties, it would be prudent to concentrate more on the agents intended to inflict fatalities or permanent injuries. If used as intended, the CNS disabling agents should temporarily incapacitate, and the victims may require only monitoring and supportive therapy. Nevertheless, agents with lower therapeutic indices can cause fatalities, since precise control of the administered dose is not possible and individuals may have varying susceptibilities to toxic effects. If time and resources permit, preparations for chemical casualties should include stockpiling and training in the use of physostigmine and naloxone, the antidotes for CNS disabling agents. Airway management equipment would likely already be part of the armamentarium for chemical casualty preparedness.

 for muscle relaxant intoxication, 700, 701t
 for nerve gas poisoning, 1178, 1491, 1495–1496
 in pediatric population, 1492–1493, 1493t
- Atropine (*Cont'd*)
 for organophosphate poisoning, 1178
 in pregnant patient, 358
 in rapid sequence intubation, 16t
 intoxication with, antidote for, 14t
 structure of, 722f
 usage of, during pregnancy and lactation, 727
- Australian funnel web spider, 437–438
- Autism, thimerosal in vaccines and, 1279
- Autoimmunity, drug-induced, 880
- Automatic dishwashing detergent
 statistics of, 1444t, 1445t
 toxicity of, 1446–1447
 management of, 1447–1448
- Automobile emissions, lead in, 1131
- Autonomic nervous system (ANS), herbal teas affecting, 1082
- Autoreceptors, in neurotransmission, 192f, 193
- Avermectines, 1189–1190, 1189f
- Axonopathy(ies), 205
- Ayahuasca, hallucinogenic effects of, 499
- Ayurvedic medicine, 1085
- Azathioprine, 944–945
 drug interactions with, 945
 intoxication with, 945, 945b
- Azotemia, in acute renal failure, 250
- B**
- Baby powder, 1415–1416
 inhalation of, 1416–1417
- Bacillus cereus*, food poisoning due to, 529–530
- Baclofen
 intoxication with, 698
 properties of, 696t
 withdrawal from, 699
- Bag-mask-valve device, in opioid toxicity therapy, 650
- BAL. *See* British antilewisite (BAL).
- Balsam azalea, 493f
- Barbiturates, 687–692, 687f. *See also specific agent.*
 abuse of, 689
 classification of, 688t
 dependence on, 689–690
 drug interactions with, 690–691, 691t
 for alcohol withdrawal syndrome, 602
 history of, 687
 in rapid sequence intubation, 16t, 17
 mechanism of action of, 203
 overdose of
 clinical presentation of, 691, 691f, 691t
 deaths from, 660, 660f
 management of, 691–692
 pharmacology and pharmacokinetics of, 687–688, 688t
 signs and tests for, 63t
 therapeutic uses of, 688–689, 689t
 tolerance to, 689
- Barium, 1158–1159
- Barium carbonate, in rodenticides, 1219
- Barium sulfate, for strontium inhalation accident, 1470
- Base(s), pK of, 81, 81f
- Bath oils, 1428–1429
- Batrachotoxin, 201
- Battery(ies), impaction of, in gastrointestinal tract, 281
- Beetle stings, 452
- Behavioral sensitization, in amphetamine toxicity, 785
- Belladonna alkaloids, 200
 anticholinergic properties of, 723b
- Bentazon herbicides, 1206–1207, 1206f
- Benzalkonium chloride
 for hydrofluoric acid burns, 312
 ingestion of, 1447

- Benzene, 1363–1368
 exposure to, 1363–1364, 1367–1368
 bone marrow depression associated with, 1365, 1366
 OSHA standards for, 1367
 metabolism of, 1365
 factors altering, 1365–1366
 poisoning with
 diagnosis of, 1366
 evidence of, 1366
 management of, 1367, 1367b
 synonymous terms for, 1363
 urinary excretion of, 1366–1367
- Benzethonium chloride, for hydrofluoric acid burns, 312
- Benzodiazepine(s). *See also specific agent.*
 absorption rates of, 675–676, 675t
 classification of, 676t
 CNS effects of, 1518
 drug interactions with, 678
 duration of action of, 676
 for alcohol withdrawal syndrome, 600–602, 601t
 for cocaine toxicity, in pregnant patients, 354
 for hyperthermic syndromes, 216
 for nerve gas poisoning, 1496
 in pediatric population, 1493, 1493t
 for neuroleptic malignant syndrome, 216
 for seizures
 alcoholic-related, 602
 NSAID-induced, 873
 strychnine-induced, 1217
 theophylline-induced, 1042
 history of, 671–673

 poisoning with, management of, 1345-1346
 polyaromatic, fires generating, 1288
- Hydrochloride acid
 ocular injury due to, 306
 uses and toxic effects of, 305t
- Hydrochlorothiazide, 995, 995f
- Hydrocortisone
 for anaphylaxis, 879
 for thyroid hormone overdose, 1072
 prophylactic, for non-native Elapidae snakebites, 430
- Hydrofluoric acid, 1323-1332
 exposure to
 clinical effects of, 1325-1328
 dermal burns in, 1326
 treatment of, 1328-1330, 1329f
 diagnosis of, 1328
 differential diagnosis of, 1328
 home and industrial, 306b, 1323
 inhalational, 1327
 treatment of, 1331
 management of, 1328-1332
 antidotes in, 14t
 ocular burns in, 306-307, 1327
 treatment of, 311t, 312, 1330-1331
 oral, 1327-1328
 treatment of, 1331
 pathophysiology of, 1323-1325
 structure-activity relationships of, 1323
 systemic, 1331-1332
 toxic effects of, 305t
- Hydrogen cyanide. *See also* Cyanide entries.
 in smoke, 1285, 1287
- Hydrogen peroxide, in hair products, 1426, 1427
- Hydrogen peroxide poisoning,
 gastrointestinal disturbances due to, 281
- Hydrogen sulfide, 1335-1341
 exposure to
 cardiovascular disturbances due to, 158t, 162
 chronic sequelae of, 1339
 clinical manifestations of, 1336-1337
 emergency planning and response to, guidelines for, 1340t
 health effects of, 1336t
 laboratory features of, 1337
 OSHA-permissible limits of, 1340
 pathophysiology of, 1336
 patient disposition with, 1338
 prevention of, 1339-1341, 1340t
 treatment of, 1337-1338
 lethality of, exposure-response curve for, 1340-1341
 mechanism of action of, 1335
 toxicokinetics of, 1335-1336
- Hydroid corals, 508-509
- Hydroxocobalamin, for cyanide poisoning, 1313
- γ -Hydroxybutyric acid. *See* Gamma-hydroxybutyric acid.
- 4-Hydroxybutyric aciduria, 814
- Hydroxycobalamin, for cyanide poisoning, 985
- 4-Hydroxycoumarin, 1055, 1056f
- Hydroxymethylglutaryl-CoA inhibitors, 336-337, 338
 hepatotoxicity of, 236
 pulmonary toxicity of, 187t
- 5-Hydroxytryptamine (5-HT). *See* Serotonin.
- Hydroxyzine, for anaphylaxis, 880
- Hydrozoa, 507
- Hygiene products, 1424t, 1432
 oral, 1424t, 1430-1431
- Hymenoptera
 classification of, 447-448, 447f
 envenomation of
 pharmacokinetics of, 449
 pharmacology of, 448-449
- Hymenoptera stings
 cardiovascular disturbances due to, 163
 clinical manifestations of, 449-450
 diagnosis of, 450
 epidemiology of, 448
 in special populations, 449
 management of, 450
 nephrotoxicity of, 256
 pathophysiology of, 448-449
 patient disposition after, 450-451
 prevention of, 448b
- Hyperamylasemia, 275
- Hyperbaric oxygen therapy. *See also* Oxygen therapy.
 for brown recluse spider bites, 437
 for carbon monoxide poisoning, 1302, 1303t, 1304-1305, 1304t
 in pregnant patient, 356, 356b
 for cyanide poisoning, 1312, 1313
 for hydrogen sulfide poisoning, 1338
- Hyperchloremic metabolic acidosis, 109
- Hyperglycemia
 calcium channel blocker-induced, 968
 protease inhibitor-induced, 902
- Hyperglycemic agents, 318, 319, 319t
- Hyperkalemia, 117t
 hydrofluoric acid-induced, 1324, 1325
 in hydrofluoric acid injury, 1332
 NSAID-induced, 872
- Hyperlipidemia, protease inhibitor-induced, 902
- Hypermagnesemia, 1163
- Hypernatremia, 117t
- Hyperoxygenation therapy, 1087
- Hyperprolactinemia, cocaine-induced, 763
- Hyperpyrexia, salicylate poisoning and, 841
 management of, 844
- Hypersensitivity pneumonitis, 173-174, 175t, 176, 180t
 work-related, 488, 1246, 1248t, 1251t
- Hypersensitivity reactions, 171-176. *See also* Anaphylactic reactions.
 quinidine-induced, 1010
 to antibiotics, 877-881, 878t
 multisystem involvement in, 878-880, 879t, 880f
 organ-specific, 880-881
 to irritant gases, 1246
 to lamotrigine, 741
 to salicylate products, 841
- Hypersensitivity vasculitis, antibiotic-induced, 880, 881
- Hypertension
 clonidine-induced, 1005
 contraceptive pills causing, 333-334
 glucocorticoid-induced, 330
 scorpion stings causing, 446
- Hypertensive reactions, with MAO inhibitors, foods implicated in, 568-569, 569b
- Hyperthermia
 cocaine-induced, 142-143, 761-762
 management of, 767
 intoxication associated with, 23
 malignant. *See* Malignant hyperthermia.
 treatment of, 238
 work-related, 1250t
- Hyperthyroidism, treatment of, 323
- Hypnotics. *See* Sedative-hypnotics; *specific agent.*
- Hypocalcemia, in hydrofluoric acid injury, 1324-1325, 1332
- Hypochlorite solutions
 for organophosphate decontamination, 1177
 for vesicant decontamination, 1504

- Hypoglycemia
 β-adrenergic blocker–induced, 978
 causes of, 1029b
 diabetic control agent–induced, 1026–1027
 diagnosis of, 1028
 management of, 1029–1031
 disopyramide–induced, 1010
 ethanol causing, 318
 signs and symptoms of, 1025b
 sulfonyleureas causing, 317
 treatment of, 318–319, 319t
 vacor causing, 318
- Hypoglycemic agents, 317–319, 317t, 318t, 1020t. *See also specific agent.*
 adverse effects of, 1026–1027, 1028
 history of, 1019
 intoxication with
 clinical manifestations of, 1025, 1025b, 1026
 diagnosis of, 1028–1029, 1029b
 epidemiology of, 1019–1020
 in elderly, 379b, 380
 management of, 1029–1030, 1031
 patient disposition and, 1031–1032
 signs and tests for, 64t
 mechanism of action of, 317
 pharmacokinetics of, 1024–1025
 pharmacology of, 1022–1024
 structure and classification of, 1020–1022, 1021f
- Hypoglycin, in ackee fruit, 318, 485, 494
- Hypokalemia, 117t
 theophylline-induced, 1039–1040
 management of, 1043
 thiazide-induced, 995
- Hypomagnesemia, in hydrofluoric acid injury, 1332
- Hyponatremia, 117t
 treatment of, 320
 vasopressin causing, 319
- Hypotension
 ACE inhibitor–induced, 992
 antihypertensive drug–induced, 148
 calcium channel blockers–induced, 151
 clonidine-induced, 1004–1005
 deferoxamine-induced, 1127
 intoxications associated with, 19b
 management of, 133–134, 715
 mechanism of, 133
 opiate overdose causing, 649
 orthostatic, antipsychotics causing, 707, 710
 refractory, tricyclic antidepressant
 intoxication causing, 541
 sympathetic-inhibiting drug–induced, 147
 theophylline-induced, 144
 tricyclic antidepressant–induced, 156
- Hypothalamic agents, 319–320
- Hypothalamus-pituitary axis, 319
- Hypothalamus-pituitary-adrenal axis, suppression of, 329

- Legal issues, in forensic toxicology, 123–124
- Leiurus quinquestriatus*, 443, 443f
- Lemon grass oil, 1441t
- Lenten rose, 491f
- Lepidoptera stings, 451
- Lethal dose, median (LD₅₀), 92
 antivenom, neutralizing units in, for
 Crotalidae snakebites, 409t
 of sulfur mustard, 1503
- Leucovorin, methotrexate toxicity limited with, 934
- Leukemia
 acute lymphoblastic, childhood, 1475
 benzene-induced, 1364, 1366
- Leukocytes, 298
- Leukoencephalopathy, progressive spongiform
 heroin overdose causing, 645
 treatment of, 652
- Leukopenia, 298, 299b
- Leukotriene antagonists, pulmonary toxicity due to, 186t
- Levamisole, 913–914
- Level of consciousness, assessment of, 24
- Levetiracetam, 743
- Levodopa
 for neuroleptic malignant syndrome, 716
 serotonin syndrome and, 573
- Levonorgestrel, implantable, 334
- Levothyroxine, 322
 mechanisms of toxicity of, 322–323
- Lewisite, 1501
 antidote for. *See* British antilewisite (BAL).
- Licorice root, 485
- Lidocaine
 for tricyclic antidepressant poisoning, 155
 for ventricular arrhythmias, 715
 cocaine-induced, 765
 in rapid sequence intubation, 16–17, 16t
- Ligand-gated ion channels, in neurotransmission, 192, 192f, 202
- Light-emitting diode (LED), for methanol-induced retinal injury, 313
- Lily of the valley, 487f
- Lindane (gamma-hexachlorocyclohexane), 1231. *See also* Organochlorine insecticides.
- Linezolid, 565
- Lionfish, 510, 510f
- Lipid(s)
 intestinal absorption of, 273
 metabolism of, 335–338
 agents affecting, 336–337
- Lipid peroxidation, in hepatic injury, 224b
- Lipid-lowering agents, 326t
- Lipstick, 1431
- Liquids, teeth-cleaning, 1430
- Lithium, 579–586
 available preparations of, 580t
 drug interactions with, 580, 581t
 half-life of, 580
 in breast milk, 366t
 nephrotoxicity of, 257, 266–267
 neuroleptic malignant syndrome and, 208–209
 pharmacokinetics of, 579–580, 581t
 pharmacology of, 579, 580t
 renal clearance of, 580
 serotonin syndrome and, 212
 SSRI inhibitor interaction with, 572, 572t
 therapeutic uses of, 579, 579t
- Lithium poisoning, 580–581, 581f
 acute-on-chronic, 580, 583
 cardiac disturbances due to, 158t, 161,
 582
 clinical manifestations of, 581–582
 diagnosis of, 582–583, 582t
 endocrine disturbances due to, 582
 gastrointestinal disturbances due to, 280,
 582
 in elderly, 380
 management of, 583–586
 decontamination in, 584
 disposition in, 585–586
 elimination in, 584–585, 585f, 586t
 hemodialysis or hemoperfusion in, 58
 supportive measures in, 583–584
 patient history in, 582
 quantitation and interventions for, 71t
 signs and tests for, 64t
- Liver. *See also* Hepatic; Hepato-*entries*.
 alterations to, in pregnancy, 348
 effect of ethanol on, 279
 fatty, 228–229, 229b
 inflammation of. *See* Hepatitis.

 for cyanide poisoning, 1312
- Oxygen-carrying capacity, in methemoglobinemia, monitoring of, 294–295
- Oxymetazoline
 dosage of, 1004t
 structure of, 1002f
- Oxytocin, 319
- P**
- Pacing. *See* Cardiac pacing.
- Paclitaxel, pharmacologic parameters of, 929t
- Pain
 chest. *See* Chest pain.
 of latrotoxin, 434
- Paint, lead-based, 1130–1131
 childhood poisoning due to, 1136–1137
- Palivizumab, 896t–897t, 906
- Pancreas
 diseases of, 275, 275b
 effect of ethanol on, 279
 structure and function of, 272
- Pancreatitis
 intoxicants and, 275, 275b
 valproate-induced, 739
- Pancuronium, in rapid sequence intubation, 16t, 17
- Papaver somniferum*, 635
- Paper wasps, 447f
- Papilledema, systemic substances causing, 309b
- Paracetamol. *See* Acetaminophen *entries*.
- Paraldehyde poisoning, metabolic acidosis in, 109
- Paralytic shellfish poisoning, 516, 517
- Para-phenylenediamine, in hair products, 1425
- Paraquat, 1197, 1197f
 toxicity of
 clinical features of, 1198–1199
 management of, 1199–1200, 1199t
 mechanisms of, 1197
- Parasympathetic activity, cardiac effects of, 135, 136f
- Parathion, 1172t
- Parathyroid gland, 324–325, 324f
 physiologic disturbances of, toxin-induced, 324–325, 324b, 325t
- Parathyroid hormone (PTH), 324
- Paregoric, for neonatal opiate withdrawal, 368t
- Parenchymal lung disease, therapeutic drug-induced, 188t
- Parenteral absorption, of drugs, 82–83
- Parkinsonism
 antipsychotic agents causing, 711
 juvenile, methylenedioxymethamphetamine-induced, 785
 management of, 715
- Paromomycin, 917
- Parotitis, toxic, 274
- Paroxetine
 overdose of, 554
 pharmacokinetics of, 551t
- Particulate material, deposition of, in lungs, 169
- Paxillus involutus* mushrooms, 469, 469f
- PCBs. *See* Polychlorinated biphenyls (PCBs).
- PCP. *See* Phencyclidine (PCP).
- PeaCe pill. *See* Phencyclidine (PCP).
- Pediatric Assessment Triangle (PAT), 1493
- Pediatric Environment Health Specialty Units (PEHSUs), 1273
- Pediatric environmental health, 1269–1273, 1269b. *See also* Children, environmental toxins in.
- Peliosis hepatitis, in anabolic steroid users, 1105
- Penciclovir, 894t–895t, 901f, 902
- D-Penicillamine, 1168t
 for arsenic poisoning, 1153
 for lead poisoning, in children, 1141
- Penicillin(s)
 action of, at GABA receptor, 204
 for cyclopeptide mushroom poisoning, 460
 overdose of, 881–882
- Penicillin G, overdose of, 882
- Pennyroyal, hepatotoxicity of, 497
- Pennyroyal oil, 1437–1438, 1441t
 hepatotoxicity of, 239b
- Pentazocine, 647–648
- Pentobarbital, 689t
- Peppermint oil, 1438–1439, 1441t
- Peptic ulcers, steroid-induced, 330
- Peptides, gastric, 271
- Peradeniya Organophosphorus Poisoning (POP) Scale, 1176
- Perceptual disturbances, hallucinogen-induced
 acute, 798–799
 recurring, 799
- Perchloroethylene, hepatotoxicity of, 236
- Perfluoroisobutylene, as choking agent, 1507t, 1508
- Performance enhancers, 1101–1108. *See also* Anabolic steroids; Creatine; Dehydroepiandrosterone.
- Perfumes, 1429
- Peripheral nervous system (PNS)
 lead poisoning affecting, 1134
 toxicity specific to, 204–205, 205b
- Peritoneal dialysis, 48–49, 49b, 50b. *See also* Dialysis; Hemodialysis.
 for lithium poisoning, 584, 586t
- Personal care soap. *See* Soap(s).
- Personal protective equipment and training, for organophosphate decontamination, 1178
- Pesticides. *See* Fungicides; Herbicides; Insecticides; Rodenticides.
- Petroleum distillates, 1343–1346. *See also* Hydrocarbons; *specific agent*.
 poisoning with
 clinical presentation of, 1344–1345
 diagnostic evaluation of, 1345
 epidemiology of, 1343
 management of, 1345–1346
 pathophysiology of, 1343–1344
 patient disposition with, 1346
- Peyote cactus, 488f
 hallucinogenic effects of, 498
- P-glycoprotein, substrates, inhibitors, and inducers of, 88, 88b
- pH
 drug absorption influenced by, 81–82
 renal elimination and, 102
- Phallotoxins, in *Amanita* mushrooms, 457–458
- Pharmacodynamics, 91–93, 92f
 in drug interactions, 103
 in elderly, 378–379
 of agonists and antagonists, 92–93
 targets of drug action in, 91–92, 92f
- Pharmacogenomics, 93–94, 94t
 future directions of, 94
- Pharmacokinetic antagonism, 92
- Pharmacokinetics, 88–91, 88f–90f
 first order kinetics in, 89–90, 90f
 in drug interactions, 98–103, 98b, 98t, 100t
 in elderly, 379
 Michaelis-Menten kinetics in, 90
 neonatal, 363–365
 vs. adult, 365t
 other models of, 89
 two-compartment model of, 88–89, 89f
 zero order kinetics in, 90
- Pharmacology, 81–94
 drug disposition in, 81–88
 genetic variability of response in, 93–94, 94t
 pharmacodynamics in, 91–93, 92f
 pharmacokinetics in, 88–91, 88f–90f
- Phenacetin, nephrotoxicity of, 263
- Phencyclidine (PCP)
 intoxication with
 clinical effects of, 774
 diagnosis of, 775
 epidemiology of, 773
 treatment of, 777–778
 neuropharmacology of, 773–774
 pharmacology of, 774
 structure of, 773f
- Phenobarbital
 for camphor-induced seizures, 1421
 for neonatal opiate withdrawal, 368t
 for seizures, 714
 intoxication with, 736
 quantitation and interventions for, 71t
 pharmacokinetics of, 735
- Phenol
 cutaneous decontamination from, 34
 ocular injury due to, 307
 treatment of, 311t, 312
 uses and toxic effects of, 305t
- Phenothiazides, cardiovascular effects of, 156
- Phenylalkylamines, structure of, 963, 964f
- Phenylbutazone, toxic effects of, 871
- Phencyclidine, cardiovascular effects of, 146
- Phenylephrine, in emergency care, 20t, 21
- Phenylethanolamine-N-methyltransferase, ethanol effects on, 599

- Phenylethylamines, 795t, 796
- Phenylpiperidines. *See also specific agent.*
pharmacology of, 636–637
- Phenylpropanolamine
cardiovascular complications of, 143
toxicity of, 196
- Phenytoin
for tricyclic antidepressant intoxication, 544
hepatotoxicity of, 233–234
intoxication with, 736–737
management of, 737
intravenous
administration of, 737
vs. intravenous fosphenytoin, 737
pharmacokinetics of, 736
prophylactic, with busulfan therapy, 933
- Phocomelia, thalidomide-associated, 8, 8f, 938
- Phorate, 1172t
- Phosdrin, 1172t
- Phosgene
as choking agent, 1507, 1507t
as irritant, 176–177, 178t
exposure to, 1509
- Phosgene oxime, 1501–1502
- Phosphene, 1225–1226
- Phosphodiesterase inhibitors, for β -adrenergic blocker intoxication, 980
- Phosphorus
cardiac disturbances due to, 158t, 163
cutaneous decontamination from, 34
in rodenticides, 1218
suicide using, 235
- Photodermatitis, plant-induced, 500
- Photosensitivity, antibiotic-induced, 881
- Physician's responsibility, in childhood poisoning prevention, 388–389
- Physostigmine
for anticholinergic intoxication, 730–731
for anticholinergic syndrome, 715
for benzodiazepine poisoning, 1519
for gamma-hydroxybutyric acid overdose, 817
for muscle relaxant intoxication, 700, 701t
for tricyclic antidepressant intoxication, 544–545
- Phytophotodermatitis, plant-induced, 495–496
- Picrotoxin, 204, 484
- Pill-associated caustic injury, 1410
- Pine oil, 1344, 1441t
systemic toxicity of, 1345
- Piperazine, 914
- Piperidine antihistamines, non-sedating, 731–732
- Piroxicam, toxic effects of, 871
- Pituitary agents, 320
mechanisms of toxicity of, 320–321
- pK, of acid or base, 81, 81f, 82f
- Placenta
carbon monoxide transfer across, 355
drug transfer across, 348
lead transfer across, 356
solvent transfer across, 1357
- Plant(s)
anticholinergic properties of, 723b, 724
cardiovascular toxicity of, 481–482
cyanogenic, 484–485
hallucinogenic, 484, 498–499
hepatotoxic, 238, 239b, 485, 494–495, 497
nephrotoxic, 256, 485
neurotoxic, 483–484, 497–498
poisonous. *See also* Plant poisoning.
types of, 474t–475t
sodium channel-binding properties of, 482
- Plant dermatitis, 495–496
- Plant hydrocarbons (terpenes), 1344. *See also* Hydrocarbons.
poisoning with, management of, 1345–1346
- Plant poisoning, 473–502. *See also specific plant.*
clinical manifestations of, 496–497
diagnosis of, 500
history of, 473
management of, 500–502
multisystem organ failure due to, 481
pathophysiology of, 477, 480–483
patient disposition and, 501–502
pharmacokinetics of, 478b–480b
structure-activity relationships of, 473, 475–477
- Plant products, occupational exposure to, disorders associated with, 175t
- Plasmapheresis
for chemotherapy overdose, 935
for cyclopeptide mushroom poisoning, 461
for cyclosporine overdose, 947
- Plastics, fires involving, 1288
- Platelet(s), 299
coagulation of, 1051–1052, 1052f
- Platelet aggregation, inhibition of, 1060–1061, 1060t
- Pneumoconioses, 179, 182
metal, 183–184
work-related, 1248t–1249t
- Pneumonia, bronchial
diquat-induced, 1196
in smoke inhalation victims, 1290
- Pneumonitis
chemical
chlorinated hydrocarbon-induced, 1357
hydrofluoric acid-induced, 1327
hypersensitivity, 173–174, 175t, 176, 180t
work-related, 488, 1246, 1248t, 1251t
interstitial, 171
- PNS. *See* Peripheral nervous system (PNS).
- Podophyllum poisoning
gastrointestinal effects of, 278
multisystem organ failure due to, 499
- Poinsettia, toxicity of, 499–500
- Point-of-care testing, 66–67

- Sodium carbonate, ocular injury due to, 307–308
- Sodium channel blockade, class IA antiarrhythmics in, 1011–1012, 1011f
- Sodium channel toxins, 497
- Sodium channel-binding properties, of plants, 482

- Sodium chloride
 ocular irrigation with, for hydrofluoric acid burns, 1330–1331
 restriction of, in acute renal failure, 258
- Sodium fluoride, in dental products, 1325–1326
- Sodium hydrate. *See* Sodium hydroxide.
- Sodium hydroxide, 1407
 exposure to, 1408
 in depilatories, 1432–1433
 ingestion of, 1408
 ocular injury due to, 304
 uses and toxic effects of, 303t
- Sodium ipodate, for thyroid hormone overdose, 1072
- Sodium metasilicate, ocular injury due to, 307–308
- Sodium monofluoroacetate, in rodenticides, 1217
- Sodium nitrite, for cyanide poisoning, 1313
- Sodium nitroprusside, 983–985, 1309
 cyanide release by, 983–984
 pharmacokinetics of, 983
 structure of, 983, 983f
 toxicity of, 984
 diagnosis of, 984–985
 management of, 985
- Sodium phosphate, ocular injury due to, 307–308
- Sodium polystyrene sulfonate, for lithium poisoning, 584
- Sodium silicate, ocular injury due to, 307–308
- Sodium thiopental, 689t
 in rapid sequence intubation, 16t, 17
- Sodium thiosulfate
 for bromate intoxication, 1388
 for cyanide poisoning, 1313
 for hydrogen sulfide poisoning, 1338
- Sodium-potassium pump, inhibition of, by class IA antiarrhythmics, 1013, 1013f
- Soil, lead in, 1131
- Solanine, toxicity of, 496
- Solubility, of irritant gases, 177, 178t
- Solvents. *See also specific solvents; classes of solvents.*
 abuse of, cardiac disturbances due to, 146–147
 aromatic, 1363–1375
 chlorinated, 1347–1359
 halogenated, 1377–1382
 nephrotoxicity of, 255b, 256
 volatile, abuse of, 1381–1382
- Soman, general properties of, 1490t
- Soot, 1288
- Sorbitol, as cathartic, 39
- Sotalol, intoxication with, 980
- Sour gas, in oil patches, 1341
- Spectrometric assays, 66, 67t, 68t
- Speed. *See* Methamphetamines.
- Spider(s)
 neurotoxin producing, 200
 venomous, 433–438
 Latrodectus species as, 433–435, 435t
 Loxosceles species as, 435–437
 other, 437–438
- Spider bites, 163, 433–438. *See also under specific spider.*
- Spirolactone, mechanism of toxicity of, 329
- Spongiform leukoencephalopathy, progressive
 heroin overdose causing, 645
 treatment of, 652
- Spontaneous chemical interconversion, of
 gamma hydroxybutyric acid, 815–816
- Sprinkler systems, 1285
- Squamous cell carcinoma, caustic injury-induced, 1410
- Squaw mint (pennyroyal) oil, 1437–1438, 1441t
 hepatotoxicity of, 239b
- SSRIs. *See* Selective serotonin reuptake inhibitors (SSRIs).
- Stannosis, 1166
- Staphylococcus*, food poisoning due to, 527
- Starfish
 crown-of-thorns, 509
 stings from, 513
 venom of, 511
- Statins. *See* Hydroxymethylglutaryl-CoA inhibitors.
- Stavudine, 890t–891t, 899, 899f
- Steatosis, drug-induced, 229, 229b
- Stephania tetrandra*, 1083
- Steroids. *See also specific agent.*
 anabolic, 1101–1106. *See also* Anabolic steroids.
 for toxin-induced liver disease, 239–240
 precursor, 1106
- Stickers, warning, in childhood poisoning prevention, 386
- Stimulants
 pulmonary toxicity due to, 187t
 signs and tests for, 64t
- Stinging nettles, toxicity of, 500
- Stingrays, 510, 511f
 venomous, 511t, 513
- Stings
 insect, 447–453. *See also specific insect sting.*
 marine life, 512–513
 scorpion, 440, 442–446. *See also* Scorpion stings.

 Trinitrotoluene, liver necrosis due to, 229
 Triptan(s), 849–856. *See also specific agent*.
 drug interactions with, 853, 854t
 intoxication with, 853–856
 cardiac disturbances due to, 161–162
 diagnosis of, 855
 management of, 855–856
 patient disposition and, 855–856
 withdrawal following, 855
 pharmacokinetics of, 851, 852t, 853
 pharmacology of, 851, 851t
 structure of, 849–851, 850f
 usage of
 FDA approval of, 850t
 in special populations, 853
 Triptan Cardiovascular Safety Expert Panel, 854
 Triterpene saponin, gastrointestinal irritation due to, 477
 Tritium isotopes, exposure to, 1469
 Troglitazone, hepatotoxicity of, 234
 Tropane alkaloids, 483
 Tryptamines, 794–795, 795t, 798t
 Tryptophan
 as food supplement, 1086–1087
 metabolism of, 566, 566f
 Tryptophan hydroxylase, 198
 TSH (thyroid-stimulating hormone), 321
 Tuberculosis, isoniazid for, 919

- Tumor(s). *See* Cancer; *under anatomy*.
- Turpentine, 1344
systemic toxicity of, 1345
- Typhoid fever, *Salmonella typhi* associated with, 531
- Typhoid Mary, 531
- Tyramine, dietary, MAO inhibitor interactions with, 568–569, 569b
- Tyrosine hydroxylase, in dopamine synthesis, 194
- U**
- United Nations, agencies of, 1265–1266
- Up-regulation, of drug receptor density, 92–93
- Uranium isotopes, exposure to, 1471–1472
- Urea, diminished excretion of, in acute renal failure, 250
- Urea herbicides, 1205–1206, 1205f
deaths from, 1206t
- Urginea maritima*, 1081t, 1082
- Urinary alkalization
for barbiturate poisoning, 692
for herbicide poisoning, 1202
for salicylate poisoning, 844–845, 846b
for uranium contamination, 1472
- Urinary retention, muscle relaxants associated with, 698
- Urine, qualitative toxicologic methods used in, 67t
- Urine composition, daily, 251t
- Urine osmolality, changes in, 250, 251f
- Urticaria, 881
contact, plant-induced, 495
- U.S. Army Medical Research Institute of Chemical Defense (USAMRICD), 1504
- U.S. Bureau of Labor Statistics, of occupational fatalities in private industry, 1237
- US Department of Agriculture (USDA), 1263

- V**
- Vaccine(s), thimerosal in, 1115
autism and, 1279
- Vacor (rodenticide), 1219
hypoglycemia due to, 318
neuropathy due to, 205, 206t
- Valacyclovir, 894t–895t, 901, 901f
- Valganciclovir, 894t–895t, 902, 902f
- Valproate, 204
intoxication with, 739
in children with fatty acid metabolic disorders, 390–391
management of, 739–740
hemodialysis or hemoperfusion in, 59
pharmacokinetics of, 739
- Vancomycin
overdose of, 882–883
toxic effects of, in neonate, 370
- Vapona, 1172t
- Vapor, definition of, 170
- Vasculitis, hypersensitivity, antibiotic-induced, 880, 881
- Vasoconstriction, triptan-induced, 855
- Vasopressin. *See* Antidiuretic hormone (ADH).
- Vasopressor therapy, in emergency care, 19–21, 20t
- Vecuronium, in rapid sequence intubation, 16t
- Venencapsan, hepatotoxicity of, 239b
- Venlafaxine, 550
overdose of, 555
pharmacokinetics of, 551t
- Venom. *See* Envenomation.
- Veno-occlusive disease, 237
- Venous thrombosis, contraceptive pills causing, 333
- Venovenous hemodiafiltration, continuous
for lithium poisoning, 585, 585f, 586t
for salicylate poisoning, 846
- Venovenous hemofiltration, continuous, 47–48, 47b, 47t, 48b
- Ventilation
mechanical, for drug-induced pulmonary edema, 140
minute, in infants, environmental toxicants and, 1272
- Ventricle, left, in anabolic steroid abusers, 1105
- Ventricular arrhythmias, 136, 138
management of, 715
sedative intoxication causing, management of, 668
- Ventricular tachycardia
amphetamine abuse causing, 541
tricyclic antidepressant abuse causing, 541
- Verapamil, in breast milk, 366t
- Veratridine, 482
- Vesicants, 1500–1506, 1501t. *See also specific agent*.
exposure to, 1502–1503
assessment of, 1504
manifestations of, 1503–1504
mass casualties in, management of, 1505
pathophysiology of, 1503, 1503t
prenatal and pediatric issues concerning, 1504
principles of preparedness in, 1505–1506
relevant history of, 1501–1502
treatment of, 1504–1505
in national stockpile, 1502t
National Research Council acute exposure guideline levels for, 1505t
- Vesicles, sulfur mustard–induced, 1503–1504
- Vespidae, 447. *See also* Hymenoptera stings.
- Vibrio cholerae*, food poisoning due to, 528–529
management of, 529
- Vigabatrin, 204, 742
- Villus(i), intestinal, 272
- Vinblastine, pharmacologic parameters of, 929t
- Vincristine
neurotoxicity of, 931–932
pharmacologic parameters of, 929t
- Vinyl chloride, carcinogenicity of, 238
- Virus cell fusion inhibitors, 894t–895t, 903–904
- Vision, color, styrene affecting, 1368
- Visual acuity, decreased, toluene-induced, 1371–1372
- Visual field constriction, peripheral, systemic substances causing, 309b
- Vital signs, 23
assessment of, in smoke inhalation victims, 1290
- Vitamin(s), 1089–1098
definition of, 1089
fat-soluble, 1089, 1090–1096, 1091t
history of, 1089–1090
reference daily intake of, 1089, 1089t
supplementary, for alcohol withdrawal syndrome, 600
water-soluble, 1089, 1096–1098
- Vitamin A, 1090–1095
anticarcinogenic effects of, 1091
deficiency of, 1092–1093
food sources of, 1091–1092
- Vitamin A (*Cont'd*)
history of, 1090
overdose of, 1091t
clinical manifestations of, 1093–1094
diagnosis of, 1094
management of, 1094
pharmacology of, 1090–1092
structure of, 1090, 1092f
- Vitamin B₁, 1097–1098
overdose of, 1091t, 1098
structure of, 1092f
- Vitamin B₃, 337, 338, 1097
for pyriminil poisoning, 1219
hepatitis due to, 235b
in breast milk, 366t
ingestion of, gastrointestinal effects of, 278
overdose of, 1091t, 1097–1098
structure of, 1092f
- Vitamin B₆, 1096–1097
effect of isoniazid on, 920–921
for *Gyromitra* mushroom poisoning, 464
for hydrazine ingestion, 1380
intravenous, for isoniazid overdose, 923
overdose of, 1091t, 1097
structure of, 1092f
- Vitamin C
for chromium poisoning, 1161–1162
for progressive spongiform leukoencephalopathy, 652
overdose of, 1091t, 1098
structure of, 1092f
- Vitamin D, 324, 325, 1094–1096
analogs of, 324b
overdose of, 1091t, 1095–1096
pharmacology of, 1095
structure of, 1092f
- Vitamin E, 1096
for progressive spongiform leukoencephalopathy, 652
overdose of, 1091t
structure of, 1092f
- Vitamin K, 1096
and coagulation, 1052–1053, 1053f
half-life of, 1056t
inhibition of, 1053, 1054f
overdose of, 1091t
structure of, 1092f
- Vitreous fibers, man-made, exposure to, 182–183
- Volatile inhalants, abuse of, 1381–1382
- Volcanic gas, 9
- Volume contraction, 116. *See also* Fluid balance.
- Volume of distribution, in decontamination, 55
- Volume overload, 116. *See also* Fluid balance.
- Vomiting. *See* Emesis.
- VX agent
general properties of, 1490t
history of, 1488
- W**
- Warfare, chemical. *See also* Chemical weapons.
stockpiled agents for, 1502, 1502t
- Warfarin, 1053–1055, 1055f. *See also* Superwarfarins.
food interaction with, 102b
in pregnancy, 1055
in rodenticides, 1056–1057, 1220
overdose of, 1055
- Wasps. *See also* Hymenoptera.
sea, 508, 509f
- Water
for caustic alkali ingestion, 1411–1412
for soap or detergent ingestions, 1447
lead in, 1131
childhood poisoning due to, 1137

- Water (*Cont'd*)
 total-body. *See also* Fluid entries.
 intracellular and extracellular movement of, 114
 redistribution of, 114–115
 regulation of, 113–114, 113f
- Water hemlock, 489f
 cicutoxin in, 498
- Water loss, restoration of, in acute renal failure, 258
- Water solubility, in dialyzability, 55
- Water-reactive materials, cutaneous decontamination from, 34, 36
- Water-soluble drug hepatotoxicity, molecular adsorbents recirculating system for, 240
- Water-soluble vitamins, 1089, 1096–1098. *See also specific vitamin.*
- Weapons, chemical, 1487–1520. *See also* Chemical weapons; *specific agent.*
- Weever fish, 510
- Wernicke's encephalopathy, 594–595
- White phosphorus. *See* Phosphorus.
- Whole bowel irrigation
 for body stuffers and packers, 768
 for calcium channel blocker toxicity, 969
 for iron poisoning, 1126
 for lithium poisoning, 584
 in decontamination, 39
- Wide complex tachycardia, of uncertain origin, 138, 138f, 139f
- Wild cherry, hallucinogenic effects of, 499
- Wilson's disease, 1162
- Wisteria, 489f
- Withdrawal headaches, following triptan overuse, 855
- Withdrawal syndrome(s), neonatal
 cocaine and, 367–368
 opioids and, 367, 368t
 selective serotonin reuptake inhibitors and, 368
- Wolf spider, 438
- Wolff-Chaikoff effect, 1390
- Woolly (pus) caterpillar, 451, 451f, 452f
- Workplace, surveillance toxicologic testing in, 77–78
- Work-related illness. *See also* Industrial poisoning.
 causative agents, associative uses, occupations, and industries associated with, 1248t–1253t
 chemical exposure levels and monitoring in, 1244
 environmental history in, 1242
 evaluation of, principles in, 1242–1243
- World Health Organization (WHO), 1266

 inflicted by pressurized paint, decontamination of, 36
- Wound botulism, 521, 526. *See also* Botulism.
- Wyeth-Ayerst Antivenin (Crotalidae) Polyvalent, 409–413
 complications of, 409–411
 dosage of, 411
 infusion guidelines for, 411–412, 412b
 route of administration of, 411
 skin test for, 411
- Wyeth-Ayerst Elapidæ antivenin, for coral snakebites, 425
- X**
- Ximelagatran, 1059–1060
- X-ray fluorescence, of lead poisoning, 1134
- Xylene, 1374–1375
- Y**
- Yanango hydroelectric power plant, industrial radiation accident at, 1479–1480
- Yarrow oil, 1441t
- Yeast extracts, tyramine in, 569, 569b
- Yellow oleander, 488f
- Yellow oleander fruit, 489f
- Yersinia enterocolitidis* sepsis, deferoxamine-induced, 1127
- Yew, 489f
- Yew toxins, 482, 497
- Yohimbine, for clonidine overdose, 1007
- Z**
- Zalcitabine, 890t–891t, 898–899, 898f
- Zaleplon
 adverse effects of, 666
 drug interactions with, 663t, 666
 intoxication with, 666
 pharmacokinetics of, 662t, 665–666
 structure of, 659f
- Zanamivir, 896t–897t, 905, 905f
- Zebra fish, 510, 510f
- Zidovudine, 890t–891t, 899, 899f
 toxic effects of, in neonate, 371
- Zinc, 1166–1167
- Zinc phosphide, in rodenticides, 1218
- Zinc-desferrioxamine, for ocular mustard injury, 312
- Zolmitriptan, drug interactions with, 854t
- Zolpidem
 adverse effects of, 666
 drug interactions with, 663t, 666
 intoxication with, 666
 pharmacokinetics of, 662t, 665–666
 structure of, 659f
- Zonisamide, 743
- Zopiclone
 adverse effects of, 666
 drug interactions with, 663t, 666
 history and structure of, 659f, 660
 intoxication with, 666
 pharmacokinetics of, 662t, 665–666
- Zykon-B, 6–7, 7f
