Casarett & Doull's

TOXICOLOGY

The Basic Science of Poisons

8TH EDITION

CURTIS D. KLAASSEN

Casarett and Doull's
TOXICOLOGY

The Basic Science of Poisons

“

What is there that is not poison?

All things are poison and nothing (is)

without poison. Solely the dose

determines that a thing is not a poison.”

Paracelsus (1493–1541)

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Dedication

This edition of *Casarett & Doull's Toxicology the Basic Science of Poisons* is dedicated to John Doull, M.D., Ph.D., the co-founder and co-editor of the first editions of this textbook, for his many contributions to the discipline of toxicology. Dr. Doull was born in Baker, Montana, on September 13, 1922, recently celebrating his 90th birthday. He obtained a B.A. with a chemistry major from Montana State College in 1944. John spent 2 years in the Navy during WWII, before attending graduate school at the University of Chicago, an outstanding center of toxicology research and education. There he was mentored by two prominent researchers in the history of toxicology, E. M. K. Geiling and Kenneth DuBois. John received his Ph.D. in 1950 and M.D. in 1953, followed by an appointment as Assistant Professor and then Associate Professor at the University of Chicago.

After 2 decades in Chicago, John became Professor of Pharmacology and Toxicology at the University of Kansas Medical School in Kansas City, Kansas, in 1967. Dr. Doull initiated the toxicology research and education programs in the Department of Pharmacology and Toxicology. Within his first year at KU Medical School, John and his colleague, Dan Azarnoff, M.D., obtained an NIH Center grant, which provided faculty salaries, scientific equipment and supplies, as well as research space for the toxicology program. During the next 4 decades, John saw the toxicology program flourish with the receipt of a NIEHS Toxicology Training grant, a NIH COBRE grant, the hiring of more than 20 faculty, and the training of more than 200 graduate and postdoctoral students in toxicology.

Dr. Doull was also active in toxicology at the national level. He has been a charter member of the Society of Toxicology since its establishment in 1961. He served on numerous SOT committees including president of the Society from 1986 to 1987. John was also a member of 20 committees of the National Academy of Science, and was chair of 7 of those committees. In addition, he served on 10 committees for the Environmental Protection Agency, as well as committees for the National Toxicology Program, and the Food and Drug Administration. For the National Institute of Health, John was a member of the Toxicology Study Section (1965–70) and NIEHS Council (1975–80), the National Institute of Occupational Health and Safety, Chairman of the TLV Committee of the American Conference of Governmental Industrial Hygienists (1989–97), the Toxicology Forum, and others too numerous to list.

In addition to these numerous contributions to the discipline of toxicology, it is probably the co-founding of this textbook that has had and will have the greatest impact in elevating the discipline of toxicology. This textbook helps to define the discipline of toxicology and has been used in educating toxicologists for almost 40 years.

Preface

The eighth edition of *Casarett and Doull's Toxicology: The Basic Science of Poisons*, as the previous seven, is meant to serve primarily as a text for, or an adjunct to, graduate courses in toxicology. Because the seven previous editions have been widely used in courses in environmental health and related areas, an attempt has been made to maintain those characteristics that make it useful to scientists from other disciplines. This edition will again provide information on the many facets of toxicology, especially the principles, concepts, and modes of thoughts that are the foundation of the discipline. Mechanisms of toxicity are emphasized. Research toxicologists will find this book an excellent reference source to find updated material in areas of their special or peripheral interests.

The design of the eighth edition has been changed markedly, in that for the first time the figures and tables are presented in full color to allow for clearer interpretation of the basic concepts throughout the text. The rainbow of colors used in this edition makes this edition much more “user-friendly.” Each book will come with a DVD with image bank features of all illustrations and tables from the text in a presentation-ready format. The book will also be available in a variety of eBook formats for all popular devices such as iPad and Kindle.

The overall framework of the eighth edition is similar to that of the seventh edition. The seven units are “General Principles of Toxicology” (Unit I), “Disposition of Toxicants” (Unit II),

“Non-Organ-Directed Toxicity” (carcinogenicity, mutagenicity, and teratogenicity) (Unit III), “Target Organ Toxicity” (Unit IV), “Toxic Agents” (Unit V), “Environmental Toxicology” (Unit VI), and “Applications of Toxicology” (Unit VII).

This edition reflects the marked progress made in toxicology during the last few years. For example, the importance of apoptosis, cytokines, growth factors, oncogenes, cell cycling, receptors, gene regulation, transcription factors, signaling pathways, transgenic animals, “knock-out” animals, “humanized” mice, polymorphisms, microarray technology, genomics, proteomics, epigenetics, etc, in understanding the mechanisms of toxicity is included in this edition. More information on environmental hormones is included. Two new chapters have been added to this edition, namely the “Toxic Effects of Calories” and the “Toxic Effects of Nanoparticles.” References in this edition include not only traditional journal and review articles, but internet sites too. (Readers who would like a Power-Point version of the figures and tables can obtain the same from the publisher.)

The editor is grateful to his colleagues in academia, industry, and government who have made useful suggestions for improving this edition, both as a book and as a reference source. The editor is especially thankful to all the contributors, whose combined expertise has made possible a volume of this breadth. I especially recognize John Doull, the original editor of this book, for his continued support.

This page intentionally left blank

Preface to the First Edition

This volume has been designed primarily as a textbook for, or adjunct to, courses in toxicology. However, it should also be of interest to those not directly involved in toxicologic education. For example, the research scientist in toxicology will find sections containing current reports on the status of circumscribed areas of special interest. Those concerned with community health, agriculture, food technology, pharmacy, veterinary medicine, and related disciplines will discover the contents to be most useful as a source of concepts and modes of thought that are applicable to other types of investigative and applied sciences. For those further removed from the field of toxicology or for those who have not entered a specific field of endeavor, this book attempts to present a selectively representative view of the many facets of the subject.

Toxicology: The Basic Science of Poisons has been organized to facilitate its use by these different types of users. The first section (Unit I) describes the elements of method and approach that identify toxicology. It includes those principles most frequently invoked in a full understanding of toxicologic events, such as dose–response, and is primarily mechanistically oriented. Mechanisms are also stressed in the subsequent sections of the book, particularly when these are well identified and extend across classic forms of chemicals and systems. However, the major focus in the second section (Unit II) is on the systemic site of action of toxins. The intent therein is to provide answers to two questions: What kinds of injury are produced in specific organs or systems by toxic agents? What are the agents that produce these effects?

A more conventional approach to toxicology has been utilized in the third section (Unit III), in which the toxic agents are grouped by chemical or use characteristics. In the final section (Unit IV) an

attempt has been made to illustrate the ramifications of toxicology into all areas of the health sciences and even beyond. This unit is intended to provide perspective for the nontoxicologist in the application of the results of toxicologic studies and a better understanding of the activities of those engaged in the various aspects of the discipline of toxicology.

It will be obvious to the reader that the contents of this book represent a compromise between the basic, fundamental, mechanistic approach to toxicology and the desire to give a view of the broad horizons presented by the subject. While it is certain that the editors' selectivity might have been more severe, it is equally certain that it could have been less so, and we hope that the balance struck will prove to be appropriate for both toxicologic training and the scientific interest of our colleague.

L.J.C.
J.D.

Although the philosophy and design of this book evolved over a long period of friendship and mutual respect between the editors, the effort needed to convert ideas into reality was undertaken primarily by Louis J. Casarett. Thus, his death at a time when completion of the manuscript was in sight was particularly tragic. With the help and encouragement of his wife, Margaret G. Casarett, and the other contributors, we have finished Lou's task. This volume is a fitting embodiment of Louis J. Casarett's dedication to toxicology and to toxicologic education.

History and Scope of Toxicology

Michael A. Gallo

History of Toxicology

Antiquity
Middle Ages
Age of Enlightenment

20th Century Toxicology: The Awakening of Understanding

The Second Half of the 19th Century The 21st Century

Toxicology has been defined as the study of the adverse effects of xenobiotics and thus is a borrowing science that has evolved from ancient poisoners. Modern toxicology goes beyond the study of the adverse effects of exogenous agents to the study of molecular biology, using toxicants as tools. Historically, toxicology formed the basis of therapeutics and experimental medicine. Toxicology in this century (1900 to the present) continues to develop and expand by assimilating knowledge and techniques from most branches of biology, chemistry, mathematics, and physics. A recent addition to the field of toxicology (1975 to the present) is the application of the discipline to safety evaluation and risk assessment.

The contributions and activities of toxicologists are diverse and widespread. In the biomedical area, toxicologists are concerned with mechanisms of action and exposure to chemical agents as a cause of acute and chronic illness. Toxicologists contribute to physiology and pharmacology by using toxic agents to understand physiological phenomena. They are involved in the recognition, identification, and quantification of hazards resulting from occupational exposure to chemicals and the public health aspects of chemicals in air, water, other parts of the environment, foods, and drugs. Traditionally, toxicologists have been intimately involved in the discovery and development of new drugs and pesticides. Toxicologists also participate in the development of standards and regulations designed to protect human health and the environment from the adverse effects of chemicals. Environmental toxicologists (a relatively new subset of the discipline) have expanded toxicology to study the effects of chemicals in flora and fauna. Molecular toxicologists are studying the mechanisms by which toxicants modulate cell growth and differentiation and cells respond to toxicants at the level of the gene. In all branches of toxicology, scientists explore the mechanisms by which chemicals produce adverse effects in biological systems. Clinical toxicologists develop antidotes and treatment regimes to ameliorate poisonings and xenobiotic injury. Toxicologists carry out some or all of these activities as members of academic, industrial, and governmental organizations. In doing so, they share methodologies for obtaining data about the toxicity of materials and the responsibility for using this information to make reasonable predictions regarding the hazards of the material to people

and the environment. These different but complementary activities characterize the discipline of toxicology.

Toxicology, like medicine, is both a science and an art. The science of toxicology is defined as the observational and data-gathering phase, whereas the art of toxicology consists of the utilization of the data to predict outcomes of exposure in human and animal populations. In most cases, these phases are linked because the facts generated by the science of toxicology are used to develop extrapolations and hypotheses to explain the adverse effects of chemical agents in situations where there is little or no information. For example, the observation that the administration of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) to female Sprague–Dawley rats induces hepatocellular carcinoma is a fact. However, the conclusion that it will also do so in humans is a prediction or hypothesis. It is important to distinguish facts from predictions. When we fail to distinguish the science from the art, we confuse facts with predictions and argue that they have equal validity, which they clearly do not. In toxicology, as in all sciences, theories have a higher level of certainty than do hypotheses, which in turn are more certain than speculations, opinions, conjectures, and guesses. An insight into modern toxicology and the roles, points of view, and activities of toxicologists can be obtained by examining the historical evolution of the discipline.

HISTORY OF TOXICOLOGY

Antiquity

Toxicology dates back to the earliest humans, who used animal venoms and plant extracts for hunting, warfare, and assassination. Elucidating the mechanisms of the toxicity of venoms continues today in the field of toxinology. The knowledge of these poisons must have predated recorded history. It is safe to assume that prehistoric humans categorized some plants as harmful and others as safe. The same is probably true for the classification of snakes and other animals. The Ebers Papyrus (circa 1500 BC) contains information pertaining to many recognized poisons, including hemlock (the state poison of the Greeks), aconite (a Chinese arrow poison), opium (used as both a poison and an antidote), and metals such

as arsenic lead, copper, and antimony. There is also an indication that plants containing substances similar to digitalis and belladonna alkaloids were known. Hippocrates (circa 400 BC) added a number of poisons and clinical toxicology principles pertaining to bioavailability in therapy and overdose, while the *Book of Job* (circa 400 BC) speaks of poison arrows (Job 6:4). In the literature of ancient Greece, there are several references to poisons and their use. Some interpretations of Homer have Odysseus obtaining poisons for his arrows (Homer, circa 600 BC). Theophrastus (370–286 BC), a student of Aristotle, included numerous references to poisonous plants in *De Historia Plantarum*. Dioscorides, a Greek physician in the court of the Roman emperor Nero, made the first attempt at a classification of poisons, which was accompanied by descriptions and drawings. His classification into plant, animal, and mineral poisons not only remained a standard for 16 centuries but also is still a convenient classification (Gunther, 1934). Dioscorides also dabbled in therapy, recognizing the use of emetics in poisoning and the use of caustic agents and cupping glasses in snakebite. Poisoning with plant and animal toxins was quite common. Perhaps the best known recipient of poison used as a state method of execution was Socrates (470–399 BC), whose cup of hemlock extract was apparently estimated to be the proper dose. Expeditious suicide on a voluntary basis also made use of toxicological knowledge. Demosthenes (385–322 BC), who took poison hidden in his pen, was one of many examples. The mode of suicide calling for one to fall on his sword, although manly and noble, carried little appeal and less significance for the women of the day. Cleopatra's (69–30 BC) knowledge of natural primitive toxicology permitted her to use the more genteel method of falling on her asp.

The Romans too made considerable use of poisons in politics. One legend tells of King Mithridates VI of Pontus, whose numerous acute toxicity experiments on unfortunate criminals led to his eventual claim that he had discovered an antidote for every venomous reptile and poisonous substance (Guthrie, 1946). Mithridates was so fearful of poisons that he regularly ingested a mixture of 36 ingredients (Galen reports 54) as protection against assassination. On the occasion of his imminent capture by enemies, his attempts to kill himself with poison failed because of his successful antidote concoction, and he was forced to use a sword held by a servant. From this tale comes the term “mithridatic,” referring to an antidotal or protective mixture. The term “theriac” also has become synonymous with “antidote,” although the word comes from the poetic treatise *Theriaca* by Nicander of Colophon (204–135 BC), which dealt with poisonous animals; his poem *Alexipharmaca* was about antidotes.

Poisonings in Rome reached epidemic proportions during the 4th century BC (Livy). It was during this period that a conspiracy of women to remove men from whose death they might profit was uncovered. Similar large-scale poisoning continued until Sulla issued the *Lex Cornelia* (circa 82 BC). This appears to be the first law against poisoning, and it later became a regulatory statute directed at careless dispensers of drugs. Nero (AD 37–68) used poisons to do away with his stepbrother Britannicus and employed his slaves as food tasters to differentiate edible mushrooms from their more poisonous kin.

Middle Ages

*Come bitter pilot, now at once run on
The dashing rocks thy seasick weary bark!
Here's to my love! O true apothecary!
Thy drugs are quick. Thus with a kiss I die.*

Romeo and Juliet, act 5, scene 3

Before the Renaissance, the writings of Maimonides (Moses ben Maimon, AD 1135–1204) included a treatise on the treatment of poisonings from insects, snakes, and mad dogs (*Poisons and their Antidotes*, 1198). Maimonides, like Hippocrates before him, wrote on the subject of bioavailability, noting that milk, butter, and cream could delay intestinal absorption. Maimonides also refuted many of the popular remedies of the day and stated his doubts about others. It is rumored that alchemists of this period (circa AD 1200), in search of the universal antidote, learned to distill fermented products and made a 60% ethanol beverage that had many interesting powers.

In the early Renaissance, the Italians, with characteristic pragmatism, brought the art of poisoning to its zenith. The poisoner became an integral part of the political scene. The records of the city councils of Florence, particularly those of the infamous Council of Ten of Venice, contain ample testimony about the political use of poisons. Victims were named, prices set, and contracts recorded; when the deed was accomplished, payment was made.

An infamous figure of the time was a lady named Toffana who peddled specially prepared arsenic-containing cosmetics (*Agua Toffana*). Accompanying the product were appropriate instructions for its use. Toffana was succeeded by an imitator with organizational genius, Hieronyma Spara, who provided a new fillip by directing her activities toward specific marital and monetary objectives. A local club was formed of young wealthy married women, which soon became a club of eligible young wealthy widows, reminiscent of the matronly conspiracy of Rome centuries earlier. Incidentally, arsenic-containing cosmetics were reported to be responsible for deaths well into the 20th century (Kallet and Schlink, 1933).

Among the prominent families engaged in poisoning, the Borgias were the most notorious. However, many deaths that were attributed to poisoning are now recognized as having resulted from infectious diseases such as malaria. It appears true, however, that Alexander VI, his son Cesare, and Lucrezia Borgia were quite active. The deft application of poisons to men of stature in the Catholic Church swelled the holdings of the papacy, which was their prime heir.

In this period Catherine de Medici exported her skills from Italy to France, where the prime targets of women were their husbands. However, unlike poisoners of an earlier period, the circle represented by Catherine and epitomized by the notorious Marchioness de Brinvillers depended on developing direct evidence to arrive at the most effective compounds for their purposes. Under the guise of delivering provender to the sick and the poor, Catherine tested toxic concoctions, carefully noting the rapidity of the toxic response (onset of action), the effectiveness of the compound (potency), the degree of response of the parts of the body (specificity, site of action), and the complaints of the victim (clinical signs and symptoms).

The culmination of the practice in France is represented by the commercialization of the service by Catherine Deshayes, a midwife sorceress who earned the title “La Voisin.” Her business was dissolved by her execution in 1680. Her trial was 1 of the most famous of those held by the *Chambre Ardente*, a special judicial commission established by Louis XIV to try such cases without regard to age, sex, or national origin. La Voisin was convicted of many poisonings, with over 2000 infants among her victims.

Age of Enlightenment

All substances are poisons; there is none which is not a poison. The right dose differentiates poison from a remedy.

Paracelsus

A significant figure in the history of science and medicine in the late Middle Ages was the renaissance man Philippus Aureolus Theophrastus Bombastus von Hohenheim-Paracelsus (1493–1541). Between the time of Aristotle and the age of Paracelsus, there was little substantial change in the biomedical sciences. In the 16th century, the revolt against the authority of the Catholic Church was accompanied by a parallel attack on the godlike authority exercised by the followers of Hippocrates and Galen. Paracelsus personally and professionally embodied the qualities that forced numerous changes in this period. He and his age were pivotal, standing between the philosophy and magic of classical antiquity and the philosophy and science willed to us by figures of the 17th and 18th centuries. Clearly, one can identify in Paracelsus's approach, point of view, and breadth of interest numerous similarities to the discipline that is now called toxicology.

Paracelsus, a physician–alchemist and the son of a physician, formulated many revolutionary views that remain an integral part of the structure of toxicology, pharmacology, and therapeutics today (Pagel, 1958). He promoted a focus on the “toxicon,” the primary toxic agent, as a chemical entity, as opposed to the Grecian concept of the mixture or blend. A view initiated by Paracelsus that became a lasting contribution held as corollaries that (1) experimentation is essential in the examination of responses to chemicals, (2) one should make a distinction between the therapeutic and toxic properties of chemicals, (3) these properties are sometimes but not always indistinguishable except by dose, and (4) one can ascertain a degree of specificity of chemicals and their therapeutic or toxic effects. These principles led Paracelsus to introduce mercury as the drug of choice for the treatment of syphilis, a practice that survived 300 years but led to his famous trial. This viewpoint presaged the “magic bullet” (arsphenamine) of Paul Ehrlich and the introduction of the therapeutic index. Further, in a very real sense, this was the first sound articulation of the dose–response relation, a bulwark of toxicology (Pachter, 1961).

The tradition of the poisoners spread throughout Europe, and their deeds played a major role in the distribution of political power throughout the Middle Ages. Pharmacology as it is known today had its beginnings during the Middle Ages and early Renaissance. Concurrently, the study of the toxicity and the dose–response relationship of therapeutic agents were commencing.

The occupational hazards associated with metalworking were recognized during the 15th century. Early publications by Ellenbog (circa 1480) warned of the toxicity of the mercury and lead exposures involved in goldsmithing. Agricola published a short treatise on mining diseases in 1556. However, the major work on the subject, *On the Miners: Sickness and Other Diseases of Miners* (1567), was published by Paracelsus. This treatise addressed the etiology of miners' disease, along with treatment and prevention strategies. Occupational toxicology was further advanced by the work of Bernardino Ramazzini. His classic, published in 1700 and entitled *Discourse on the Diseases of Workers*, set the standard for occupational medicine well into the 19th century. Ramazzini's work broadened the field by discussing occupations ranging from miners to midwives and including printers, weavers, and potters.

The developments of the industrial revolution stimulated a rise in many occupational diseases. The recognition, in 1775, of the renowned 18th-century English surgeon Percival Pott (1714–1788) of the role of soot in scrotal cancer among chimney sweeps was the first reported example of polyaromatic hydrocarbon (PAH) carcinogenicity, a problem the mechanism of which still intrigues

toxicologists today. These findings led to improved medical practices, particularly in prevention of occupationally related diseases. It should be noted that Paracelsus and Ramazzini also pointed out the toxicity of smoke and soot.

The 19th century dawned in a climate of industrial and political revolution. Organic chemistry was in its infancy in 1800, but by 1825 phosgene (COCl_2) and mustard gas (bis[β -chloroethyl]sulfide) had been synthesized. These 2 agents, along with chlorine gas, were used by the German forces in World War I as chemical warfare agents. They were stockpiled throughout World War II, and used by Iraq in the Iran–Iraq War in the 1980s (*Marine Corps History*). By 1880 over 10,000 organic compounds had been synthesized including chloroform, carbon tetrachloride, diethyl ether, and carbonic acid, and petroleum and coal gasification by-products were used in trade. Determination of the toxicological potential of these newly created chemicals became the underpinning of the science of toxicology as it is practiced today. However, there was little interest during the mid-19th century in hampering industrial development. Hence, the impact of industrial toxicology discoveries was not felt until the passage of worker's insurance laws, first in Germany (1883), then in England (1897), and later in the United States (1910). Experimental toxicology accompanied the growth of organic chemistry and developed rapidly during the 19th century. Magendie (1783–1885), Orfila (1787–1853), and Bernard (1813–1878) carried out truly seminal research in experimental toxicology and medicine, and laid the groundwork for pharmacology, drug safety toxicology, and experimental therapeutics as well as occupational toxicology.

Orfila, a Spanish physician in the French court, was the first toxicologist to use autopsy material and chemical analysis systematically as legal proof of poisoning. His introduction of this detailed type of analysis survives as the underpinning of forensic toxicology (Orfila, 1818). Orfila published the first major work devoted expressly to the toxicity of natural agents (1814–1815). Magendie, a physician and experimental physiologist, studied the mechanisms of action of emetine, strychnine, and “arrow poisons” (Olmsted, 1944). His research into the absorption and distribution of these compounds in the body (the precursor to ADME studies today) remains a classic in toxicology and pharmacology. One of Magendie's more famous students, Claude Bernard, continued the study of arrow poisons (Bernard, 1850) but also added works on the mechanism of action of carbon monoxide. Bernard's treatise, *Introduction to the Study of Experimental Medicine* (translated by Greene and Schuman in 1949), is a classic in the development of toxicology.

Many German scientists contributed greatly to the growth of toxicology in the late 19th and early 20th centuries. Among the giants of the field are Oswald Schmiedeberg (1838–1921) and Louis Lewin (1850–1929). Schmiedeberg made many contributions to the science of toxicology, not the least of which was the training of approximately 120 students who later populated the most important laboratories of pharmacology and toxicology throughout the world. Schmiedeberg's research focused on the synthesis of hippuric acid in the liver and the detoxification mechanisms of the liver in several animal species (Schmiedeberg and Koppe, 1869). Lewin, who was educated originally in medicine and the natural sciences, trained in toxicology under Liebreich at the Pharmacological Institute of Berlin (1881). His contributions on the chronic toxicity of narcotics and other alkaloids remain a classic. Lewin also published much of the early work on the toxicity of methanol, glycerol, acrolein, and chloroform (Lewin, 1920, 1929).

20TH CENTURY TOXICOLOGY: THE AWAKENING OF UNDERSTANDING

The doubter is a true man of science; he doubts only himself and his interpretations, but he believes in science.

Claude Bernard

The latter part of the 19th century saw the introduction of “patent medicines” in many parts of the world.

Toxicology evolved rapidly during the 20th century. The early controversies focusing on patent medicines and sale of consumer products of questionable safety (Kallett and Schlink) were followed by the rapid advances in analytical chemistry methods that fostered the advancement of forensic toxicology specifically at the New York City Medical Examiner’s Office. However, the exponential growth of the discipline can be traced to the World War II era with its marked increase in the production of drugs, pesticides, munitions, synthetic fibers, and industrial chemicals. The history of many sciences represents an orderly transition based on theory, hypothesis testing, and synthesis of new ideas. Toxicology, as a gathering and an applied science, has, by contrast, developed in fits and starts. It calls on almost all the basic sciences to test its hypotheses. This fact, coupled with the health and occupational regulations that have driven toxicology research since 1900, has made toxicology exceptional in the history of science. The differentiation of toxicology as an art and a science, though arbitrary, permits the presentation of historical highlights along 2 major lines.

Modern toxicology can be viewed as a continuation of the development of the biological and physical sciences in the late 19th and 20th centuries (Table 1-1). During the second half of the 19th century, the world witnessed an explosion in science that produced the beginning of the modern era of medicine, synthetic chemistry, physics, and biology. Toxicology has drawn its strength and diversity from its proclivity to borrowing. With the advent of anesthetics and disinfectants and the advancement of experimental pharmacology in the late 1850s, toxicology as it is currently understood got its start. The introduction of ether, chloroform, and carbonic acid led to several iatrogenic deaths. These unfortunate outcomes spurred research into the causes of the deaths and early experiments on the physiological mechanisms by which these compounds caused both beneficial and adverse effects. By the late 19th century the use of organic chemicals was becoming more widespread, and benzene, toluene, and the xylenes, as well as the chlorinated solvents related to chloroform, went into large-scale commercial production. During this period, the use of patent medicines, consisting primarily of “medicinal herbs,” nonsugar sweeteners, and alcohol, was prevalent, and there were several incidents of poisonings from these medicaments. In 1902 Congress approved \$5000 to fund the “Poison Squad,” professional tasters under the direction of Harvey Washington Wiley that harkened back to the food tasters used by royalty to avoid intentional poisoning from their foods. The case of “Doctor” Munyan versus Harvey Wiley, MD (1844–1930), a classic battle between the federal government and the most infamous purveyor of patent medicines, over mislabeling, false advertisement, lack of efficacy, and serious toxicity led to further Congressional action. The adverse reactions to patent medicines and mislabeled foods coupled with the response to Upton Sinclair’s exposé of the Chicago meat-packing industry in *The Jungle* (1905) culminated in the passage of the Wiley Bill (*The Pure Foods Act of 1906*).

Table 1-1

Selection of Developments in Toxicology

Development of early advances in analytical methods

Marsh: development of method for arsenic analysis

Reinsh: combined method for separation and analysis of As and Hg

Fresenius and von Babo: development of screening method for general poisons

Stas-Otto: detection and identification of phosphorus

Early mechanistic studies

F. Magendie: study of “arrow poisons,” mechanism of action of emetine and strychnine

C. Bernard (1850): carbon monoxide combination with hemoglobin, study of mechanism of action of strychnine, site of action of curare

R. Bohm (ca. 1890): active anthelmintics from fern, action of croton oil catharsis, poisonous mushrooms

Introduction of new toxicants and antidotes

R. A. Peters, L. A. Stocken, and R. H. S. Thompson: development of British anti-Lewisite (BAL) as a relatively specific antidote for arsenic, toxicity of monofluorocarbon compounds

K. K. Chen: introduction of modern antidotes (nitrite and thiosulfate) for cyanide toxicity

C. Voegtlin *et al.* (1923): mechanism of action of As and other metals on the SH groups

P. Müller: introduction and study of dichlorodiphenyltrichloroethane (DDT) and related insecticide compounds

G. Schrader: introduction and study of organophosphorus compounds

R. N. Chopra: indigenous drugs of India

Miscellaneous toxicological studies

R. T. Williams: study of detoxication mechanisms and species variation

A. Rothstein: effects of uranium ion on cell membrane transport

R. A. Kehoe: investigation of acute and chronic effects of lead

A. Vorwald: studies of chronic respiratory disease (beryllium)

H. Hardy: community and industrial poisoning (beryllium)

A. Hamilton: introduction of modern industrial toxicology

H. C. Hodge: toxicology of uranium, fluorides; standards of toxicity

A. Hoffman: introduction of lysergic acid and derivatives; psychotomimetics

R. A. Peters: biochemical lesions, lethal synthesis

A. E. Garrod: inborn errors of metabolism

T. T. Litchfield and F. Wilcoxon: simplified dose–response evaluation

C. J. Bliss: method of probits, calculation of dosage–mortality curves

This was the first of many US pure food and drug laws (see Hutt and Hutt, 1984, for regulatory history of foods). The Wiley Bill as it was known was widely supported in Congress at its passage. However, the support did not last. The Bill required prior toxicity testing, the establishment of a government analytical laboratory, and the removal of toxic compounds, particularly ethanol, herbal mixtures, and coloring agents. It also prohibited false advertising. After enactment of the Bill, individual federal leaders including Congressmen and judges, as well as “Dr” Munyan (who claimed his remedies were effective and had cured thousands), campaigned against its enforcement. Parts of the Bill were overturned by Justice Oliver Wendell Holmes and the US Supreme Court in 1911 stating that “hype is not false advertising.” In part because of the opposition to the Bill, Wiley left the government to direct the fledgling Consumer Union in 1912. Today, a century later, similar battles are being fought over dietary supplements and food additives.

A working hypothesis about the development of toxicology is that the discipline expands in response to legislation, which itself is a response to a real or perceived tragedy. The Wiley Bill was the first such reaction in the area of food and drugs, and the workers’ compensation laws cited above were a response to occupational toxicities. In addition, the National Safety Council was established in 1911, and the Division of Industrial Hygiene was established by the US Public Health Service in 1914. A corollary to this hypothesis might be that the founding of scientific journals and/or societies is sparked by the development of a new field. The *Journal of Industrial Hygiene* began in 1918. The major chemical manufacturers in the United States (Dow, Union Carbide, and Du Pont) established internal toxicology research laboratories to help guide decisions on worker health and product safety.

During the 1890s and early 1900s, European scientists Becquerel, Roentgen, and the Curies reported the discovery of radioactivity and x-rays. This opened up for exploration a very large area in physics, biology, and medicine. Interestingly, many of these early researchers died of radiation poisoning. Radiation exposure became widespread in consumer usage. Radium-containing rocks were touted as health cures, and the Radiothor and radium dial watches were widespread. The adverse effects were virtually unknown and radiation would not actively affect the science of toxicology until the World War II era.

However, another discovery, that of vitamins, or “vital amines,” led to the use of the first large-scale bioassays (multiple animal studies) to determine whether these new synthetic chemicals were beneficial or harmful to laboratory animals, and by extension to humans. The initial work in this area took place at around the time of World War I in several laboratories, including the laboratory of Philip B. Hawk in Philadelphia. Hawk and a young associate, Bernard L. Oser, were responsible for the development and verification of many early toxicological assays that are still used in a slightly amended form. The results from these animal studies formed the underpinnings of risk assessment. Oser’s contributions to food and regulatory toxicology were extraordinary. These early bioassays were made possible by a major advance in toxicology: the availability of developed and refined strains of inbred laboratory rodents (Donaldson, 1912) and the rapid development of analytical chemistry.

The 1920s saw many events that began to mold the fledgling field of toxicology. The discovery by Paul Ehrlich (1854–1915) of arsenicals for the treatment of syphilis (arsenicals had been used in agriculture since the mid-19th century) resulted in acute

and chronic toxicity. Arsenic remains a major toxicant in many developing nations. Prohibition of alcoholic beverages in the United States opened the door for early studies of neurotoxicology, with the discovery that triorthocresyl phosphate (TOCP), methanol, and lead (all found in bootleg liquor) are neurotoxins. TOCP, which was a recent gasoline additive, caused a syndrome that became known as “ginger-jake” walk, a spastic gait resulting from drinking ginger beer adulterated with TOCP. Methanol, used as a cheap ethanol substitute, blinded and killed many unsuspecting people (see *Poisoners Handbook*, 2011). Mueller’s discovery of dichlorodiphenyltrichloroethane (DDT) and several other organohalides, such as hexachlorobenzene and hexachlorocyclohexane, during the late 1920s resulted in widespread use of these insecticidal agents. Toxicity testing of the new organohalide compounds was in its infancy. Understanding of the modes of action and persistence of these compounds would have to wait 40 years.

Other scientists were hard at work attempting to elucidate the structures and activity of the estrogens and androgens. Work on the steroid hormones led to the use of several assays for the determination of the biological activity of organ extracts and synthetic compounds. Allen and Doisy published the first uterotrophic assay (1928) that accelerated the study of estrogenic chemicals. Modifications of this assay are used today in studying endocrine disruption by xenobiotics. Efforts to synthesize estrogen-active chemicals were spearheaded by E. C. Dodds and his co-workers, one of whom was Leon Golberg, a young organic chemist and a future leader in toxicology. Dodds’s work on the bioactivity of the estrogenic compounds resulted in the synthesis of diethylstilbestrol (DES), hexestrol, other stilbenes, and bisphenol A (BPA) and the discovery of the strong estrogenic activity of substituted stilbenes. Golberg’s intimate involvement in this work stimulated his interest in biology, leading to degrees in biochemistry and medicine and a career in toxicology in which he oversaw the creation of the laboratories of the British Industrial Biological Research Association (BIBRA) and the Chemical Industry Institute of Toxicology (CIIT). Interestingly, the initial observations that led to the discovery of DES were the findings of feminization of animals treated with the experimental carcinogen 7,12-dimethylbenz[*a*]anthracene (DMBA).

Occupational illnesses became more pronounced after the 1920s, and occupational toxicology developed into a field of its own. The seminal works of Alice Hamilton (1869–1970) (Exploring the Dangerous Trades) and Ethel Browning (Toxicity of Industrial Solvents, 1937) are critical readings.

The 1930s saw the world preparing for World War II and a major effort by the pharmaceutical and chemical industry in Europe and the United States to manufacture the first mass-produced antibiotics. One of the first journals expressly dedicated to experimental toxicology, *Archiv für Toxikologie*, began publication in Europe in 1930, the same year that Herbert Hoover signed the act that established the National Institutes of Health (NIH) in the United States.

The discovery of sulfanilamide was heralded as a major event in combating bacterial diseases. However, for a drug to be effective, there must be a reasonable delivery system, and sulfanilamide is highly insoluble in an aqueous medium. Therefore, it was originally prepared in ethanol (elixir). However, it was soon discovered that the drug was more soluble in diethylene glycol. The drug was sold in glycol solutions but was labeled as an elixir, and several patients (mostly children) died of acute kidney failure resulting from the metabolism of the glycol to oxalic acid

and glycolic acid, with the acids and the active drug crystallizing in the kidney tubules. This tragic event led to the passage of the Copeland Bill in 1938, the second major bill involving the formation of the US Food and Drug Administration (FDA). The sulfanilamide disaster played a critical role in the further development of toxicology, resulting in work by Eugene Maximilian Geiling in the Pharmacology Department of the University of Chicago that elucidated the mechanism of toxicity of both sulfanilamide and diethylene glycol. Studies of the glycols were simultaneously carried out at the US FDA by a group led by Arnold Lehman. The scientists associated with Lehman and Geiling were to become the leaders of toxicology (especially the Society of Toxicology) over the next 40 years. With few exceptions, toxicology in the United States owes its heritage to Geiling's innovativeness and ability to stimulate and direct young scientists, and Lehman's vision of the use of experimental toxicology in public health decision making. Because of Geiling's reputation, the US government turned to this group for help in the war effort. There were 3 main areas in which the Chicago group took part during World War II: the toxicology and pharmacology of organophosphate (OP) chemicals, antimalarial drugs, and radionuclides. Each of these areas produced teams of toxicologists who became academic, governmental, and industrial leaders in the field.

It was also during this time that DDT and the phenoxy herbicides were developed for increased food production and, in the case of DDT, control of insect-borne diseases. These efforts between 1940 and 1946 led to an explosion in toxicology. Thus, in line with the hypothesis advanced above, the crisis of World War II caused the next major leap in the development of toxicology.

If one traces the history of the toxicology of metals over the past 45 years, the role of the Chicago and Rochester groups is quite visible. This story commences with the use of uranium for the "bomb" and continues today with research on the role of metals in their interactions with DNA, RNA, and growth factors. Indeed, the Manhattan Project created a fertile environment that resulted in the initiation of quantitative biology, radiotracer technology, and inhalation toxicology. These innovations have revolutionized modern biology, chemistry, therapeutics, and toxicology.

Inhalation toxicology began at the University of Rochester under the direction of Stafford Warren, who headed the Department of Radiology. He developed a program with colleagues such as Harold Hodge (pharmacologist), Herb Stokinger (chemist), Sid Laskin (inhalation toxicologist), and Lou and George Casarett (toxicologists). These young scientists were to go on to become giants in the field. The other sites for the study of radionuclides were Chicago for the "internal" effects of radioactivity and Oak Ridge, Tennessee, for the effects of "external" radiation. The work of the scientists on these teams gave the scientific community data that contributed to the early understanding of macromolecular binding of xenobiotics, cellular mutational events, methods for inhalation toxicology and therapy, and toxicological properties of trace metals, along with a better appreciation of the complexities of the dose-response curve.

Another seminal event in toxicology that occurred during the World War II era was the discovery by Lange and Schrader in 1938 of OP cholinesterase inhibitors including sarin, tabun (chemical warfare agents), and less potent OP insecticides. This class of chemicals was destined to become a driving force in the study of neurophysiology and toxicology for several decades. Again, the scientists in Chicago played major roles in elucidating the mechanisms of action of this new class of compounds. Geiling's group, Kenneth DuBois in particular, was the leader in this area of toxicology and pharmacology. DuBois's colleagues, particularly

Sheldon Murphy, continued to be in the forefront of this special area. The importance of the early research on the OPs has taken on special meaning in the years since 1960, when these nonbioaccumulating insecticides were destined to replace DDT and other organochlorine insecticides. Today, a third generation of insecticides has replaced much of the OP use.

Early in the 20th century, it was demonstrated experimentally that quinine has a marked effect on the malaria parasite (it had been known for centuries that cinchona bark extract is efficacious for "Jesuit fever" [malaria]). This discovery led to the development of quinine derivatives for the treatment of the disease and the formulation of the early principles of chemotherapy. The Pharmacology Department of the University of Chicago was charged with the development of antimalarials for the war effort. The original protocols called for testing of efficacy and toxicity in rodents and perhaps dogs and then the testing of efficacy in human volunteers. One of the investigators charged with generating the data needed to move a candidate drug from animals to humans was Fredrick Coulston. This young parasitologist and his colleagues, working in Chicago, were to evaluate potential drugs in animal models and then establish human clinical trials. It was during these experiments that the use of nonhuman primates came into vogue for toxicology testing. It had been noted by Russian scientists that some antimalarial compounds caused retinopathies in humans but did not apparently have the same adverse effect in rodents and dogs. This finding led the Chicago team to add 1 more step in the development process: toxicity testing in rhesus monkeys just before efficacy studies in people. This resulted in the prevention of blindness in untold numbers of volunteers and perhaps some of the troops in the field. It also led to the school of thought that nonhuman primates may be one of the better models for humans and the establishment of primate colonies for the study of toxicity. Coulston pioneered this area of toxicology and remained committed to it.

Another area not traditionally thought of as toxicology but one that evolved during the 1940s as an exciting and innovative field is experimental pathology. This branch of experimental biology developed from bioassays of estrogens and early experiments in chemical- and radiation-induced carcinogenesis. It is from these early studies that hypotheses on tumor promotion and cancer progression have evolved.

Toxicologists today owe a great deal to the researchers of chemical carcinogenesis of the 1940s. Much of today's work can be traced to Elizabeth and James Miller at Wisconsin. This husband and wife team started under the mentorship of Professor Rusch, the director of the newly formed McArdle Laboratory for Cancer Research, and Professor Baumann. The seminal research of the Millers led to the discovery of the role of reactive intermediates in carcinogenicity and that of mixed-function oxidases in the endoplasmic reticulum. These findings, which initiated the great works on the cytochrome P450 family of proteins, were aided by 2 other major discoveries for which toxicologists (and all other biological scientists) are deeply indebted: paper chromatography in 1944 and the use of radiolabeled dibenzanthracene in 1948. Other major events of note in drug metabolism included the work of Bernard Brodie on the metabolism of methyl orange in 1947. This piece of seminal research led to the examination of blood and urine for chemical and drug metabolites. It became the tool with which one could study the relationship between blood levels and biological action. The classic treatise of R. T. Williams, *Detoxication Mechanisms*, was published in 1947. This text described the many pathways and possible mechanisms of detoxication and opened the field to several new areas of study.

The decade after World War II was not as boisterous as the period from 1935 to 1945. The first major US pesticide act was signed into law in 1947. The significance of the initial Federal Insecticide, Fungicide, and Rodenticide Act was that for the first time in US history a substance that was neither a drug nor a food had to be shown to be safe and efficacious. This decade, which coincided with the Eisenhower years, saw the dispersion of the groups from Chicago, Rochester, and Oak Ridge and the establishment of new centers of research. Adrian Albert's classic *Selective Toxicity* was published in 1951. This treatise, which has appeared in several editions, presented a concise documentation of the principles of the site-specific action of chemicals.

THE SECOND HALF OF THE 19TH CENTURY

You too can be a toxicologist in two easy lessons, each of ten years.

Arnold Lehman (circa 1955)

The mid-1950s witnessed the strengthening of the US FDA's commitment to toxicology under the guidance of Arnold Lehman. Lehman's tutelage and influence are still felt today. The adage "You too can be a toxicologist" is as important a summation of toxicology as the often-quoted statement of Paracelsus: "The dose makes the poison." The period from 1955 to 1958 produced 2 major events that would have a long-lasting impact on toxicology as a science and a professional discipline. Lehman, Fitzhugh, and their co-workers formalized the experimental program for the appraisal of food, drug, and cosmetic safety in 1955, updated by the US FDA in 1982, and the Gordon Research Conferences established a conference on toxicology and safety evaluation, with Bernard L. Oser as its initial chairman. These 2 events led to close relationships among toxicologists from several groups and brought toxicology into a new phase. At about the same time, the US Congress passed and the president of the United States signed the additives amendments to the Food, Drug, and Cosmetic Act. The Delaney Clause (1958) of these amendments stated broadly that any chemical found to be carcinogenic in laboratory animals or humans could not be added to the US food supply. The impact of this legislation cannot be overstated. Delaney became a battle cry for many groups and resulted in the inclusion at a new level of biostatisticians and mathematical modelers in the field of toxicology. It fostered the expansion of quantitative methods in toxicology and led to innumerable arguments about the "1-hit" theory of carcinogenesis. Regardless of one's view of Delaney, it has served as an excellent starting point for understanding the complexity of the biological phenomenon of carcinogenicity and the development of risk assessment models. One must remember that at the time of Delaney, the analytical detection level for most chemicals was 20 to 100 ppm (today, parts per quadrillion). Interestingly, the Delaney Clause has been invoked only on a few occasions, and it has been stated that Congress added little to the food and drug law with this clause (Hutt and Hutt, 1984).

Shortly after the Delaney amendment and after 3 successful Gordon Conferences, the first American journal dedicated to toxicology was launched by Coulston, Lehman, and Hayes. *Toxicology and Applied Pharmacology* has been a flagship journal of toxicology ever since. The founding of the Society of Toxicology (1961) followed shortly afterward, and this journal became its official publication of the SOT through the 20th century. The society's founding members were Fredrick Coulston, William Deichmann, Kenneth DuBois, Victor Drill, Harry Hayes, Harold Hodge, Paul Larson, Arnold Lehman, and C. Boyd Shaffer. These researchers

deserve a great deal of credit for the growth of toxicology. DuBois and Geiling published their *Textbook of Toxicology* in 1959.

In 1975, Louis Casarett and John Doull followed this short text with what has become the most widely accepted general toxicology text—*Toxicology: The Basic Science of Poisons*. This volume is the eighth addition of the classic text.

The 1960s were a tumultuous time for society, and toxicology was swept up in the tide, starting with the tragic thalidomide incident, in which several thousand children were born with serious birth defects. Dr Frances O. Kelsey, a protégé of E. M. K. Geiling, was instrumental in keeping this notorious teratogen off the US market. Interestingly, as the mechanism of thalidomide became known later in the 20th century, the drug and its derivatives were developed for several life-threatening diseases. The publication of Carson's *Silent Spring* (1962) energized the field of environmental toxicology that developed at a feverish pitch. Attempts to understand the effects of chemicals on the embryo and fetus and on the environment as a whole gained momentum. New legislation was passed, and new journals were founded. The education of toxicologists spread from the deep traditions of Chicago and Rochester to Harvard, Miami, Albany, Iowa, Jefferson, and beyond. Geiling's fledglings spread as Schmiedeberg's had a half century before. Many new fields were influencing and being assimilated into the broad scope of toxicology, including environmental sciences, aquatic and avian biology, cell biology, analytical chemistry, and genetics.

During the 1960s the analytical tools used in toxicology were developed to a level of sophistication that allowed the detection of chemicals in tissues and other substrates at part per billion concentrations (see *The Vanishing Zero*, 1972). Today parts per quadrillion and less are detected. Pioneering work in the development of point mutation assays that were replicable, quick, and inexpensive led to a better understanding of the genetic mechanisms of carcinogenicity (Ames, 1983). The combined work of Ames and the Millers (Elizabeth C. and James A.) at McArdle Laboratory allowed the toxicology community to make major contributions to the understanding of the carcinogenic process.

The low levels of detection of chemicals and the ability to detect point mutations rapidly created several problems and opportunities for toxicologists and risk assessors that stemmed from interpretation of the Delaney amendment. Cellular and molecular toxicology developed as a subdiscipline, and risk assessment became a major product of toxicological investigations.

The establishment of the National Center for Toxicologic Research (NCTR), the expansion of the role of the US FDA, and the establishment of the US Environmental Protection Agency (EPA) and the National Institute of Environmental Health Sciences (NIEHS) were considered clear messages that the government had taken a strong interest in toxicology. Several new journals appeared during the 1960s, and new legislation was written quickly after *Silent Spring* and the thalidomide disaster.

Elwood Jensen and his colleagues discovered the high-affinity estradiol-binding protein (the estrogen receptor) in the mid-1960s. The end of the 1960s witnessed the "discovery" of TCDD as a contaminant in the herbicide Agent Orange (the original discovery of TCDD toxicity was reported in 1957). The research on the toxicity of this compound has produced some very good and some very poor research in the field of toxicology. The discovery of a high-affinity cellular binding protein, using techniques established by Jensen, was designated the "Ah" receptor (see Poland and Knutsen, 1982, for a review) at the McArdle Laboratory. Works on the genetics of the receptor at NIH (Nebert and Gonzalez, 1987) revolutionized the field of toxicology. The importance of TCDD

to toxicology lies in the fact that it forced researchers, regulators, and the legal community to look at the role of mechanisms of toxic action in a different fashion.

At least one other event precipitated a great deal of legislation during the 1970s: Love Canal. The “discovery” of Love Canal led to major concerns regarding hazardous wastes, chemical dump sites, and disclosure of information about those sites. Soon after Love Canal, the EPA listed several equally contaminated sites in the United States. The agency was given the responsibility to develop risk assessment methodology to determine health risks from exposure to effluents and to attempt to remediate these sites. These combined efforts led to broad-based support for research into the mechanisms of action of individual chemicals and complex mixtures. Love Canal and similar issues created the legislative environment that led to the Toxic Substances Control Act and eventually to the Superfund Bill. These omnibus bills were created to cover the toxicology of chemicals from initial synthesis to disposal (cradle to grave).

The expansion of legislation, journals, and new societies involved with toxicology was exponential during the 1970s and 1980s and shows no signs of slowing down. Currently, in the United States there are dozens of professional, governmental, and other scientific organizations with thousands of members and over 120 journals dedicated to toxicology and related disciplines.

In addition, toxicology continues to expand in stature and in the number of programs worldwide. The International Congress of Toxicology is made up of toxicology societies from Europe, South America, Asia, Africa, and Australia and brings together the broadest representation of toxicologists.

The original Gordon Conference series that celebrated its 50th anniversary in 2007 has evolved to *Cellular & Molecular Mechanisms of Toxicity*, and several other conferences related to special areas of toxicology are now in existence. The Society of Toxicology formed specialty sections and regional chapters to accommodate the over 6000 scientists involved in toxicology today. The SOT celebrated its 50th anniversary in March 2011. Texts and reference books for toxicology students and scientists abound. Toxicology has evolved from a borrowing science to a seminal discipline seeding the growth and development of several related fields of science and science policy.

The history of toxicology has been interesting and varied but never dull. Perhaps as a science that has grown and prospered by borrowing from many disciplines, it has suffered from the absence of a single goal, but its diversification has allowed for the interspersion of ideas and concepts from higher education, industry, and government. As an example of this diversification, one now finds toxicology graduate programs in medical schools, schools of public health, and schools of pharmacy as well as programs in environmental science and engineering and undergraduate programs in toxicology at several institutions. Surprisingly, courses in toxicology are now being offered in several liberal arts undergraduate schools as part of their biology and chemistry curricula. This has resulted in an exciting, innovative, and diversified field that is serving science and the community at large.

THE 21ST CENTURY

Genetics loads the gun but the environment pulls the trigger.

Judith Stein

The sequencing of the human genome and several other genomes has markedly affected all biological sciences. Toxicology is

no exception. Today new animal models, especially zebrafish, *C. elegans*, and *D. melanogaster* (all of which have orthologs of human genes), are widely used in toxicology. The understanding of epigenetics is opening novel approaches to the fetal origin of adult diseases including cancers, diabetes, and neurodegenerative diseases and disorders. These are discussed in subsequent chapters.

Few disciplines can point to both basic sciences and direct applications at the same time. Toxicology—the study of the adverse effects of xenobiotics—may be unique in this regard. The mechanisms of action of the xenobiotics studied by toxicologists, in the tradition of Claude Bernard, continue to be the tools of modern biology.

INTRODUCTION TO TOXICOLOGY

Toxicology is the study of the adverse effects of chemical or physical agents on living organisms. A *toxicologist* is trained to examine and communicate the nature of those effects on human, animal, and environmental health. Toxicological research examines the cellular, biochemical, and molecular mechanisms of action as well as functional effects such as neurobehavioral and immunological, and assesses the probability of their occurrence. Fundamental to this process is characterizing the relation of exposure (or dose) to the response. *Risk assessment* is the quantitative estimate of the potential effects on human health and environmental significance of various types of chemical exposures (eg, pesticide residues in food, contaminants in drinking water). The variety of potential adverse effects and the diversity of chemicals in the environment make toxicology a broad science, which often demands specialization in one area of toxicology. Our society's dependence on chemicals and the need to assess potential hazards have made toxicologists an increasingly important part of the decision-making processes.

Different Areas of Toxicology

The professional activities of toxicologists fall into 3 main categories: descriptive, mechanistic, and regulatory (Fig. 2-1). Although each has distinctive characteristics, each contributes to the other, and all are vitally important to chemical risk assessment (see Chap. 4).

A *mechanistic toxicologist* is concerned with identifying and understanding the cellular, biochemical, and molecular mechanisms by which chemicals exert toxic effects on living organisms (see Chap. 3 for a detailed discussion of mechanisms of toxicity). The results of mechanistic studies are very important in many areas of applied toxicology. In risk assessment, mechanistic data may be very useful in demonstrating that an adverse outcome (eg, cancer, birth defects) observed in laboratory animals is directly relevant to humans. For example, the relative toxic potential of organophosphorus (OP) insecticides in humans, rodents, and insects can be accurately predicted on the basis of an understanding of common mechanisms (inhibition of acetylcholinesterase) and differences in biotransformation for these insecticides among the different species. Similarly, mechanistic data may be very useful in identifying

Figure 2-1. Graphical representation of the interconnections between different areas of toxicology.

adverse responses in experimental animals that may not be relevant to humans. For example, the propensity of the widely used artificial sweetener saccharin to cause bladder cancer in rats may not be relevant to humans at normal dietary intake rates. This is because mechanistic studies have demonstrated that bladder cancer is induced only under conditions where saccharin is at such a high concentration in the urine that it forms a crystalline precipitate (Cohen, 1998). Dose–response studies suggest that such high concentrations would not be achieved in the human bladder even after extensive dietary consumption.

Mechanistic data are also useful in the design and production of safer alternative chemicals and in rational therapy for chemical poisoning and treatment of disease. For example, the drug thalidomide was originally marketed in Europe and Australia as a sedative agent for pregnant women. However, it was banned for clinical use in 1962 because of devastating birth defects that occurred if the drug was ingested during a critical period in pregnancy. But mechanistic studies over the past several decades have demonstrated that this drug may have a unique molecular mechanism of action that interferes with the expression of certain genes responsible for blood vessel formation (angiogenesis). With an understanding of this mechanism, thalidomide has been “rediscovered” as a valuable therapeutic agent that may be highly effective in the treatment of certain infectious diseases (eg, leprosy) and multiple myeloma. This provides an interesting example of how a highly toxic drug with selectivity toward a specific population (pregnant women) can be used relatively safely with proper precautions. Following its approval for therapeutic use in 1998, a program was established that required all clinicians, pharmacists, and patients who receive thalidomide to enroll in a specific program (System for Thalidomide Education and Prescribing Safety [STEPS]). The population at risk for the potential teratogenic effects of thalidomide (all women of childbearing age) was required to use 2 forms of birth control, and also have a negative pregnancy test within 24 hours of beginning therapy, and periodically thereafter. Among the patients registered with the STEPS program, 6000 were females of childbearing age. Remarkably, after 6 years of use, only 1 patient actually received thalidomide during her pregnancy. She initially tested negative at the beginning of therapy; on a subsequent test she was identified as positive, and the drug was stopped. The pregnancy ended up as a miscarriage (Uhl *et al.*, 2006). Thus, a clear understanding of mechanism of action led to the development of strict prescribing guidelines and patient monitoring, thereby allowing a potentially dangerous drug to be used safely and effectively to treat disease in tens of thousands of patients who would otherwise not have benefited from the therapeutic actions of the drug (Lary *et al.*, 1999).

In addition to aiding directly in the identification, treatment, and prevention of chemical toxicity, an understanding of the mechanisms of toxic action contributes to the knowledge of basic physiology, pharmacology, cell biology, and biochemistry. The advent of new technologies in molecular biology and genomics now provides mechanistic toxicologists with the tools to explore exactly how humans may differ from laboratory animals in their response to toxic substances. These same tools are also being utilized to identify individuals who are genetically susceptible to factors in the environment or respond differently to a chemical exposure. For example, a small percentage of the population genetically lacks the ability to detoxify the chemotherapeutic drug, 6-mercaptopurine, used in the treatment of some forms of leukemia. Young children with leukemia who are homozygous for this genetic trait (about 1 in 300) may experience serious toxic effects from a standard therapeutic dose of this drug (Weinshilboum *et al.*, 1999). Numerous genetic tests for polymorphisms in drug-metabolizing enzymes and transporters are now available that can identify genetically susceptible individuals in advance of pharmacological treatment (Eichelbaum *et al.*, 2006).

The development of new approaches to identifying associations between diseases or adverse outcomes and common genetic variants (polymorphisms) has changed from a focus on individual candidate genes to “genome-wide association studies” (GWAS). GWAS are based on a rapid scan of hundreds of thousands of specific genetic variants (markers called “tag SNP”) across the genome of persons affected by a particular disorder or adverse-response phenotype and persons who are not affected, with robust statistical tests to identify associations between a specific genetic marker and the phenotype (eg, disease state or adverse drug response). These tools have resulted in the discovery of many “gene–environment interactions,” including associations between adverse drug responses and particular genetic polymorphisms (Wang *et al.*, 2011). Moving from the single, “candidate gene” approach to genome-wide studies has led to the development of the relatively new fields of pharmacogenomics and toxicogenomics. These areas provide an exciting opportunity for mechanistic toxicologists to identify and protect genetically susceptible individuals from harmful environmental exposures, and to customize drug therapies that enhance efficacy and minimize toxicity, based on an individual’s genetic makeup.

A *descriptive toxicologist* is concerned directly with toxicity testing, which provides information for safety evaluation and regulatory requirements. The appropriate toxicity tests (as described later in this chapter and other chapters) in cell culture systems or experimental animals are designed to yield information to evaluate risks posed to humans and the environment from exposure to specific chemicals. The concern may be limited to effects on humans, as in the case of drugs and food additives. Toxicologists in the chemical industry, however, must be concerned not only with the risk posed by a company’s chemicals (insecticides, herbicides, solvents, etc) to humans but also with potential effects on fish, birds, and plants, as well as other factors that might disturb the balance of the ecosystem. Descriptive toxicology is of course not divorced from mechanistic studies, as such studies provide important clues to a chemical’s mechanism of action, and thus contribute to the development of mechanistic toxicology through hypothesis generation. Such studies are also a key component of risk assessments that are used by regulatory toxicologists. The development of so-called omics technologies (genomics, transcriptomics, proteomics, metabolomics/metabolomics, etc) forms the basis of the subdiscipline of toxicogenomics. The application of these technologies to toxicity testing is in many ways “descriptive” in nature, yet affords great mechanistic insights into how chemicals produce their toxic effects. This exciting area of toxicology is discussed in more detail later in the chapter.

A *regulatory toxicologist* has the responsibility for deciding, on the basis of data provided by descriptive and mechanistic toxicologists, whether a drug or other chemical poses a sufficiently low risk (or, in the case of drugs, a favorable risk/benefit profile) to be marketed for a stated purpose or subsequent human or environmental exposure resulting from its use. The Food and Drug Administration (FDA) is responsible for allowing drugs, cosmetics, and food additives to be sold in the market according to the Federal Food, Drug and Cosmetic Act (FFDCA). The US Environmental Protection Agency (EPA) is responsible for regulating most other chemicals according to a variety of different legislative acts, including the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), the Toxic Substances Control Act (TSCA), the Resource Conservation and Recovery Act (RCRA), the Safe Drinking Water Act, and the Clean Air Act. In 1996, the US Congress passed the Food Quality Protection Act (FQPA) that fundamentally changed the pesticide and food safety laws to consider stricter safety standards particularly for infants and children, who were recognized as more susceptible to health effects of pesticides. The EPA is also responsible for enforcing the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA, later revised as the Superfund Amendments Reauthorization Act [SARA]), more commonly called the Superfund Act. This regulation provides direction and financial support for the cleanup of waste sites that contain toxic chemicals that may present a risk to human health or the environment. The Occupational Safety and Health Administration (OSHA) of the Department of Labor was established to ensure that safe and healthful conditions exist in the workplace. The National Institute for Occupational Safety and Health (NIOSH) as part of the Centers for Disease Control and Prevention (CDC) in the Department of Health and Human Services (DHHS) is responsible for conducting research and making recommendations for the prevention of work-related injury and illness. The Consumer Product Safety Commission (CPSC) is responsible for protecting consumers from hazardous household substances, whereas the Department of Transportation (DOT) ensures that materials shipped in interstate commerce are labeled and packaged in a manner consistent with the degree of hazard they present. The Nuclear Regulatory Commission (NRC), established in 1974, regulates the civilian use of nuclear material to protect public health and safety, and the environment. Regulatory toxicologists are also involved in the establishment of standards for the amount of chemicals permitted in ambient air, industrial atmospheres, and drinking water, often integrating scientific information from basic descriptive and mechanistic toxicology studies with the principles and approaches used for risk assessment (see Chap. 4).

In addition to the above categories, there are other specialized areas of toxicology such as forensic, clinical, and environmental toxicology. *Forensic toxicology* is a hybrid of analytic chemistry and fundamental toxicological principles. It is concerned primarily with the medicolegal aspects of the harmful effects of chemicals on humans and animals. The expertise of forensic toxicologists is invoked primarily to aid in establishing the cause of death and determining its circumstances in a post-mortem investigation (see Chap. 31). *Clinical toxicology* designates an area of professional emphasis in the realm of medical science that is concerned with disease caused by or uniquely associated with toxic substances (see Chap. 32). Generally, clinical toxicologists are physicians who receive specialized training in emergency medicine and poison management. Efforts are directed at treating patients poisoned with drugs or other chemicals and at the development of new techniques to treat those intoxications. Public information about treatment and prevention is often provided through the national network of poison

control centers. *Environmental toxicology* focuses on the impacts of chemical pollutants in the environment on biological organisms. Although toxicologists concerned with the effects of environmental pollutants on human health fit into this definition, it is most commonly associated with studies on the impacts of chemicals on nonhuman organisms such as fish, birds, terrestrial animals, and plants. *Ecotoxicology* is a specialized area within environmental toxicology that focuses more specifically on the impacts of toxic substances on population dynamics in an ecosystem. The transport, fate, and interactions of chemicals in the environment constitute a critical component of both environmental toxicology and ecotoxicology.

Toxicology and Society

Information from the toxicological sciences, gained by experience or research, has a growing influence on our personal lives as well as on human and environmental health across the globe. Knowledge about the toxicological effects of a compound affects consumer products, drugs, manufacturing processes, waste cleanup, regulatory action, civil disputes, and broad policy decisions. The expanding influence of toxicology on societal issues is accompanied by the responsibility to be increasingly sensitive to the ethical, legal, and social implications of toxicological research and testing.

The convergence of multiple elements has highlighted the evolving ethical dynamics of toxicology. First, experience and new discoveries in the biological sciences have emphasized our interconnectedness with nature and the need for well-articulated visions of human, animal, and environmental health. One vision is that we have “condition(s) that ensure that all living things have the best opportunity to reach and maintain their full genetic potential” (Gilbert, 2005a). Second, we have experience with the health consequences of exposure to such things as lead, asbestos, and tobacco, along with the detailed mechanistic research to understand the long-term risks to individuals and society. This has precipitated many regulatory and legal actions and public policy decisions, not to mention costly and time-consuming lawsuits. Third, we have an increasingly well-defined framework for discussing our social and ethical responsibilities. There is growing recognition that ethics play a crucial role in public health decision making that involves conflicts between individual, corporate, and social justice goals (Callahan and Jennings, 2002; Kass, 2001; Lee, 2002). Fourth is the appreciation that all research involving humans or animals must be conducted in a responsible and ethical manner. Fifth is managing both the uncertainty and biological variability inherent in the biological sciences. Decision making often includes making judgments with limited or uncertain information, which often includes an overlay of individual values and ethics. Finally, individuals involved in toxicological research must be aware of and accountable to their own individual biases and possible conflicts of interest and adhere to the highest ethical standards of the profession (Maurissen *et al.*, 2005; Coble *et al.*, 2009; Gilbert and Eaton, 2009).

Ethical reasoning and philosophy has a long and deep history, but more pragmatic bioethical reasoning can be traced to Leopold, who is arguably America’s first bioethicist: “A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise” (Leopold, 1949). The essence of toxicology is to understand the effects of chemicals on the biotic community. This broader definition of an ethic became more focused with examples such as the mercury poisoning in Minamata Bay, Japan, thalidomide, and the effects of pesticides as brought to public awareness by Carson’s *Silent Spring* (Carson, 1962). In the United States, these events supported the public and

political will to establish the EPA and strengthen the FDA and other regulations designed to protect human and environmental health. The knowledge that some segments of our society were differentially at risk from chemical exposures evolved into an appreciation of environmental justice (Corburn, 2002; EPA, 2005; Lee, 2002; Morello-Frosch *et al.*, 2002). The EPA defines environmental justice as “the fair treatment and meaningful involvement of all people regardless of race, color, national origin, or income with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies...” (EPA, 2005). Environmental justice is now an important component of numerous community-based programs of interest, and is relevant to the field of toxicology (Nweke, 2011). There is growing recognition of the direct financial and indirect costs to individuals and society from environmental exposures that are not equally distributed across society (Landrigan *et al.*, 2002).

On a parallel track, biomedical ethics developed out of the lessons of World War II and related abuses of human subjects. The 4 principle of biomedical ethics—respect for autonomy, beneficence (do good), nonmaleficence (do no harm), and justice (be fair)—became well established as a basis for decision making in health care settings (Beauchamp and Childress, 1994). These principles formed the basis of rules and regulations regarding the conduct of human research. The demands of ethics and science made it clear that the highest standards of care produced the best results in both human and animal research. Rules and regulations regarding the housing and conduct of animal studies evolved similarly. Professional toxicology societies now require their members to adhere to the highest ethical standards when conducting research with humans or animals. A further refinement and expansion of biomedical ethical principles is the development of community-based participatory research that takes into consideration community needs to ensure the best results and benefit to the community (Arcury *et al.*, 2001; Gilbert, 2006; O’Fallon and Dearry, 2002).

A glance at the daily newspaper confirms the number of current, sometimes controversial issues that are relevant to the field of toxicology. Decisions and action are often demanded or required even when there is a certain level of uncertainty in the toxicological data. The classic example of this challenge is establishing causation of the health effects of tobacco products. In part to address issues related to the health effects of tobacco products, Hill, a distinguished epidemiologist, defined a set of guidelines for evaluating “causation”—for example, whether a causal connection between a particular “exposure” and a particular outcome, condition, or disease can be scientifically established (Hill, 1965). These criteria are briefly summarized as follows:

1. Strength of association (relationship between independent and dependent variables)
2. Consistency of findings (replication of results by different studies)
3. Biological gradient (strength of the dose–response relationship)
4. Temporal sequence (“cause” before effect)
5. Biological or theoretical plausibility (mechanism of action)
6. Coherence with established knowledge (no competing hypotheses)
7. Specificity of association (cause is tightly linked to an outcome)

Although the guidelines provided by Hill were originally designed for interpretation of epidemiological data, they are equally applicable to establishing causation in toxicology, which often relies on a mix of both epidemiological and toxicological data.

Quantitative risk assessment was developed in part to address issues of uncertainty related to potential harm. The risk assessment process summarizes data for risk managers and other decision makers, who must take into consideration to some degree the qualitative elements of ethical, social, and political issues. Whereas risk management clearly has an ethical and values-based aspect, risk assessment is not immune from the influence of one’s values, bias, or perspective. Ultimately action is required and as Hill (1965) noted: “All scientific work is incomplete—whether it be observational or experimental. All scientific work is liable to be upset or modified by advancing knowledge. That does not confer upon us a freedom to ignore the knowledge we already have or postpone the action that it appears to demand at a given time.” These so-called Bradford Hill criteria were developed largely as a “weight-of-evidence” approach for interpreting a body of epidemiology data, yet are relevant as well to toxicology. Guzelian *et al.* (2005) provided a more detailed, evidence-based approach for determining causation in toxicology, primarily for application in the legal arena.

Although the scientific data may be the same, there are substantial differences in how toxicological data are used in a regulatory framework to protect public health versus establishing individual causation in the courtroom (Eaton, 2003). The approach to regulatory decision making is in part directed by policy. For example, the experience with thalidomide and other drugs motivated the US Congress to give the FDA broad power to ensure the efficacy and safety of new medicines or medical procedures. In this situation the pharmaceutical company or proponents of an activity must invest in the appropriate animal and human studies to demonstrate safety of the product. In general, a relatively precautionary approach has historically been taken with regard to drugs and medical devices. The approach to industrial chemicals is defined by the Toxic Substance Control Act and does not stipulate such a rigorous approach when introducing a new chemical into commerce.

Building on the work of Hill and others particularly from Europe, the Precautionary Principle was defined at the Wingspread Conference, in 1998: “When an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause and effect relationships are not fully established scientifically” (Gilbert, 2005b; Myers and Raffensperger, 2006; Raffensperger and Tickner, 1999). The precautionary principle incorporates elements of science and ethical philosophy into a single statement, acknowledging that ethics and values are part of the decision-making process. Although the conceptual value of the precautionary principle to public health protection is obvious, its actual implementation in toxicological risk assessment is not straightforward, and remains a point of considerable debate (Marchant, 2003; Goldstein, 2006; Peterson, 2006). The challenge remains to develop a regulatory environment that is responsive to issues of public health and the stewardship of societal resources (Simon, 2011).

With the increased relevance of toxicological data and evaluation in issues fundamental to society, there has been increased awareness of the possibility of conflicts of interest influencing the decision-making process (Maurissen *et al.*, 2005). The disclosure of conflicts of interest as well as the development of appropriate guidelines continues to be a challenge (NAS, 2003; Goozner, 2004; Krinsky and Rothenberg, 2001). These issues go to the core of one’s individual values and integrity in the interpretation and communication of research results. Many professional societies, including the Society of Toxicology (<http://www.toxicology.org/ai/asot/ethics.asp>), have developed codes of ethics for their members. Conflict of interest has also been addressed by most publishers of toxicology journals (Krinsky and Sweet, 2009).

Table 2-1

Approximate Acute LD₅₀s of Some Representative Chemical Agents

AGENT	LD ₅₀ (mg/kg)*
Ethyl alcohol	10,000
Sodium chloride	4000
Ferrous sulfate	1500
Morphine sulfate	900
Phenobarbital sodium	150
Picrotoxin	5
Strychnine sulfate	2
Nicotine	1
D-Tubocurarine	0.5
Hemicholinium-3	0.2
Tetrodotoxin	0.10
Dioxin (TCDD)	0.001
Botulinum toxin	0.00001

*LD₅₀ is the dosage (mg/kg body weight) causing death in 50% of exposed animals.

As the field of toxicology has matured and its influence on societal issues has increased, so has the need for the profession to make a commitment to examine the ethical, legal, and social implications of research and practice of toxicology.

General Characteristics of the Toxic Response

One could define a poison as any agent capable of producing a deleterious response in a biological system, seriously injuring function or producing death. This is not, however, a useful working definition for the very simple reason that virtually every known chemical has the potential to produce injury or death if it is present in a sufficient amount. Paracelsus (1493–1541), a Swiss/German/Austrian physician, scientist, and philosopher, phrased this well when he noted, “What is there that is not poison? All things are poison and nothing [is] without poison. Solely the dose determines that a thing is not a poison.”

Among chemicals there is a wide spectrum of doses needed to produce deleterious effects, serious injury, or death. This is demonstrated in Table 2-1, which shows the dosage of chemicals needed to produce death in 50% of treated animals (lethal dose 50 [LD₅₀]). Some chemicals produce death in microgram doses and are commonly thought of as being extremely poisonous. Other chemicals may be relatively harmless after doses in excess of several grams. It should be noted, however, that measures of acute lethality such as LD₅₀ do not accurately reflect the full spectrum of toxicity, or hazard, associated with exposure to a chemical. For example, some chemicals with low acute toxicity may have carcinogenic, teratogenic, or neurobehavioral effects at doses that produce no evidence of acute toxicity. In addition, there is growing recognition that genetic factors can account for individual susceptibility to a range of responses. Finally, it should be recognized that, for a given chemical, multiple different effects can occur in a given

organism, each with its own “dose–response relationship.” In some circumstances, effects that occur at low doses may not be evident at higher doses because other adverse responses overwhelm or mask more subtle effects that may occur at low doses. Although some have argued that such low-dose effects, not seen at higher doses, make the classical interpretation of the “dose–response” relationship no longer relevant, such low-dose effects also follow their own “dose–response” relationship, but with a “saturation” of the effect occurring at higher doses that induces other molecular, biochemical, and cellular effects that tend to obscure the effects seen at lower doses. The effects of exogenous chemicals that bind to and activate or inhibit endogenous hormone receptors (so-called endocrine disruptors—see Chap. 21) may often have “low-dose” effects that are quite different from those seen at much higher doses.

CLASSIFICATION OF TOXIC AGENTS

Toxic agents are classified in a variety of ways, depending on the interests and needs of the classifier. In this textbook, for example, toxic agents are discussed in terms of their target organs (liver, kidney, hematopoietic system, etc), use (pesticide, solvent, food additive, etc), source (animal and plant toxins), and effects (cancer, mutation, liver injury, etc). The term *toxin* generally refers to toxic substances that are produced by biological systems such as plants, animals, fungi, or bacteria. The term *toxicant* is used in speaking of toxic substances that are produced by or are a by-product of anthropogenic (human-made) activities. Thus, zearalenone, produced by a mold, is a toxin, whereas “dioxin” (2,3,7,8-tetrachlorodibenzo-*p*-dioxin [TCDD]), produced during the production and/or combustion of certain chlorinated organic chemicals, is a toxicant. Some toxicants can be produced by both natural and anthropogenic activities. For example, polyaromatic hydrocarbons are produced by the combustion of organic matter, which may occur both through natural processes (eg, forest fires) and through anthropogenic activities (eg, combustion of coal for energy production; cigarette smoking). Arsenic, a toxic metalloid, may occur as a natural contaminant of groundwater or may contaminate groundwater secondary to industrial activities. Generally, such toxic substances are referred to as toxicants, rather than toxins, because, although they are naturally produced, they are not produced by biological systems. Distinguishing a “toxin” from a “toxicant” is not always easy. For example, many pesticides, such as the pyrethroids, are synthetic analogs of natural products, such that one would call the pyrethrum found in the chrysanthemum flower a “toxin,” but the synthetic (and slightly altered in structure) form produced for use in pesticide formulations would be a “toxicant.” Thus, although technically incorrect, many physicians and others involved in the diagnosis and treatment of poisonings often use the term “toxin” to refer to any toxic substance, regardless of origin.

Toxic agents may also be classified in terms of their physical state (gas, dust, liquid, size, eg, nanotoxicology), their chemical stability or reactivity (explosive, flammable, oxidizer), general chemical structure (aromatic amine, halogenated hydrocarbon, etc), or poisoning potential (extremely toxic, very toxic, slightly toxic, etc). Classification of toxic agents on the basis of their biochemical mechanisms of action (eg, alkylating agent, cholinesterase inhibitor, endocrine disruptor) is usually more informative than classification by general terms such as irritants and corrosives. But more general classifications such as air pollutants, occupation-related agents, and acute and chronic poisons can provide a useful focus on a specific problem. It is evident from this discussion that no single classification is applicable to the entire spectrum of toxic agents and that a combination of classification systems or a classification based on

other factors is generally needed to provide the best characterization of a toxic substance. Nevertheless, classification systems that take into consideration both the chemical and the biological properties of an agent and the exposure characteristics are most likely to be useful for regulatory or control purposes and for toxicology in general.

SPECTRUM OF UNDESIRABLE EFFECTS

The spectrum of undesired effects of chemicals is often broad. Some effects are deleterious and others are not. In therapeutics, for example, each drug produces a number of effects, but usually only one effect is associated with the primary objective of the therapy; all the other effects are referred to as *undesirable* or *side effects* of that drug for that therapeutic indication. However, some of these side effects may be desired for another therapeutic indication. For example, the “first-generation” antihistamine diphenhydramine (Benadryl) is effective in reducing histamine responses associated with allergies, but it readily enters the brain and causes mild central nervous system (CNS) depression (drowsiness, delayed reaction time). With the advent of selective histamine receptor antagonists that do not cross the blood–brain barrier and thus do not have this CNS-depressant side effect, diphenhydramine is used less commonly today as an antihistamine. However, it is widely used as an “over-the-counter” sleep remedy, often in combination with analgesics (eg, Tylenol PM, Excedrin PM), taking advantage of the CNS-depressant effects. Some side effects of drugs are never desirable and are always deleterious to the well-being of humans. These are referred to as the *adverse*, *deleterious*, or *toxic* effects of the drug.

Allergic Reactions

Chemical allergy is an immunologically mediated adverse reaction to a chemical resulting from previous sensitization to that chemical or to a structurally similar one. The term *hypersensitivity* is most often used to describe this allergic state, but *allergic reaction* and *sensitization reaction* are also used to describe this situation when preexposure of the chemical is required to produce the toxic effect (see Chap. 12). Once sensitization has occurred, allergic reactions may result from exposure to relatively very low doses of chemicals; therefore, population-based dose–response curves for allergic reactions have seldom been obtained. Because of this omission, some people assumed that allergic reactions are not dose-related. Thus, they do not consider the allergic reaction to be a true toxic response. However, for a given allergic individual, allergic reactions are dose-related. For example, it is well known that the allergic response to pollen in sensitized individuals is related to the concentration of pollen in the air. In addition, because the allergic response is an undesirable, adverse, deleterious effect, it obviously is also a toxic response. Sensitization reactions are sometimes very severe and may be fatal.

Most chemicals and their metabolic products are not sufficiently large to be recognized by the immune system as a foreign substance and thus must first combine with an endogenous protein to form an antigen (or immunogen). A molecule that must combine with an endogenous protein to elicit an allergic reaction is called a *hapten*. The hapten–protein complex (antigen) is then capable of eliciting the formation of antibodies, and usually at least one or two weeks is required for the synthesis of significant amounts of antibodies. Subsequent exposure to the chemical results in an antigen–antibody interaction, which provokes the typical manifestations of allergy. The manifestations of allergy are numerous.

They may involve various organ systems and range in severity from minor skin disturbance to fatal anaphylactic shock. The pattern of allergic response differs in various species. In humans, involvement of the skin (eg, dermatitis, urticaria, and itching) and involvement of the eyes (eg, conjunctivitis) are most common, whereas in guinea pigs, bronchiolar constriction leading to asphyxia is the most common. However, chemically induced asthma (characterized by bronchiolar constriction) certainly does occur in some humans, and the incidence of allergic asthma has increased substantially in recent years. Hypersensitivity reactions are discussed in more detail in Chap. 12.

Idiosyncratic Reactions

Chemical idiosyncrasy refers to a genetically determined abnormal reactivity to a chemical (Goldstein *et al.*, 1974; Levine, 1978; Uetrecht, 2007). The response observed is usually qualitatively similar to that observed in all individuals but may take the form of extreme sensitivity to low doses or extreme insensitivity to high doses of the chemical. However, while some people use the term *idiosyncratic* as a catchall to refer to all reactions that occur with low frequency, it should not be used in that manner (Goldstein *et al.*, 1974). A classic example of an idiosyncratic reaction is provided by patients who exhibit prolonged muscular relaxation and apnea (inability to breathe) lasting several hours after a standard dose of succinylcholine. Succinylcholine usually produces skeletal muscle relaxation of only short duration because of its very rapid metabolic degradation by an enzyme that is present normally in the bloodstream called plasma butyrylcholinesterase (also referred to as pseudocholinesterase). Patients exhibiting this idiosyncratic reaction have a genetic polymorphism in the gene for the enzyme butyrylcholinesterase, which results in a protein that is less active in breaking down succinylcholine. Family pedigree and molecular genetic analyses have demonstrated that the presence of low plasma butyrylcholinesterase activity is due to the presence of one or more single-nucleotide polymorphisms (SNPs) in this gene (Bartels *et al.*, 1992). Similarly, there is a group of people who are abnormally sensitive to nitrites and certain other chemicals that have in common the ability to oxidize the iron in hemoglobin to produce *methemoglobin*, which is incapable of carrying oxygen to the tissues. The unusual phenotype is inherited as an autosomal recessive trait and is characterized by a deficiency in NADH-cytochrome b_5 reductase activity. The genetic basis for this idiosyncratic response has been identified as a single nucleotide change in codon 127, which results in replacement of serine with proline (Kobayashi *et al.*, 1990). The consequence of this genetic deficiency is that these individuals may suffer from a serious lack of oxygen delivery to tissues after exposure to doses of methemoglobin-producing chemicals that would be harmless to individuals with normal NADH-cytochrome b_5 reductase activity.

It is now recognized that many of the so-called idiosyncratic adverse drug reactions and many drug–drug interactions are due to specific genetic polymorphisms in drug-metabolizing enzymes, transporters, or receptors. As discussed previously, the growing field of pharmacogenomics and toxicogenomics has helped to identify the molecular basis for many previously described idiosyncratic responses to drugs and other toxic substances (Wang *et al.*, 2011). However, not all “idiosyncratic” responses to toxic substances are easily described by a single genetic polymorphism in a drug-metabolizing enzyme. It is generally thought that most, but not all, idiosyncratic drug responses are due to a combination of individual differences in the ability to: (1) form a reactive intermediate (usually through oxidation to an electrophilic intermediate), (2) detoxify

that reactive intermediate (usually through hydrolysis or conjugation), and/or (3) exhibit differences in immune response to adducted proteins (Utrecht, 2007). The role of the immune system in mediating rare drug-induced toxic reactions in the liver, skin, and other organ systems is widely recognized, and specific genetic variants in certain parts of the genome that code for the major histocompatibility complexes (MHCs) give rise to specific immune responses to proteins that have been damaged by reactive intermediates of certain drugs. Thus, it is only the individuals who genetically form sufficient amounts of a reactive drug metabolite, *and* who then have an immune response to the modified protein, who have an adverse response to the drug (Utrecht, 2007).

For example, troglitazone, introduced into the marketplace in 1997 as an effective treatment for type II diabetes, was subsequently withdrawn from the market because of a relatively rare (1 adverse response per 30,000 patients) but often fatal hepatotoxic response. Subsequent studies of tissues from patients who had developed hepatotoxic responses at the normal therapeutic doses revealed that individuals who lacked functional genes for 2 forms of glutathione *S*-transferase (GSTM1 and GSTT1) were more than 3 times as likely to develop troglitazone-induced hepatotoxicity than individuals with 1 or more functional GSTM1 or T1 genes (Ikeda, 2011). However, this does not explain the rarity of the adverse response, since there were many individuals who lacked GSTM1 and T1 genes who took troglitazone with no evident hepatotoxicity. Further studies have suggested that the idiosyncratic hepatotoxicity from troglitazone also has an immune system component, and genetic differences in specific human lymphocyte antigen (HLA) loci might contribute to idiosyncratic drug-induced hepatotoxicity (Ikeda, 2011).

Immediate versus Delayed Toxicity

Immediate toxic effects can be defined as those that occur or develop rapidly after a single administration of a substance, whereas delayed toxic effects are those that occur after the lapse of some time. Carcinogenic effects of chemicals usually have a long latency period, often 20 to 30 years after the initial exposure, before tumors are observed in humans. For example, daughters of mothers who took diethylstilbestrol (DES) during pregnancy have a greatly increased risk of developing vaginal cancer, in young adulthood, approximately 20 to 30 years after their in utero exposure to DES (Hatch *et al.*, 1998). Also, delayed neurotoxicity is observed after exposure to some OP insecticides that act by covalent modification of an enzyme referred to as *neuropathy target esterase* (NTE), a neuronal protein with serine esterase activity (Glynn *et al.*, 1999). Binding of certain OP chemicals to this protein initiates degeneration of long axons in the peripheral and CNS. The most notorious of the compounds that produce this type of neurotoxic effect is triorthocresylphosphate (TOCP). The effect is not observed until at least several days after exposure to the toxic compound. In contrast, most substances produce immediate toxic effects but do not produce delayed effects.

Reversible versus Irreversible Toxic Effects

Some toxic effects of chemicals are reversible, and others are irreversible. If a chemical produces pathological injury to a tissue, the ability of that tissue to regenerate largely determines whether the effect is reversible or irreversible. Thus, for a tissue such as liver, which has a high ability to regenerate, most injuries are reversible, whereas injury to the CNS is largely irreversible because differentiated cells of the CNS cannot divide and be replaced (although recovery from chemically induced damage to the CNS can occur,

primarily through the “plasticity” of the brain that allows developed neurons to learn new functions; see Chap. 16). Carcinogenic and teratogenic effects of chemicals, once they occur, are usually considered irreversible toxic effects.

Local versus Systemic Toxicity

Another distinction between types of effects is made on the basis of the general site of action. Local effects are those that occur at the site of first contact between the biological system and the toxicant. Such effects are produced by the ingestion of caustic substances or the inhalation of irritant materials. For example, chlorine gas reacts with lung tissue at the site of contact, causing damage and swelling of the tissue, with possibly fatal consequences, even though very little of the chemical is absorbed into the bloodstream. The alternative to local effects is systemic effects. Systemic effects require absorption and distribution of a toxicant from its entry point to a distant site at which deleterious effects are produced. Most substances except highly reactive materials produce systemic effects. For some materials, both effects can be demonstrated. For example, tetraethyl lead produces effects on skin at the site of absorption and then is transported systemically to produce its typical effects on the CNS and other organs. If the local effect is marked, there may also be indirect systemic effects. For example, kidney damage after a severe acid burn is an indirect systemic effect because the toxicant does not reach the kidney.

Most chemicals that produce systemic toxicity do not cause a similar degree of toxicity in all organs; instead, they usually elicit their major toxicity in only 1 or 2 organs. These sites are referred to as the *target organs* of toxicity of a particular chemical. The target organ of toxicity is often not the site of the highest concentration of the chemical. For example, lead is concentrated in bone, but its toxicity is due to its effects in soft tissues, particularly the brain. DDT is concentrated in adipose tissue but produces no known toxic effects in that tissue.

The target organ of toxicity most frequently involved in systemic toxicity is the CNS (brain and spinal cord). Even with many compounds having a prominent effect elsewhere, damage to the CNS can be demonstrated by the use of appropriate and sensitive methods. Next in order of frequency of involvement in systemic toxicity are the circulatory system; the blood and hematopoietic system; visceral organs such as the liver, kidney, and lung; and the skin. Muscle and bone are least often the target tissues for systemic effects. With substances that have a predominantly local effect, the frequency with which tissues react depends largely on the portal of entry (skin, gastrointestinal tract, or respiratory tract).

Interaction of Chemicals

Because of the large number of different chemicals an individual may come in contact with at any given time (workplace, drugs, diet, hobbies, etc), it is necessary, in assessing the spectrum of responses, to consider how different chemicals may interact with each other. Interactions can occur in a variety of ways. Chemical interactions are known to occur by a number of mechanisms, such as alterations in absorption, protein binding, and the biotransformation and excretion of 1 or both of the interacting toxicants. In addition to these modes of interaction, the response of the organism to combinations of toxicants may be increased or decreased because of toxicological responses at the site of action.

The effects of 2 chemicals given simultaneously produce a response that may simply be additive of their individual responses or may be greater or less than that expected by addition of their individual responses. The study of these interactions often leads to a

better understanding of the mechanism of toxicity of the chemicals involved. A number of terms have been used to describe pharmacological and toxicological interactions. An *additive* effect occurs when the combined effect of 2 chemicals is equal to the sum of the effects of each agent given alone (eg, $2 + 3 = 5$). The effect most commonly observed when 2 chemicals are given together is an additive effect. For example, when 2 OP insecticides are given together, the cholinesterase inhibition is usually additive. A *synergistic* effect occurs when the combined effects of 2 chemicals are much greater than the sum of the effects of each agent given alone (eg, $2 + 2 = 20$). For example, both carbon tetrachloride and ethanol are hepatotoxic compounds, but together they produce much more liver injury than the mathematical sum of their individual effects on liver at a given dose would suggest. *Potentiation* occurs when 1 substance does not have a toxic effect on a certain organ or system but when added to another chemical makes that chemical much more toxic (eg, $0 + 2 = 10$). Isopropanol, for example, is not hepatotoxic, but when it is administered in addition to carbon tetrachloride, the hepatotoxicity of carbon tetrachloride is much greater than when it is given alone. *Antagonism* occurs when 2 chemicals administered together interfere with each other's actions or 1 interferes with the action of the other (eg, $4 + 6 = 8$; $4 + (-4) = 0$; $4 + 0 = 1$). Antagonistic effects of chemicals are often very desirable in toxicology and are the basis of many antidotes. There are 4 major types of antagonism: functional, chemical, dispositional, and receptor. *Functional antagonism* occurs when 2 chemicals counterbalance each other by producing opposite effects on the same physiological function. For example, advantage is taken of this principle in that the blood pressure can markedly fall during severe barbiturate intoxication, which can be effectively antagonized by the intravenous administration of a vasopressor agent such as norepinephrine or metaraminol. Similarly, many chemicals, when given at toxic dose (TD) levels, produce convulsions, and the convulsions often can be controlled by giving anticonvulsants such as the benzodiazepines (eg, diazepam). *Chemical antagonism or inactivation* is simply a chemical reaction between 2 compounds that produces a less toxic product. For example, 2,3-dimercaptosuccinic acid (DMSA; Succimer) chelates with metal ions such as arsenic, mercury, and lead and decreases their toxicity. The use of antitoxins in the treatment of various animal toxins is also an example of chemical antagonism. The use of the strongly basic low-molecular-weight protein protamine sulfate to form a stable complex with heparin, which abolishes its anticoagulant activity, is another example. *Dispositional antagonism* occurs when the disposition—that is, the absorption, distribution, biotransformation, or excretion of a chemical—is altered so that the concentration and/or duration of the chemical at the target organ are diminished. Thus, the prevention of absorption of a toxicant by ipecac or charcoal and the increased excretion of a chemical by administration of an osmotic diuretic or alteration of the pH of the urine are examples of dispositional antagonism. If the parent compound is responsible for the toxicity of the chemical (such as the anticoagulant warfarin) and its metabolic breakdown products are less toxic than the parent compound, increasing the compound's biotransformation (metabolism) by administering a drug that increases the activity of the metabolizing enzymes (eg, a “microsomal enzyme inducer” such as phenobarbital) will decrease its toxicity. However, if the chemical's toxicity is largely due to a metabolic product (as in the case of the organophosphate insecticide parathion), inhibiting its biotransformation by an inhibitor of microsomal enzyme activity (SKF-525A or piperonyl butoxide) will decrease its toxicity. *Receptor antagonism* occurs when 2 chemicals that bind to the same receptor produce less of an effect when given together than the addition of their separate effects

(eg, $4 + 6 = 8$) or when 1 chemical antagonizes the effect of the second chemical (eg, $0 + 4 = 1$). Receptor antagonists are often termed *blockers*. This concept is used to advantage in the clinical treatment of poisoning. For example, the receptor antagonist naloxone is used to treat the respiratory depressive effects of morphine and other morphine-like narcotics by competitive binding to the same receptor. Another example of receptor antagonism is the use of the antiestrogen drug tamoxifen to lower breast cancer risk among women at high risk for this estrogen-related cancer. Tamoxifen competitively blocks estradiol from binding to its receptor. Treatment of organophosphate insecticide poisoning with atropine is an example not of the antidote competing with the poison for the receptor (cholinesterase) but of blocking the receptor (cholinergic receptor) for the excess acetylcholine that accumulates by poisoning of the cholinesterase by the organophosphate (see Chap. 22).

Tolerance

Tolerance is a state of decreased responsiveness to a toxic effect of a chemical resulting from prior exposure to that chemical or to a structurally related chemical. Two major mechanisms are responsible for tolerance: 1 is due to a decreased amount of toxicant reaching the site where the toxic effect is produced (*dispositional tolerance*) and the other is due to a reduced responsiveness of a tissue to the chemical. Comparatively less is known about the cellular mechanisms responsible for altering the responsiveness of a tissue to a toxic chemical than is known about dispositional tolerance. Two chemicals known to produce dispositional tolerance are carbon tetrachloride and cadmium. The barbiturate, phenobarbital, produces tolerance to itself by increasing the expression of enzymes in the liver that are responsible for its biotransformation to pharmacologically inactive products, a process known as “biotransformation enzyme induction.” The mechanism of cadmium tolerance is explained by induction of metallothionein, a metal-binding protein. Subsequent binding of cadmium to metallothionein rather than to critical cellular macromolecules decreases its toxicity.

CHARACTERISTICS OF EXPOSURE

Toxic effects in a biological system are not produced by a chemical agent unless that agent or its metabolic breakdown (biotransformation) products reach appropriate sites in the body at a concentration and for a length of time sufficient to produce a toxic manifestation. Many chemicals are of relatively low toxicity in the “native” form but, when acted on by enzymes in the body, are converted to intermediate forms that interfere with normal cellular biochemistry and physiology. Thus, whether a toxic response occurs is dependent on the chemical and physical properties of the agent, the exposure situation, how the agent is metabolized by the system, the concentration of the active form at the particular target site(s), and the overall susceptibility of the biological system or subject. Thus, to characterize fully the potential hazard of a specific chemical agent, we need to know not only what type of effect it produces and the dose required to produce that effect but also information about the agent, the exposure, and its disposition by the subject. Two major factors that influence toxicity as it relates to the exposure situation for a specific chemical are the route of exposure and the duration and frequency of exposure.

Route and Site of Exposure

The major routes (pathways) by which toxic agents gain access to the body are through the gastrointestinal tract (ingestion), the lungs (inhalation), or the skin (topical, percutaneous, or dermal). Toxic

agents generally produce the greatest effect and the most rapid response when given directly into the bloodstream (the intravenous route). An approximate descending order of effectiveness for the other routes would be inhalation, intraperitoneal, subcutaneous, intramuscular, intradermal, oral, and dermal. The “vehicle” (the material in which the chemical is dissolved) and other formulation factors can markedly alter absorption after ingestion, inhalation, or topical exposure. In addition, the route of administration can influence the toxicity of agents. For example, an agent that acts on the CNS, but is efficiently detoxified in the liver, would be expected to be less toxic when given orally than when given via inhalation, because the oral route requires that nearly all of the dose pass through the liver before reaching the systemic circulation and then the CNS.

Occupational exposure to toxic agents most frequently results from breathing contaminated air (inhalation) and/or direct and prolonged contact of the skin with the substance (dermal exposure), whereas accidental and suicidal poisoning occurs most frequently by oral ingestion. Comparison of the toxic dose (TD) of a toxic substance by different routes of exposure often provides useful information about its extent of absorption. In instances when the TD after oral or dermal administration is similar to the TD after intravenous administration, the assumption is that the toxic agent is absorbed readily and rapidly. Conversely, in cases where the TD by the dermal route is several orders of magnitude higher than the oral TD, it is likely that the skin provides an effective barrier to absorption of the agent. Toxic effects by any route of exposure can also be influenced by the concentration of the agent in its vehicle, the total volume of the vehicle and the properties of the vehicle to which the biological system is exposed, and the rate at which exposure occurs. Studies in which the concentration of a chemical in the blood is determined at various times after exposure are often needed to clarify the role of these and other factors in the toxicity of a compound. For more details on the absorption of toxicants, see Chap. 5.

Duration and Frequency of Exposure

Toxicologists usually divide the exposure of experimental animals to chemicals into 4 categories: acute, subacute, subchronic, and chronic. Acute exposure is defined as exposure to a chemical for less than 24 hours, and examples of exposure routes are intraperitoneal, intravenous, and subcutaneous injection; oral intubation; and dermal application. Whereas acute exposure usually refers to a single administration, repeated exposures may be given within a 24-hour period for some slightly toxic or practically nontoxic chemicals. Acute exposure by inhalation refers to continuous exposure for less than 24 hours, most frequently for 4 hours. Repeated exposure is divided into 3 categories: subacute, subchronic, and chronic. *Subacute exposure* refers to repeated exposure to a chemical for 1 month or less, *subchronic* for 1 to 3 months, and *chronic* for more than 3 months, although usually this refers to studies with at least 1 year of repeated dosing. These 3 categories of repeated exposure can be by any route, but most often they occur by the oral route, with the chemical added directly to the diet.

In human exposure situations, the frequency and duration of exposure are usually not as clearly defined as in controlled animal studies, but many of the same terms are used to describe general exposure situations. Thus, workplace or environmental exposures may be described as *acute* (occurring from a single incident or episode), *subchronic* (occurring repeatedly over several weeks or months), or *chronic* (occurring repeatedly for many months or years).

Figure 2-2. Diagrammatic view of the relationship between dose and concentration at the target site under different conditions of dose frequency and elimination rate. (Line A) A chemical with very slow elimination (eg, half-life of 1 year). (Line B) A chemical with a rate of elimination equal to frequency of dosing (eg, 1 day). (Line C) Rate of elimination faster than the dosing frequency (eg, 5 hours). Blue shaded area is representative of the concentration of chemical at the target site necessary to elicit a toxic response.

For many chemicals, the toxic effects that follow a single exposure are quite different from those produced by repeated exposure. For example, the primary acute toxic manifestation of benzene is CNS depression, but repeated exposures can result in bone marrow toxicity and an increased risk for leukemia. Acute exposure to chemicals that are rapidly absorbed is likely to produce immediate toxic effects but also can produce delayed toxicity that may or may not be similar to the toxic effects of chronic exposure. Conversely, chronic exposure to a toxic chemical may produce some immediate (acute) effects after each administration in addition to the long-term, low-level, or chronic effects of the toxic substance. In characterizing the toxicity of a specific chemical, it is evident that information is needed not only for the single-dose (acute) and long-term (chronic) effects but also for exposures of intermediate duration. The other time-related factor that is important in the temporal characterization of repeated exposures is the frequency of exposure. The relationship between elimination rate and frequency of exposure is shown in Fig. 2-2. A chemical that produces severe effects with a single dose may have no effect if the same total dose is given in several intervals. For the chemical depicted by line B in Fig. 2-2, in which the half-life for elimination (time necessary for 50% of the chemical to be removed from the bloodstream) is approximately equal to the dosing frequency, a theoretical toxic concentration (shown conceptually as 2 concentration units in Fig. 2-2) is not reached until the fourth dose, whereas that concentration is reached with only 2 doses for chemical A, which has an elimination rate much slower than the dosing interval (time between each repeated dose). Conversely, for chemical C, where the elimination rate is much shorter than the dosing interval, a toxic concentration at the site of toxic effect will never be reached regardless of how many doses are administered. Of course, it is possible that residual cell or tissue damage occurs with each dose even though the chemical itself is not accumulating. The important consideration, then, is whether the interval between doses is sufficient to allow for complete repair of tissue damage. It is evident that with any type of repeated exposure, the production of a toxic effect not only is influenced by the frequency of exposure but may also, in fact, be totally dependent on the frequency rather than the duration of exposure. Chronic toxic effects may occur, therefore, if the chemical accumulates in the biological system (rate

of absorption exceeds the rate of biotransformation and/or excretion), if it produces irreversible toxic effects, or if there is insufficient time for the system to recover from the toxic damage within the exposure frequency interval. For additional discussion of these relationships, see Chaps. 5 and 7.

DOSE–RESPONSE RELATIONSHIP

The characteristics of exposure and the spectrum of toxic effects come together in a correlative relationship customarily referred to as the *dose–response relationship*. Whatever response is selected for measurement, the relationship between the degree of response of the biological system and the amount of toxicant administered assumes a form that occurs so consistently as to be considered the most fundamental and pervasive concept in toxicology.

From a practical perspective, there are 2 types of dose–response relationships: (1) the individual dose–response relationship, which describes the response of an *individual* organism to varying doses of a chemical, often referred to as a “graded” response because the measured effect is continuous over a range of doses, and (2) a quantal dose–response relationship, which characterizes the distribution of individual responses to different doses in a *population* of individual organisms. It is also important to recognize that a given chemical may have multiple different molecular, biochemical, and cellular effects, each with its own “dose–response” relationship. Thus, the nature of a toxic response might very well be different at low doses than at higher doses. In the case of population-level “dose–response” characterization, the observed response is an integration of multiple individual “dose–response relationships” occurring in different cell types, and at different molecular sites within those cells. Subtle effects that occur at low doses may be masked or overwhelmed by more evident responses occurring at higher doses.

Individual, or Graded, Dose–Response Relationships

Individual dose–response relationships are characterized by a dose-related increase in the severity of the response. The dose relatedness of the response often results from an alteration of a specific biochemical process. For example, Fig. 2-3 shows the dose–response relationship between different dietary doses of the organophosphate insecticide chlorpyrifos and the extent of inhibition of 2 different enzymes in the brain and liver: acetylcholinesterase and carboxylesterase. In the brain, the degree of inhibition of both enzymes is clearly dose-related and spans a wide range, although the amount of inhibition per unit dose is different for the 2 enzymes. From the shapes of these 2 dose–response curves it is evident that, in the brain, cholinesterase is more easily inhibited than carboxylesterase. The toxicological response that results is directly related to the degree of cholinesterase enzyme inhibition in the brain. Thus, clinical signs and symptoms for chlorpyrifos would follow a dose–response relationship similar to that for brain cholinesterase. However, as noted above, for many chemicals, more than 1 effect may result because of multiple different target sites in different tissues. Thus, the observed response to varying doses of a chemical in the whole organism is often complicated by the fact that most toxic substances have multiple sites or mechanisms of toxicity, each with its own “dose–response” relationship and subsequent adverse effect. Note that when these dose–response data are plotted using the base 10 log of the dose on the abscissa (Fig. 2.3B), a better “fit” of the data to a straight line usually occurs. This is typical of many graded as well as quantal dose–response relationships.

Figure 2-3. Dose–response relationship between different doses of the organophosphate insecticide chlorpyrifos and esterase enzyme inhibition in the brain. Open circles and blue lines represent acetylcholinesterase activity and closed circles represent carboxylesterase activity in the brains of pregnant female Long–Evans rats given 5 daily doses of chlorpyrifos. (A) Dose–response curve plotted on an arithmetic scale. (B) Same data plotted on a semi-log scale. (Data from Lassiter *et al.*, 1999, with permission.)

Quantal Dose–Response Relationships

In contrast to the “graded” or continuous-scale dose–response relationship that occurs in individuals, the dose–response relationships in a *population* are by definition quantal—or “all or none”—in nature, that is, at any given dose, an individual in the population is classified as either a “responder” or a “nonresponder.” Although these distinctions of “quantal population” and “graded individual” dose–response relationships are useful, the 2 types of responses are conceptually identical. The ordinate in both cases is simply labeled *the response*, which may be the degree of response in an individual or system or the fraction of a population responding, and the abscissa is the range in administered doses.

A widely used statistical approach for estimating the response of a population to a toxic exposure is the “effective dose” (ED). Generally, the midpoint, or 50%, response level is used, giving rise to the “ED₅₀” value. However, any response level, such as an ED₀₁, ED₁₀, or ED₃₀, could be chosen. A graphical representation of an approximate ED₅₀ is shown in Fig. 2-4. Note that these data are “quantal.” Where death is the measured end point, the ED₅₀ would be referred to as the LD₅₀. Historically, determination of the LD₅₀ was often the first experiment performed with a new chemical. Today, it is widely recognized that the LD₅₀ is of marginal value as a measure of hazard, although it does provide a useful “ball park” indication of the relative hazard of a compound to cause serious, life-threatening poisoning from a single exposure. Although death is an obvious quantal end point to measure, it should be noted that any

Figure 2-4. Diagram of quantal dose–response relationship. The abscissa is a log dosage of the chemical. In the top panel the ordinate is response frequency, in the middle panel the ordinate is percent response, and in the bottom panel the response is in probit units (see text).

quantal response could be used. For example, the LD_{50} of lead or DDT is not a relevant end point when characterizing hazards of the agents to children or wildlife, respectively. Even continuous variables can be converted to quantal responses if desired. For example, an antihypertensive drug that lowers blood pressure might be evaluated in a population by assigning a “responder” as an individual whose blood pressure was lowered by 10 mm Hg or more. Note that, in this example, an individual who responded to a change in blood pressure of 50 mm Hg would be classified the same as an individual with a change in only 10 mm Hg, yet an individual with a change in 8 mm Hg would be classified as a “nonresponder.” The top panel of Fig. 2-4 shows that quantal dose responses typically exhibit a normal or Gaussian distribution. The frequency histogram in this panel also shows the relationship between dose and effect. The bars represent the percentage of animals that responded at each dose minus the percentage that responded at the immediately lower dose. One can clearly see that only a few animals responded to the lowest dose and the highest dose. Larger numbers of animals responded to doses intermediate between these 2 extremes, and the maximum frequency of response occurred in the middle portion of the dose range. Thus, we have a bell-shaped curve known as a *normal frequency distribution*. The reason for this normal distribution is that there are

differences in susceptibility to chemicals among individuals; this is known as biological variation. Animals responding at the left end of the curve are referred to as *hypersusceptible*, and those at the right end of the curve are called *resistant*. If the numbers of individuals responding at each consecutive dose are added together, a cumulative, quantal dose–response relationship is obtained. When a sufficiently large number of doses is used with a large number of animals per dose, a sigmoid dose–response curve is observed, as depicted in the middle panel of Fig. 2-4. With the lowest dose (6 mg/kg), 1% of the animals respond. A normally distributed sigmoid curve such as this one approaches a response of 0% as the dose is decreased and approaches 100% as the dose is increased, but—*theoretically*—it never passes through 0% and 100%. However, the minimally ED of any chemical that evokes a stated all-or-none response is called the *threshold dose* even though it cannot be determined experimentally.

For a normally distributed population response, the sigmoid curve has a relatively linear portion between 16% and 84%. These values represent the limits of 1 standard deviation (SD) of the mean (and the median) in a population with truly normal or Gaussian distribution. However, it is usually not practical to describe the dose–response curve from this type of plot because one does not usually have large enough sample sizes to define the sigmoid curve adequately. In a normally distributed population, the mean ± 1 SD represents 68.3% of the population, the mean ± 2 SD represents 95.5% of the population, and the mean ± 3 SD equals 99.7% of the population. Because quantal dose–response phenomena are usually normally distributed, one can convert the percent response to units of deviation from the mean or normal equivalent deviations (NEDs). Thus, the NED for a 50% response is 0; an NED of +1 is equated with an 84.1% response. Traditionally, units of NED are converted by the addition of 5 to the value to avoid negative numbers; these converted units are called *probit units* (Bliss, 1957). The probit (from the contraction of *probability unit*), then, is an NED plus 5. In this transformation, a 50% response becomes a probit of 5, a +1 deviation becomes a probit of 6, and a –1 deviation is a probit of 4.

The data given in the top 2 panels of Fig. 2-4 are replotted in the bottom panel with the response plotted in probit units. The data in the middle panel (which was in the form of a sigmoid curve) and the top panel (a bell-shaped curve) form a straight line when transformed into probit units. In essence, what is accomplished in a probit transformation is an adjustment of quantal data to an assumed normal population distribution, resulting in a straight line. The ED_{50} is obtained by drawing a horizontal line from the probit unit 5, which is the 50% response point, to the dose–effect line. At the point of intersection, a vertical line is drawn, and this line intersects the abscissa at the ED_{50} point. It is evident from the line that information with respect to the ED for 90% or for 10% of the population also may be derived by a similar procedure. Mathematically, it can be demonstrated that the range of values encompassed by the confidence limits is narrowest at the midpoint of the line (ED_{50}) and widest at both extremes (ED_{10} and ED_{90}) of the dose–response curve (dotted lines in Fig. 2-5). In addition to the ED_{50} , the slope of the dose–response curve can also be obtained. Fig. 2-5 demonstrates the dose–response curves for the response of 2 compounds. Compound A exhibits a “flat” dose–response curve, showing that a large change in dosage is required before a significant change in response will be observed. However, compound B exhibits a “steep” dose–response curve, where a relatively small change in dosage will cause a large change in response. It is evident that the ED_{50} for both compounds is the same (8 mg/kg). However, the slopes of the dose–response curves are quite different. At one half of ED_{50} of the compounds (4 mg/kg), less than 1% of the animals exposed to compound B would respond but 20% of the animals given compound A would respond.

Figure 2-5. Comparison of dose–response relationship for 2 different chemicals, plotted on a log dose–probit scale. Note that the slope of the dose–response is steeper for chemical B than for chemical A. Dotted lines represent the confidence limits for chemical A.

In Figs. 2-4 and 2-5 the dosage has been given on a log basis. Although the use of the log of the dosage is empiric, log dosage plots for normally distributed quantal data provide a more nearly linear representation of the data. It must be remembered, however, that this is not universally the case. Some radiation effects, for example, give a better probit fit when the dose is expressed arithmetically rather than logarithmically. There are other situations in which other functions (eg, exponentials) of dosage provide a better fit to the data than does the log function. It is also conventional to express the dosage in milligrams per kilogram. It might be argued that expression of dosage on a mole-per-kilogram basis would be better, particularly for making comparisons among a series of compounds. Although such an argument has considerable merit, dosage is usually expressed in milligrams per kilogram.

One might also view dosage on the basis of body weight as being less appropriate than other bases, such as surface area. The term *allometry* refers to the field of study that examines the relationships between body weight and other biological and physical parameters such as rate of basal metabolism (caloric consumption),

heart rate, blood flow, etc. Allometric studies revealed that the relationship between body weight and various other physiological parameters can be closely estimated by the following formula: $Y = aW^b$, where Y is the biological parameter of interest and a and b are constants that relate Y to body weight (Rodricks *et al.*, 2008). In general, organ sizes between species seem to scale best when b is equal to 1, whereas metabolically derived parameters scale better when b is 0.67 to 0.75. The relationship between body surface area and body weight across most mammalian species is closely described by the formula $SA = 10.5 \times (\text{body weight [grams]})^{0.67}$ (Harkness and Wagner, 1995). Empirical comparisons of toxicity data across species confirm that this relationship is appropriate for toxicological scaling. For example, Travis and White (1988) analyzed a number of toxicity testing data sets for 27 different chemotherapeutic drugs for which toxicity data were available in mouse, rat, hamster, dog, monkey, and human. They found that the exponent of body weight that gave the best correlation with toxicity was 0.73, with 95% confidence bounds of 0.69 to 0.77 (Rodricks *et al.*, 2008). Table 2-2 illustrates the differences in comparative doses when scaling is done by body weight (mg/kg) versus an allometric approach that uses an exponent of either 0.67 or 0.75. Thus, if a scaling factor of $(BW)^{2/3}$ is used, a mouse would need to receive a dose 13 times greater than that required for humans for an equivalent toxic response, whereas the dose would be 7 times greater if a scaling factor of $(BW)^{3/4}$ was used. However, not all toxic responses will necessarily scale across species in the same way. For example, acute lethality seemed to correlate better across species when body weight, rather than body surface area, was used (Rhomberg and Wolff, 1998). The selection of the most appropriate scaling factor should also take into account pharmacokinetic differences, including physiologically based pharmacokinetic modeling (PBPK). When toxicity is attributable to the formation of a toxic metabolite, or when xenobiotic biotransformation is saturated at high doses, a scaling factor of 1 may be more appropriate than 0.75 (Kirman *et al.*, 2003).

Shape of the Dose–Response Curve

Essential Nutrients The shape of the dose–response relationship has many important implications in toxicity assessment. For example, for substances that are required for normal physiological

Table 2-2

Allometric Scaling of Dose Across Different Species

SPECIES	WEIGHT (kg)	SURFACE AREA (cm ²)*	FOLD DIFFERENCE, RELATIVE TO HUMANS, NORMALIZED BY BODY WEIGHT		
			mg/kg	(BW) ^{2/3}	(BW) ^{3/4}
Mouse	0.30	103	1	13.0	7.0
Rat	0.2	365	1	6.9	4.3
Guinea pig	0.4	582	1	5.5	3.6
Rabbit	1.5	1410	1	3.5	2.6
Cat	2	1710	1	3.2	2.4
Monkey	4	2720	1	2.6	2.0
Dog	12	5680	1	1.8	1.5
Human	70	18,500	1	1.0	1.0

* Surface area of animals is closely approximated by the following formula: $SA = 10.5 \times (\text{body weight [grams]})^{2/3}$.

Figure 2-6. Individual dose–response relationship for an essential substance such as a vitamin or trace element. It is generally recognized that, for most types of toxic responses, a threshold exists such that at doses below the threshold, no toxicity is evident. For essential substances, doses below the minimum daily requirement, as well as those above the threshold for safety, may be associated with toxic effects. The blue shaded region represents the “region of homeostasis”—the dose range that results in neither deficiency nor toxicity.

function and survival (eg, vitamins and essential trace elements such as chromium, cobalt, and selenium), the “graded” dose–response relationship in an individual over the entire dose range is actually U-shaped (Fig. 2-6). That is, at very low doses, there is a high level of adverse effect, which decreases with an increasing dose. This region of the dose–response relationship for essential nutrients is commonly referred to as a *deficiency*. As the dose is increased to a point where the deficiency no longer exists, no adverse response is detected and the organism is in a state of homeostasis. However, as the dose is increased to abnormally high levels, an adverse response (usually qualitatively different from that observed at deficient doses) appears and increases in magnitude with increasing dose, just as with other toxic substances. Thus, it is recognized that high doses of vitamin A can cause liver toxicity and birth defects, high doses of selenium can affect the brain, and high doses of estrogens may increase the risk of breast cancer, even though low doses of all these substances are essential for life.

Hormesis There is considerable evidence to suggest that some nonnutritional toxic substances may also impart beneficial or stimulatory effects at low doses but that, at higher doses, they produce adverse effects. This concept of “hormesis” was first described for radiation effects but may also pertain to most chemical responses (Calabrese and Blaine, 2005). Thus, in plotting dose versus response over a wide range of doses, the effects of hormesis may also result in a “U-shaped” dose–response curve. In its original development, the concept of hormesis pertained to the ability of substances to stimulate biological systems at low doses but to inhibit them at high doses. The application of the concept of hormesis to whole-animal toxicological dose–response relationships may also be relevant but requires that the “response” on the ordinate be variant with dose. For example, chronic alcohol consumption is well recognized to increase the risk of esophageal cancer, liver cancer, and cirrhosis of the liver at relatively high doses, and this response is dose-related (curve A, Fig. 2-7). However, there is also substantial clinical and epidemiological evidence that low to moderate consumption of alcohol reduces the incidence of coronary heart disease and stroke (curve B, Fig. 2-7) (Hanna *et al.*, 1997). Thus, when all responses are plotted on the ordinate, a “U-shaped” dose–response curve is obtained (curve C, Fig. 2-7). U-shaped dose–response relationships

Figure 2-7. Hypothetical dose–response relationship depicting characteristics of hormesis. Hormetic effects of a substance are hypothesized to occur when relatively low doses result in the stimulation of a beneficial or protective response (B), such as induction of enzymatic pathways that protect against oxidative stress. Although low doses provide a potential beneficial effect, a threshold is exceeded as the dose increases and the net effects will be detrimental (A), resulting in a typical dose-related increase in toxicity. The complete dose–response curve (C) is conceptually similar to the individual dose–response relationship for essential nutrients shown in Fig. 2-6.

have obvious implications for the process of low-dose extrapolation in risk assessment.

Threshold Another important aspect of the dose–response relationship at low doses is the concept of the threshold. It has long been recognized that acute toxicological responses are associated with thresholds, that is, there is some dose below which the probability of an individual responding is zero. Obviously, the identification of a threshold depends on the particular response that is measured, the sensitivity of the measurement, and the number of subjects studied. For the individual dose–response relationship, thresholds for most toxic effects certainly exist, although interindividual variability in response and qualitative changes in response pattern with dose make it difficult to establish a true “no effects” threshold for any chemical. The biological basis of thresholds for acute responses is well established and frequently can be demonstrated on the basis of mechanistic information (Aldridge, 1986). The traditional approaches to establishing acceptable levels of exposure to chemicals are inherently different for threshold versus nonthreshold responses. The existence of thresholds for chronic responses is less well defined, especially in the area of chemical carcinogenesis. It is, of course, impossible to scientifically prove the absence of a threshold, as one can never prove a negative.

Nevertheless, for the identification of “safe” levels of exposure to a substance, the absence or presence of a threshold is important for practical reasons (see Chap. 4). A classic example of the difficulty of establishing thresholds experimentally is provided by the “ED₀₁” study, where over 24,000 mice and 81 different treatment groups were used to determine the shape of the dose–response relationship for the prototypical carcinogen 2-acetylaminofluorene (2-AAF). The study was designed to identify a statistically significant response of 1% (0.01 probability). The mice were exposed to 2-AAF at 1 of 7 different doses in the dose range of 30 to 150 ppm (plus 0 dose control) (Littlefield *et al.*, 1979). Eight “sacrifice intervals” were used to determine how quickly tumors developed. Both types of tumors demonstrated increasing incidence with increasing dose, but the shapes of the 2 curves are dramatically different. For liver tumors, no clear threshold was evident, whereas for bladder tumors, an apparent threshold was evident. However, the apparent threshold, or “no observable adverse effect level” (NOAEL), for bladder cancer was lower at 33 months (45 ppm) than at 24 months (75 ppm). Of course, the ability to detect a low incidence of tumors depends on the number of animals used in the study. Thus, although a threshold (a dose below which no response occurs) appears evident for bladder tumors, one cannot say for certain that tumors would not occur if more animals had been included in the lower-dose groups. A different animal model that relies on relatively brief exposure of rainbow trout embryos to carcinogens has allowed an even more statistically stringent analysis of the shape of the dose–response curve at low doses for mutagenic carcinogens. Using this model with 2 different genotoxic carcinogens, dibenzo[*d,e,f,p*]chrysene (DBC, also referred to as dibenzo[*a,l*]pyrene) and aflatoxin B₁ (AFB₁), estimates of the shape of the dose–response curve down to a response level of 1 additional tumor in 5000 animals could be obtained, because very large numbers of animals could be exposed. In both studies, over 40,000 trout were exposed to different doses ranging over a factor of 200 (AFB₁, lowest dose 0.5 ppb, highest dose 110 ppb) to 500 (DBC, lowest dose 0.45 ppm, highest dose 225 ppm), with over 8000 animals in the control and low-dose groups (Williams, 2012). Both of these chemicals are potent mutagens, so it was assumed that both the rate of DNA adduct formation and the tumor incidence would be linear throughout the dose range. However, for DBC, there was a clear deviation from linearity at the lower doses, such that the extrapolated dose–response curve crossed the y-axis at 1 cancer in a million exposed animals at a dose 500- to 1500-fold (depending on the statistical model) higher than would have been predicted from the linear extrapolation below the 10% response range (ED₁₀) (Bailey *et al.*, 2009) (Fig. 2-8). Remarkably, although the tumor response exhibited a clear “threshold,” the formation of DBC–DNA adducts was quite linear through the lowest dose used. In contrast, in a similarly designed study using the potent carcinogen, AFB₁, both tumor response and AFB–DNA adduct formation appear approximately linear down through the lowest dose; the liver tumor response to AFB₁ remained linear to the lowest dose, although the slope was about 1.5 and the predicted dose resulting in 1 cancer in a million exposed animals was about 10-fold higher than that predicted from the extrapolated LED₁₀ line, although the lowest doses tested yielded tumor incidence that was close (within a factor of 2) to the background tumor rate (Fig. 2-9) (Williams *et al.*, 2009a; Williams, 2012).

(See Chap. 4 for more discussion on statistical issues related to extrapolation of dose–response curves and the determination of NOAELs.)

In evaluating the shape of the dose–response relationship in populations, it is realistic to consider inflections in the shape of the dose–response curve rather than absolute thresholds. That is, the

Figure 2-8. Dose–response relationship for carcinogens—rodents and 2-AAF.

slope of the dose–response relationship at high doses may be substantially different from the slope at low doses, usually because of dispositional differences in the chemical. Saturation of biotransformation pathways, protein-binding sites or receptors, and depletion of intracellular cofactors represent some reasons why sharp inflections in the dose–response relationship may occur. For example, the widely used analgesic acetaminophen has a very low rate of liver toxicity at normal therapeutic doses. Even though a toxic metabolite (*N*-acetyl-*p*-benzoquinone imine [NAPQI]) is produced in the liver

Figure 2-9. Dose–response relationship for carcinogens—fish and aflatoxin B₁. (Reproduced with permission from Williams, 2012.)

at therapeutic doses, it is rapidly detoxified through conjugation with the intracellular antioxidant glutathione. However, at very high doses, the level of intracellular glutathione in the liver is depleted and NAPQI accumulates, causing serious and potentially fatal liver toxicity. This effect is analogous to the rapid change in pH of a buffered solution that occurs when the buffer capacity is exceeded. Some toxic responses, most notably the development of cancer after the administration of genotoxic carcinogens, are often considered to be linear at low doses and thus do not exhibit a threshold. In such circumstances, there is no dose with “zero” risk, although the risk decreases proportionately with a decrease in the dose. The existence or lack of existence of a threshold dose for carcinogens has many regulatory implications and is a point of considerable controversy and research in the field of quantitative risk assessment for chemical carcinogens (see Chap. 4).

Nonmonotonic Dose–Response Curves For chemicals that exert their primary toxic effects via modification of hormonal responses (endocrine disruptors), it is possible that effects occur at relatively low doses that are not seen at higher doses, thereby seemingly defying the traditional concept of “dose–response”.

The characterization of so-called nonmonotonic dose–response (NMDR) curves is an important refinement in our understanding of dose–response relationships in toxicology (Fig. 2-10). Indeed, some chemicals, such as the plastics monomer bisphenol A (BPA), exhibit relatively little evident toxicity at high doses in traditional acute toxicity testing procedures, yet may have important biological effects when exposure occurs during sensitive periods of development, even at doses well below those shown to cause evident toxicity. For example, human pituitary cells cultured in the presence of BPA elicited significant responses at concentrations of 0.001 and

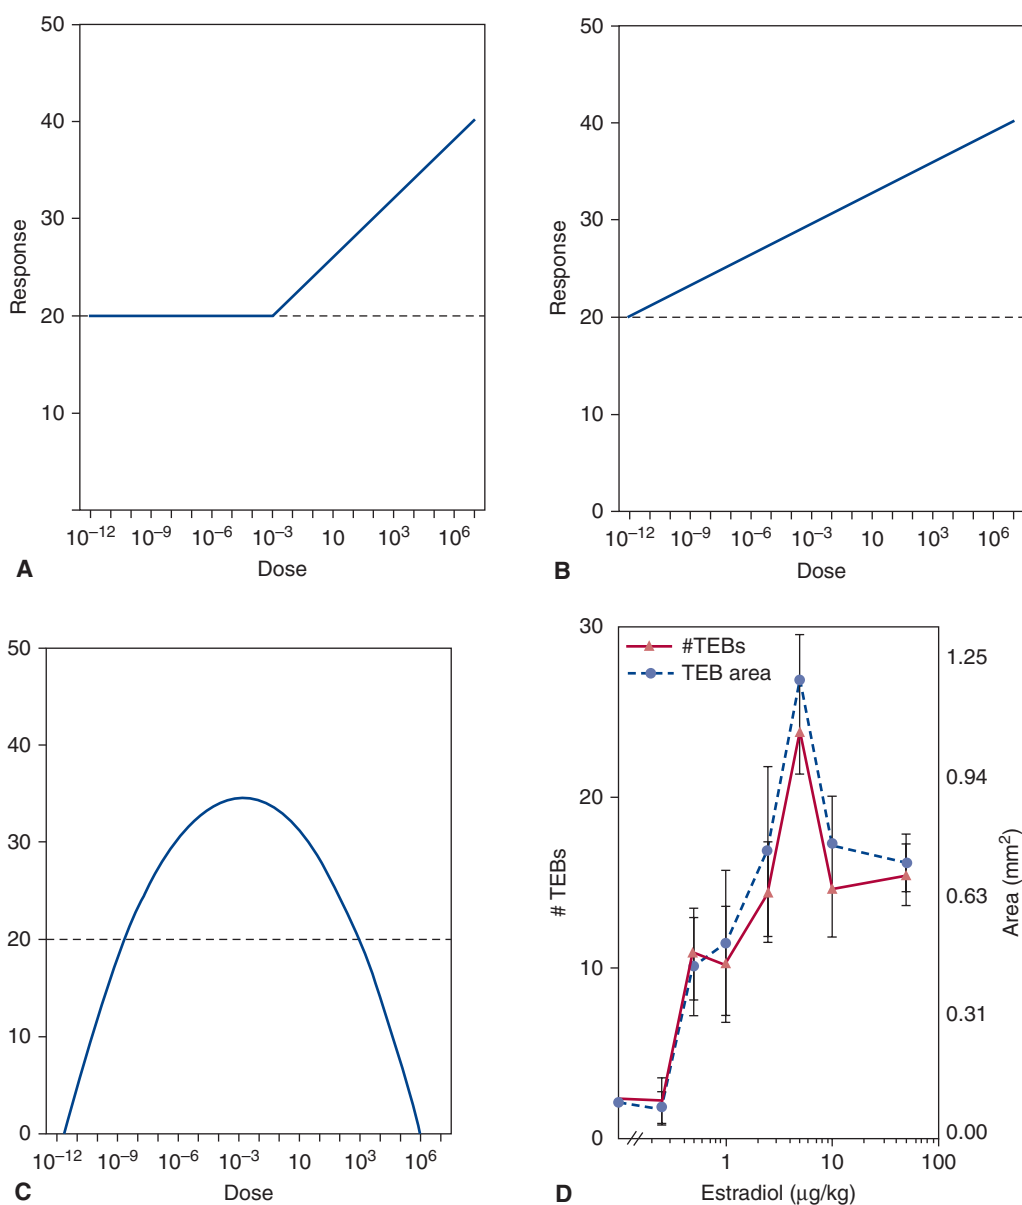

Figure 2-10. Hypothetical dose–response curves for the (A) threshold responses, (B) nonthreshold linear response, and (C and D) nonmonotonic dose–response (NMDR). Curves A and B reflect traditional dose–response relationships. However, in the NMDR curve (C), an increase in dose does not necessarily correspond to an increase in response, such that, in this example, doses from 10^{-12} to 10^{-3} dose units result in an increase in response, and doses from 10^{-3} to 10^6 dose units result in a decrease in response. Curve D represents the NMDR curves observed in mammary gland morphological parameters after administration of estradiol to ovariectomized females. The left y-axis is the number of terminal end buds (TEBs), and the right y-axis is total area of all TEBs; the TEB is an estrogen-dependent structure. (Based on Vandenberg *et al.*, 2009.)

0.01 nM, but not at 1 and 10 nM, yet the response was seen at 100 nM (Vandenberg *et al.*, 2009). Several other studies have found that BPA and other endocrine-active xenobiotics can elicit NMDR relationships for a variety of other specific receptors and/or cell signaling pathways (reviewed in Vandenberg *et al.*, 2009).

Specific cellular/molecular mechanisms that might explain NMDR curves include: (1) upregulation of some receptors at low concentrations, with downregulation of the same receptors at higher levels, and/or (2) integration of 2 or more monotonic dose–response curves that occur through different molecular/cellular pathways with common end points but opposite effects (Vandenberg *et al.*, 2009). Since endocrine-active xenobiotics may act as weak agonists for specific hormone receptors, it is reasonable that low doses could have different effects than high doses if, as partial agonists, they competitively inhibit endogenous ligands at higher concentrations, but have either no or positive agonist effects at low concentrations. Another explanation for NMDR curves is that we simply do not understand all the varied and interconnected molecular pathways that work in concert to produce an observable response at the organismal level. Indeed, BPA has been shown to have multiple different effects on a myriad of putative molecular pathways involved in hormone function, so it perhaps is not surprising to see NMDR functions over dose ranges of many orders of magnitude (Vandenberg *et al.*, 2009).

Assumptions in Deriving the Dose–Response Relationship

A number of assumptions must be considered before dose–response relationships can be used appropriately. The first is that the response is due to the chemical administered. To describe the relationship between a toxic material and an observed effect or response, one must know with reasonable certainty that the relationship is indeed a causal one. For some data, it is not always apparent that the response is a result of chemical exposure. For example, an epidemiological study might result in the discovery of an “association” between a response (eg, disease) and 1 or more variables. Frequently, the data are presented similarly to the presentation of “dose response” in pharmacology and toxicology. Use of the dose response in this context is suspect unless other convincing evidence supports a causal connection between the estimated dose and the measured end point (response). Unfortunately, in nearly all retrospective and case–control studies and even in many prospective studies, the dose, duration, frequency, and routes of exposure are seldom quantified, and other potential etiologic factors are frequently present. In its most strict usage, then, the dose–response relationship is based on the knowledge that the effect is a result of a known toxic agent or agents.

A second assumption seems simple and obvious: the magnitude of the response is in fact related to the dose. Perhaps because of its apparent simplicity, this assumption is often a source of misunderstanding. It is really a composite of 3 other assumptions that recur frequently:

1. There is a molecular target site (or sites) with which the chemical interacts to initiate the response.
2. The production of a response and the degree of response are related to the concentration of the chemical at the target site.
3. The concentration at the site is, in turn, related to the dose administered.

The third assumption in using the dose–response relationship is that there exist both a quantifiable method of measuring and a precise means of expressing the toxicity. For any given dose–response

relationship, a great variety of criteria or end points of toxicity could be used. The ideal criterion would be one closely associated with the molecular events resulting from exposure to the toxicant. It follows from this that a given chemical may have a family of dose–response relationships, 1 for each toxic end point. For example, a chemical that produces cancer through genotoxic effects, liver damage through inhibition of a specific enzyme, and CNS effects via a different mechanism, may have 3 distinct dose–response relationships, 1 for each end point. Early in the assessment of toxicity, little mechanistic information is usually available; thus, establishing a dose–response relationship based on the molecular mechanism of action is usually impossible. Indeed, it might not be approachable even for well-known toxicants. In the absence of a mechanistic, molecular ideal criterion of toxicity, one looks to a measure of toxicity that is unequivocal and clearly relevant to the toxic effect. Such measures are often referred to as “effects-related biomarkers.” For example, with a new compound chemically related to the class of organophosphate insecticides, one might approach the measurement of toxicity by measuring the inhibition of cholinesterase in blood. In this way, one would be measuring, in a readily accessible system and using a technique that is convenient and reasonably precise, a prominent effect of the chemical and one that is usually pertinent to the mechanism by which toxicity is produced.

The selection of a toxic end point for measurement is not always so straightforward. Even the example cited above may be misleading, as an organophosphate may produce a decrease in blood cholinesterase, but this change may not be directly related to its toxicity. As additional data are gathered to suggest a mechanism of toxicity for any substance, other measures of toxicity may be selected. Although many end points are quantitative and precise, they are often indirect measures of toxicity. Changes in enzyme levels in blood can be indicative of tissue damage. For example, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are used to detect liver damage. Use of these enzymes in serum is yet another example of an effects-related biomarker because the change in enzyme activity in the blood is directly related to damage to liver cells. Much of clinical diagnostic medicine relies on effects-related biomarkers, but to be useful the relationship between the biomarker and the disease must be carefully established. Patterns of isozymes and their alteration may provide insight into the organ or system that is the site of toxic effects. As discussed later in this chapter, the new tools of toxicogenomics provide an unprecedented opportunity to discover new “effects-related biomarkers” in toxicology.

Many direct measures of effects are also not necessarily related to the mechanism by which a substance produces harm to an organism but have the advantage of permitting a causal relation to be drawn between the chemical and its action. For example, measurement of the alteration of the tone of smooth or skeletal muscle for substances acting on muscles represents a fundamental approach to toxicological assessment. Similarly, measures of heart rate, blood pressure, and electrical activity of heart muscle, nerve, and brain are examples of the use of physiological functions as indices of toxicity. Measurement can also take the form of a still higher level of integration, such as the degree of motor activity or behavioral change.

The measurements used as examples in the preceding discussion all assume prior information about the toxicant, such as its target organ or site of action or a fundamental effect. However, such information is usually available only after toxicological screening and testing based on other measures of toxicity. With a new substance, the customary starting point is a single-dose acute toxicity test designed to provide preliminary identification of target organ

toxicity. Studies specifically designed with lethality as an end point are no longer recommended by the United States or international agencies. Data from acute studies provide essential information for choosing doses for repeated dosing studies as well as choosing specific toxicological end points for further study. Key elements of the study design must be a careful, disciplined, detailed observation of the intact animal extending from the time of administration of the toxicant to any clinical signs of distress, which may include detailed behavioral observations or physiological measures. It is recommended that these observations be taken over a 14-day period. From properly conducted observations, immensely informative data can be gathered by a trained toxicologist. Second, an acute toxicity study ordinarily is supported by histological examination of major tissues and organs for abnormalities. From these observations, one can usually obtain more specific information about the events leading to the various end points, the target organs involved, and often a suggestion about the possible mechanism of toxicity at a relatively fundamental level.

Evaluating the Dose–Response Relationship

Comparison of Dose Responses Fig. 2-11 illustrates a hypothetical quantal dose–response curve for a desirable effect of a chemical (effective dose, ED) such as anesthesia, a toxic effect (toxic dose, ED) such as liver injury, and the lethal dose (LD). As depicted in Fig. 2-11, a parallelism is apparent between the ED curve and the curve depicting mortality (LD). It is tempting to view the parallel dose–response curves as indicative of identity of mechanism—that is, to conclude that the lethality is a simple extension of the therapeutic effect. Whereas this conclusion may ultimately prove to be correct in any particular case, it is not warranted solely on the basis of the 2 parallel lines. The same admonition applies to any pair of parallel “effect” curves or any other pair of toxicity or lethality curves.

Therapeutic Index The hypothetical curves in Fig. 2-11 illustrate 2 other interrelated points: the importance of the selection of the toxic criterion and the interpretation of comparative effect. The concept of the “therapeutic index” (TI), which was introduced by Paul Ehrlich in 1913, can be used to illustrate this relationship. Although the TI is directed toward a comparison of the therapeutically ED to the TD of a chemical, it is equally applicable to considerations of comparative toxicity. The TI in its broadest sense is defined as the ratio of the dose required to produce a toxic effect to

the dose needed to elicit the desired therapeutic response. Similarly, an index of comparative toxicity is obtained by the ratio of doses of 2 different materials to produce an identical response or the ratio of doses of the same material necessary to yield different toxic effects.

The most commonly used index of effect, whether beneficial or toxic, is the median effect dose (ED_{50}). The TI of a drug is an approximate statement about the relative safety of a drug expressed as the ratio of the adverse end point or TD (historically the LD) to the therapeutic dose:

$$TI = \frac{TD_{50}}{ED_{50}}$$

From Fig. 2-11 one can approximate a TI by using these median doses. The larger the ratio, the greater is the relative safety. The ED_{50} is approximately 20, and the TD_{50} is about 60; thus, the TI is 3, a number indicating that reasonable care in exposure to the drug is necessary to avoid toxicity. However, the use of the median effective and median toxic doses is not without disadvantages, because median doses tell nothing about the slopes of the dose–response curves for therapeutic and toxic effects.

Margins of Safety and Exposure One way to overcome this deficiency is to use the ED_{99} for the desired effect and the TD_1 for the undesired effect. These parameters are used in the calculation of the margin of safety (MOS):

$$MOS = \frac{TD_1}{ED_{99}}$$

The quantitative comparisons described above have been used mainly after a single administration of chemicals. However, for chemicals for which there is no beneficial or effective dose and exposures are likely to occur repeatedly, the ratio of TD_1 to ED_{99} has little relevance. Thus, for nondrug chemicals, the term *MOS* has found use in risk assessment procedures as an indicator of the magnitude of the difference between an estimated “exposed dose” to a human population and the NOAEL or other benchmark dose determined in experimental animals.

A measure of the degree of accumulation of a chemical and/or its toxic effects can also be estimated from quantal toxicity data. The *chronicity index* of a chemical is a unitless value obtained by dividing its 1-dose TD_{50} by its 90-dose (90-day) TD_{50} , with both expressed in milligrams per kilogram per day. Theoretically, if no cumulative effect occurs over the doses, the chronicity index will be 1. If a compound were absolutely cumulative, the chronicity index would be 90.

Historically, statistical procedures similar to those used to calculate the LD_{50} can also be used to determine the lethal time 50 (LT_{50}), or the time required for half the animals to die (Litchfield, 1949). The LT_{50} value for a chemical indicates the time course of the toxic effects but does not indicate whether 1 chemical is more toxic than another.

Frequently, dose–response curves from repeated-dose experimental animal studies (subacute, subchronic, or chronic) are used to estimate the NOAEL, or some other “benchmark” measure of minimal toxic response, such as the dose estimated to produce toxic effects in 10% of the population (TD_{10}) (see also Chap. 4). These estimates of minimal TD, derived from quantal dose–response curves, can be used in risk assessment to derive a “margin of exposure” (MOE) index. This index compares the estimated daily exposure, in milligrams per kilogram per day, that might occur under a given set of circumstances with some estimated value from the quantal dose–response relationship (eg, NOAEL or TD_{10}). Like the

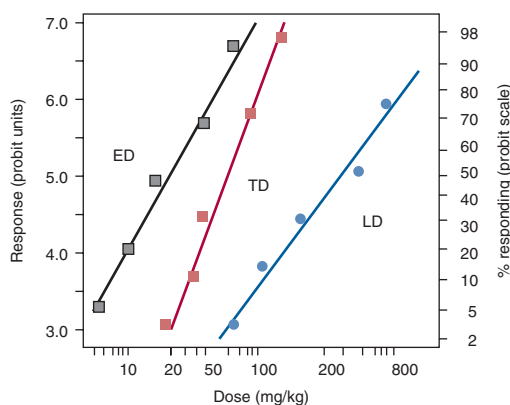

Figure 2-11. Comparison of effective dose (ED), toxic dose (TD), and lethal dose (LD). The plot is of log dosage versus percentage of population responding in probit units.

Figure 2-12. Schematic representation of the difference in the dose–response curves for 4 chemicals (A–D), illustrating the difference between potency and efficacy (see text).

MOS, the MOE is often expressed as a ratio of these 2 values. Thus, for example, if an estimate of human exposure to a pesticide residue yielded a value of 0.001 mg/kg per day, and a TD_{10} of 1 mg/kg per day was determined for that same pesticide, the MOE would be 1000. This value indicates that the estimate of daily exposure under the described set of conditions is 1/1000 the estimated daily dose that would cause evident toxicity in 10% of exposed animals. (See Chap. 4 for a more complete discussion of benchmark doses, NOAELs, and MOE.)

Potency versus Efficacy To compare the toxic effects of 2 or more chemicals, the dose response to the toxic effects of each chemical must be established. One can then compare the potency and maximal efficacy of the 2 chemicals to produce a toxic effect. These 2 important terms can be explained by reference to Fig. 2-12, which depicts dose–response curves to 4 different chemicals for the frequency of a particular toxic effect, such as the production of tumors. Chemical A is said to be more potent than chemical B because of their relative positions along the dosage axis. Potency thus refers to the range of doses over which a chemical produces increasing responses. Thus, A is more potent than B and C is more potent than D. Maximal efficacy reflects the limit of the dose–response relationship on the response axis to a certain chemical. Chemicals A and B have equal maximal efficacy, whereas the maximal efficacy of C is less than that of D.

VARIATION IN TOXIC RESPONSES

Selective Toxicity

Selective toxicity means that a chemical produces injury to 1 kind of living matter without harming another form of life even though the 2 may exist in intimate contact (Albert, 1973). The living matter that is injured is termed the *uneconomic form* (or undesirable), and the matter protected is called the *economic form* (or desirable). They may be related to each other as parasite and host or may be 2 tissues in 1 organism. This biological diversity interferes with the ability of ecotoxicologists to predict the toxic effects of a chemical in 1 species (humans) from experiments performed in another species (laboratory animals). However, by taking advantage of the biological diversity, it is possible to develop chemicals that are lethal for an undesired species and harmless for other species. In agriculture, for example, there are fungi, insects, and even competitive plants that injure the crop, and thus selective pesticides are needed. Similarly, animal husbandry and human medicine require

chemicals, such as antibiotics, that are selectively toxic to the undesirable form but do not produce damage to the desirable form.

Drugs and other chemicals used for selective toxic purposes are selective for 1 of 2 reasons. Either (1) the chemical is equally toxic to both economic and uneconomic cells but is accumulated mainly by uneconomic cells or (2) it reacts fairly specifically with a cytological or a biochemical feature that is absent from or does not play an important role in the economic form (Albert, 1973). Selectivity resulting from differences in distribution usually is caused by differences in the absorption, biotransformation, or excretion of the toxicant. The selective toxicity of an insecticide spray may be partly due to a larger surface area per unit weight that causes the insect to absorb a proportionally larger dose than does the mammal being sprayed. The effectiveness of radioactive iodine in the treatment of hyperthyroidism (as well as its thyroid carcinogenicity) is due to the selective ability of the thyroid gland to accumulate iodine. A major reason why chemicals are toxic to one, but not to another, type of tissue is that there are differences in accumulation of the ultimate toxic compound in various tissues. This, in turn, may be due to differences in the ability of various tissues to transport or biotransform the chemical into the ultimate toxic product.

Selective toxicity caused by differences in comparative cytology is exemplified by a comparison of plant and animal cells. Plants differ from animals in many ways—for example, absence of a nervous system, an efficient circulatory system, and muscles as well as the presence of a photosynthetic mechanism and cell walls. The fact that bacteria contain cell walls and humans do not has been utilized in developing selective toxic chemotherapeutic agents, such as penicillin and cephalosporins, that kill bacteria but are relatively nontoxic to mammalian cells.

Selective toxicity can also be a result of a difference in biochemistry in the 2 types of cells. For example, bacteria do not absorb folic acid but synthesize it from *p*-aminobenzoic acid, glutamic acid, and pteridine, whereas mammals cannot synthesize folic acid but have to absorb it from the diet. Thus, sulfonamide drugs are selectively toxic to bacteria because the sulfonamides, which resemble *p*-aminobenzoic acid in both charge and dimensions, antagonize the incorporation of *p*-aminobenzoic acid into the folic acid molecule—a reaction that humans do not carry out.

Species Differences

Although a basic tenet of toxicology is that “experimental results in animals, when properly qualified, are applicable to humans,” it is important to recognize that both quantitative and qualitative

differences in response to toxic substances may occur among different species. As discussed above, there are many reasons for selective toxicity among different species. Even among phylogenetically similar species (eg, rats, mice, guinea pigs, and hamsters), large differences in response may occur. For example, the LD₅₀ for the highly toxic dioxin, TCDD, differs by more than 1000-fold between guinea pigs and hamsters. Not only the lethal dose for TCDD but also the particular target organs affected vary widely among species. Species differences in response to carcinogenic chemicals represent an important issue in regulatory risk assessment. As discussed in Chap. 4, extrapolation of laboratory animal data to infer human cancer risk is currently a key component of regulatory decision making. The validity of this approach of course depends on the relevance of the experimental animal model to humans. Large differences in carcinogenic response between experimental animal species are not unusual. For example, mice are highly resistant to the hepatocarcinogenic effects of the fungal toxin AFB₁. Dietary doses as high as 10,000 ppb failed to produce liver cancer in mice, whereas in rats dietary doses as low as 15 ppb produced a significant increase in liver tumors (Wogan *et al.*, 1974). The mechanistic basis for this dramatic difference in response appears to be entirely related to species differences in the expression of a particular form of glutathione *S*-transferase (mGSTA3-3) that has unusually high catalytic activity toward the carcinogenic epoxide of aflatoxin (Eaton and Gallagher, 1994). Mice express this enzyme constitutively, whereas rats normally express a closely related form with much less detoxifying activity toward aflatoxin epoxide. Interestingly, rats do possess the gene for a form of glutathione *S*-transferase with high catalytic activity toward aflatoxin epoxide (rGSTA5-5) that is inducible by certain dietary antioxidants and drugs. Thus, dietary treatment can dramatically change the sensitivity of a species to a carcinogen.

Other examples in which large species differences in response to carcinogens have been observed include the development of renal tumors from 2,3,5-trimethylpentane and D-limonene in male rats (Lehman-McKeeman and Caudill, 1992), the production of liver tumors from “peroxisomal proliferators” such as the antilipidemic drug clofibrate and the common solvent trichloroethylene (Roberts, 1999), and the induction of nasal carcinomas in rats after inhalation exposure to formaldehyde (Monticello and Morgan, 1997).

Identifying the mechanistic basis for species differences in response to chemicals is an important part of toxicology because only through a thorough understanding of these differences can the relevance of animal data to human response be verified.

Individual Differences in Response

Even within a species, large interindividual differences in response to a chemical can occur because of subtle genetic differences. Hereditary differences in a single gene that occur in more than 1% of the population are referred to as *genetic polymorphism* and may be responsible for idiosyncratic reactions to chemicals, as discussed earlier in this chapter. However, genetic polymorphism may have other important but less dramatic effects than those described for acute idiosyncratic responses (such as that occurring in pseudocholinesterase-deficient individuals after succinylcholine exposure). For example, it is recognized that approximately 50% of the Caucasian population has a gene deletion for the enzyme glutathione *S*-transferase M1. This enzyme has no apparent significant physiological function, and thus homozygotes for the gene deletion (eg, those who lack both copies of the normal gene) are functionally and physiologically normal. However, epidemiological studies have indicated that smokers who are homozygous for the null

allele may be at slightly increased risk of developing lung cancer compared with smokers who have 1 or both copies of the normal gene (Mohr *et al.*, 2003). Chap. 6 provides additional examples of genetic differences in biotransformation enzymes that may be important determinants of variability in individual susceptibility to chemical exposures.

Genetic polymorphism in physiologically important genes may also be responsible for interindividual differences in toxic responses. For example, studies in transgenic mice have shown that mice possessing 1 copy of a mutated *p53* gene (a so-called tumor suppressor gene; see Chap. 8) are much more susceptible to some chemical carcinogens than are mice with 2 normal copies of the gene (Tennant *et al.*, 1999). In humans, there is evidence that possessing 1 mutated copy of a tumor suppressor gene greatly increases the risk of developing certain cancers. For example, retinoblastoma is a largely inherited form of cancer that arises because of the presence of 2 copies of a defective tumor suppressor gene (the Rb gene) (Wiman, 1993). Individuals with 1 mutated copy of the Rb gene and 1 normal copy are not destined to acquire the disease (as are those with 2 copies of the mutated gene), although their chance of acquiring it is much greater than that of persons with 2 normal Rb genes. This is the case because both copies of the gene must be nonfunctional for the disease to develop. With 1 mutated copy present genetically, the probability of acquiring a mutation of the second gene (potentially from exposure to environmental mutagens) is much greater than the probability of acquiring independent mutations in both copies of the gene as would be necessary in people with 2 normal Rb alleles. (See Chap. 8 for additional discussion of tumor suppressor genes.)

As our understanding of the human genome increases, more “susceptibility” genes will be discovered, and it is likely that the etiology of many chronic diseases will be shown to be related to a combination of genetics and environment. Simple blood tests may ultimately be developed that allow an individual to learn whether he or she may be particularly susceptible to specific drugs or environmental pollutants. Although the public health significance of this type of information could be immense, the disclosure of such information raises many important ethical and legal issues that must be addressed before wide use of such tests.

The study of “gene–environment” interactions, or “ecogenetics” (Costa and Eaton, 2006), is a rapidly developing field of substantial relevance to toxicology. It is likely that the majority of chronic diseases develop as a result of the complex interplay between multiple genes and the myriad of environmental factors, including diet, lifestyle, and occupational and/or environmental exposures to toxic substances. The growing field of epigenetics, discussed in more detail later in this chapter, is likely to have an equally great impact on the science of toxicology, as it is likely that many xenobiotics will be found to exert many of their chronic adverse effects through subtle effects on gene expression.

DESCRIPTIVE ANIMAL TOXICITY TESTS

Two main principles underlie all descriptive animal toxicity testing. The first is that the effects produced by a compound in laboratory animals, when properly qualified, are applicable to humans. This premise applies to all of experimental biology and medicine. Most, if not all, known chemical carcinogens in humans are carcinogenic in some species, but not necessarily in all species of laboratory animals. It has become increasingly evident that the converse—that all chemicals identified as carcinogenic in laboratory animals are also carcinogenic in humans—is not true (Dybing and Sanner, 1999; Grisham, 1997; Hengstler *et al.*, 1999). However, for regulatory

and risk assessment purposes, positive carcinogenicity tests in animals are usually interpreted as indicative of potential human carcinogenicity. If a clear understanding of the mechanism of action of the carcinogen indicates that a positive response in animals is not relevant to humans, a positive animal bioassay may be considered irrelevant for human risk assessment (see Chap. 4). This species variation in carcinogenic response appears to be due in many instances to differences in biotransformation of the procarcinogen to the ultimate carcinogen (see Chap. 6).

The second principle is that exposure of experimental animals to chemicals in high doses is a necessary and valid method of discovering possible hazards in humans. This principle is based on the quantal dose–response concept that the incidence of an effect in a population is greater as the dose or exposure increases. Practical considerations in the design of experimental model systems require that the number of animals used in toxicology experiments always be small compared with the size of human populations at risk. Obtaining statistically valid results from such small groups of animals requires the use of relatively large doses so that the effect will occur frequently enough to be detected. However, the use of high doses can create problems in interpretation if the response(s) obtained at high doses does not occur at low doses. Thus, for example, it has been shown that bladder tumors observed in rats fed very high doses of saccharin will not occur at the much lower doses of saccharin encountered in the human diet. At the high concentrations fed to rats, saccharin forms an insoluble precipitate in the bladder that subsequently results in chronic irritation of bladder epithelium, enhanced cell proliferation, and ultimately bladder tumors (Cohen, 1998, 1999). In vitro studies have shown that precipitation of saccharin in human urine will not occur at the concentrations

that could be obtained from even extraordinary consumption of this artificial sweetener. As noted above and shown in Fig. 2-8, even for mutagenic chemicals that form DNA adducts, the response at high doses, as seen for DBC, may not be linear at low doses, although for another DNA-reactive carcinogen, AFB₁, the high-dose data were reflective of low-dose response in an approximately linear fashion. Examples such as these illustrate the importance of considering the molecular, biochemical, and cellular mechanisms responsible for toxicological responses when extrapolating from high to low dose and across species.

Toxicity tests are not designed to demonstrate that a chemical is safe but to characterize the toxic effects a chemical can produce. Although there are no set toxicology tests that have to be performed on every chemical intended for commerce, a tiered approach typical of many hazard assessment programs is illustrated in Fig. 2-13. Depending on the eventual use of the chemical, the toxic effects produced by structural analogs of the chemical, as well as the toxic effects produced by the chemical itself, contribute to the determination of the toxicology tests that should be performed. The FDA, EPA, and Organization for Economic Cooperation and Development (OECD) have written good laboratory practice (GLP) standards and other guidance that stipulate that procedure must be defined and accountability documented. These guidelines are expected to be followed when toxicity tests are conducted in support of the introduction of a chemical to the market.

The following sections provide an overview of basic toxicity testing procedures in use today. For a detailed description of these tests, the reader is referred to several authoritative texts on this subject (Barile, 2010; Hayes, 2008; Jacobson-Kram and Keller, 2006; Eaton and Gallagher, 2010).

Although different countries have often had different testing requirements for toxicity testing/product safety evaluation, efforts to “harmonize” such testing protocols have resulted in more standardized approaches. The International Conference on Harmonization (ICH) of Technical Requirements for Registration of Pharmaceuticals for Human Use includes regulatory authorities from Europe, Japan, and the United States (primarily the FDA), as well as experts from the pharmaceutical industry in the 3 regions, who worked together to develop internationally recognized scientific and technical approaches to pharmaceutical product registration. ICH has adopted guidelines for most areas of toxicity testing (Table 2-3). In addition to safety assessment (ICH guidelines designated with an “S”), ICH has also established guidelines on quality (Q), efficacy (E), and multidisciplinary (M) topics. (See <http://www.ich.org/products/guidelines.html> for a description of current ICH guidelines and reviews by Pugsley *et al.* (2008, 2011) for a detailed discussion of *in vitro* and *in vivo* approaches to safety pharmacology that has been informed by the ICH regulatory guidance document for preclinical safety testing of drugs.)

Typically, a tiered approach is used, with subsequent tests dependent on results of initial studies. A general framework for how new chemicals are evaluated for toxicity is shown in Fig 2-13. Early studies require careful chemical evaluation of the compound

or mixture to assess purity, stability, solubility, and other physicochemical factors that could impact the ability of the test compound to be delivered effectively to animals. Once this information is obtained, the chemical structure of the test compound is compared with similar chemicals for which toxicological information is already available. Structure–activity relationships may be derived from a review of existing toxicological literature, and can provide additional guidance on design of acute and repeated-dose experiments, and what specialized tests need to be completed. Once such basic information has been compiled and evaluated, the test compound is then administered to animals in acute and repeated-dose studies.

Because of increased societal pressure to reduce or eliminate the use of animals in toxicity testing, while also ensuring that new chemicals do not represent unreasonable risks to human health or the environment, regulatory agencies have been encouraging new approaches to descriptive toxicity tests that do not rely on laboratory animals. For example, the European Union (EU) promulgated an important regulatory initiative for the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH). The implementation of REACH “will have significant impact on applied toxicology and exposure assessment by stimulating innovation in sampling and analysis, toxicology testing, exposure modeling, alternative toxicity testing, and risk assessment practices”

(Williams *et al.*, 2009b). Alternative, *in vitro* approaches to toxicity assessment are likely to transform the way that product safety evaluation is done in the future, although the standard approaches to hazard evaluation described in this section are likely to continue as the mainstay of toxicity evaluation for the next decade, irrespective of the fact that some areas, such as acute toxicity testing and eye irritation, are likely to be largely replaced by *in vitro* tests in the next decade (Ukelis *et al.*, 2008).

The development of new “omics” technologies (discussed later in this section) may have profound implications for toxicity testing in the future (NAS/NRC, 2007). The recognition that many of the existing chemicals in commercial use today, as well as new chemicals being introduced into commerce, have little toxicological information about them has prompted calls for new “high-throughput” approaches to toxicity testing that will allow at least basic hazard characterization for the thousands of untested chemicals currently in the marketplace, as well as the many new chemicals that are introduced each year. A report from the National Academy of Sciences/National Research Council in 2007 called for a “paradigm shift” in how toxicity testing is done (NAS/NRC, 2007). A key component of this new vision on toxicity testing is the use of an extensive battery of *in vitro* tests to evaluate “pathways” of toxicity (NAS/NRC, 2010). The hope is that new technologies in genomics, transcriptomics, proteomics, metabolomics, and bioinformatics (discussed later in this chapter) can be combined with automated high-throughput technologies to create a tiered structure for toxicity testing. The approach to using biochemical and molecular pathway-based analyses, rather than apical end points (eg, target organ damage, mutagenesis, carcinogenesis, reproductive and developmental effects), to identify potentially problematic chemicals early in their development is particularly attractive from a time frame and economic perspective (NAS/NRC, 2010). However, it is also recognized that validation of such tests is critically important to the reliable use of such screening technologies, and that the traditional *in vivo* studies described in the following section will continue to serve an important role in hazard evaluations for years to come, especially as a means of validating new high-throughput screening approaches.

Acute Toxicity Testing

Generally, the first toxicity test performed on a new chemical is acute toxicity, determined from the administration of a single exposure. The objectives of acute toxicity testing are to: (1) provide an estimate of the intrinsic toxicity of the substance, often times expressed as an approximate LD (eg, LD₅₀), (2) provide information on target organs and other clinical manifestations of toxicity, (3) identify species differences and susceptible species, (4) establish the reversibility of the toxic response, and (5) provide information that will assist in the design and dose selection for longer-term (subchronic, chronic) studies. It should be noted that the ICH recommended in 1991 (D’Arcy and Harron, 1992) the elimination of LD₅₀ determinations for pharmaceuticals, although other regulatory requirements, for example, pesticide registration, may still require determinations of LD₅₀s.

The LD₅₀ and other acute toxic effects are determined after 1 or more routes of administration (1 route being oral or the intended route of exposure) in 1 or more species. The species most often used are the mouse and rat. Studies are performed in both adult male and female animals. Food is often withheld the night before dosing. The number of animals that die in a 14-day period after a single dosage is tabulated. In addition to mortality and weight, daily examination of test animals should be conducted for signs

of intoxication, lethargy, behavioral modifications, morbidity, food consumption, and so on.

Determination of the LD₅₀ has become a public issue because of increasing concern for the welfare and protection of laboratory animals. The LD₅₀ is not a biological constant. Many factors influence toxicity and thus may alter the estimation of the LD₅₀ in any particular study. Factors such as animal strain, age, and weight, type of feed, caging, pretrial fasting time, method of administration, volume and type of suspension medium, and duration of observation have all been shown to influence adverse responses to toxic substances. These and other factors have been discussed in detail in earlier editions of this textbook (Doull, 1980). Because of this inherent variability in LD₅₀ estimates, it is now recognized that for most purposes it is only necessary to characterize the LD₅₀ within an order of magnitude range such as 5 to 50 mg/kg, 50 to 500 mg/kg, and so on.

There are several traditional approaches to determining the LD₅₀ and its 95% confidence limit as well as the slope of the probit line. The reader is referred to the classic works of Litchfield and Wilcoxon (1949), Bliss (1957), and Finney (1971) for a description of the mechanics of these procedures. Other statistical techniques that require fewer animals, such as the “moving averages” method of Thompson and Weill (Weil, 1952), are available but do not provide confidence limits for the LD₅₀ and the slope of the probit line. Finney (1985) has succinctly summarized the advantages and deficiencies of many of the traditional methods. For most circumstances, an adequate estimate of the LD₅₀ and an approximation of the 95% confidence intervals can be obtained with as few as 6 to 9 animals, using the “up-and-down” method as modified by Bruce (1985). When this method was compared with traditional methods that typically utilize 40 to 50 animals, excellent agreement was obtained for all 10 compounds tested (Bruce, 1987). In mice and rats the LD₅₀ is usually determined as described above, but in the larger species only an approximation of the LD₅₀ is obtained by increasing the dose in the same animal until serious toxic effects are evident.

Alternative *in vitro* approaches to estimating the LD₅₀ have been proposed. For example, the *Registry of Cytotoxicity* (RC), originally published in German in 1998 (Halle, 2003), was developed by linear regression analysis of the mean IC₅₀ values determined in mammalian cells in culture and the LD₅₀ values reported in the literature from various laboratory species. Using this approach, the authors predicted (within a reasonable dose range) the acute oral LD₅₀ for 252 of 347 xenobiotics, and the intravenous LD₅₀ for rats and/or mice for 117 of 150 xenobiotics (Halle, 2003). Of course, such *in vitro* approaches do not fully account for dispositional effects that could result in large species differences in acute toxicity, but do provide a rapid first approximation of acute toxicity without the use of experimental animals.

If there is a reasonable likelihood of substantial exposure to the material by dermal or inhalation exposure, acute dermal and acute inhalation studies are performed. When animals are exposed acutely to chemicals in the air they breathe or the water they (fish) live in, the dose the animals receive is usually not known. For these situations, the lethal concentration 50 (LC₅₀) is usually determined, that is, the concentration of chemical in the air or water that causes death to 50% of the animals. In reporting an LC₅₀, it is imperative that the time of exposure be indicated. The acute dermal toxicity test is usually performed in rabbits. The site of application is shaved. The test substance is kept in contact with the skin for 24 hours by wrapping the skin with an impervious plastic material. At the end of the exposure period, the wrapping is removed and the skin is wiped to remove any test substance still remaining. Animals are observed at various intervals for 14 days, and the LD₅₀ is calculated. If no

toxicity is evident at 2 g/kg, further acute dermal toxicity testing is usually not performed. Acute inhalation studies are performed that are similar to other acute toxicity studies except that the route of exposure is inhalation. Most often, the length of exposure is 4 hours.

By themselves LD_{50} and LC_{50} values are of limited significance given the growing sophistication of target organ toxicity end points and mechanistic analysis. The most meaningful scientific information derived from acute toxicity tests comes from clinical observations and post-mortem examination of animals rather than from the specific LD_{50} value.

Skin and Eye Irritations

The ability of a chemical to irritate the skin and eye after an acute exposure is usually determined in rabbits. For the dermal irritation test (Draize test), rabbits are prepared by removal of fur on a section of the back by electric clippers. The chemical is applied to the skin (0.5 mL of liquid or 0.5 g of solid) under 4 covered gauze patches (1 in square; 1 intact and 2 abraded skin sites on each animal) and usually kept in contact for 4 hours. The nature of the covering patches depends on whether occlusive, semioclusive, or nonocclusive tests are desired. For occlusive testing, the test material is covered with an impervious plastic sheet; for semioclusive tests, a gauze dressing may be used. Occasionally, studies may require that the material be applied to abraded skin. The degree of skin irritation is scored for erythema (redness), eschar (scab), and edema (swelling) formation, and corrosive action. These dermal irritation observations are repeated at various intervals after the covered patch has been removed. To determine the degree of ocular irritation, the chemical is instilled into 1 eye (0.1 mL of liquid or 100 mg of solid) of each test rabbit. The contralateral eye is used as the control. The eyes of the rabbits are then examined at various times after application.

Controversy over this test has led to the development of alternative in vitro models for evaluating cutaneous and ocular toxicity of substances. The various in vitro methods that have been evaluated for this purpose include epidermal keratinocyte and corneal epithelial cell culture models. Several commercially available “reconstructed human epidermis” models have been developed explicitly for the purposes of in vitro skin irritation and corrosion tests (Netzlaff *et al.*, 2005).

Sensitization

Information about the potential of a chemical to sensitize skin is needed in addition to irritation testing for all materials that may repeatedly come into contact with the skin. Numerous procedures have been developed to determine the potential of substances to induce a sensitization reaction in humans (delayed hypersensitivity reaction), including the Draize test, the open epicutaneous test, the Buehler test, Freund’s complete adjuvant test, the optimization test, the split adjuvant test, and the guinea pig maximization test (Hayes *et al.*, 2008; Rush *et al.*, 1995). Although they differ in regard to route and frequency of duration, they all utilize the guinea pig as the preferred test species. In general, the test chemical is administered to the shaved skin topically, intradermally, or both and may include the use of adjuvant to enhance the sensitivity of the assay. Multiple administrations of the test substance are generally given over a period of 2 to 4 weeks. Depending on the specific protocol, the treated area may be occluded. Approximately 2 to 3 weeks after the last treatment, the animals are challenged with a nonirritating concentration of the test substance and the development of erythema is evaluated.

Subacute (Repeated-Dose Study)

Subacute toxicity tests are performed to obtain information on the toxicity of a chemical after repeated administration and as an aid to establish doses for subchronic studies. A typical protocol is to give 3 to 4 different dosages of the chemicals to the animals by mixing it in their feed. For rats, 10 animals per sex per dose are often used; for dogs, 3 dosages and 3 to 4 animals per sex are used. Clinical chemistry and histopathology are performed after either 14 or 28 days of exposure, as described in the section “Subchronic.”

Subchronic

The toxicity of a chemical after subchronic exposure is then determined. Subchronic exposure can last for different periods of time, but 90 days is the most common test duration. The principal goals of the subchronic study are to establish a NOAEL and to further identify and characterize the specific organ or organs affected by the test compound after repeated administration. One may also obtain a “lowest observed adverse effect level” (LOAEL) as well as the NOAEL for the species tested. The numbers obtained for NOAEL and LOAEL will depend on how closely the dosages are spaced and the number of animals examined. Determinations of NOAELs and LOAELs have numerous regulatory implications. For example, the EPA utilizes the NOAEL to calculate the *reference dose* (RfD), which may be used to establish regulatory values for “acceptable” pollutant levels (Barnes and Dourson, 1988) (see Chap. 4). An alternative to the NOAEL approach referred to as the *benchmark dose* uses all the experimental data to fit 1 or more dose–response curves (Crump, 1984). These curves are then used to estimate a benchmark dose that is defined as “the statistical lower bound on a dose corresponding to a specified level of risk” (Allen *et al.*, 1994a). Although subchronic studies are frequently the primary or sole source of experimental data to determine both the NOAEL and the benchmark dose, these concepts can be applied to other types of toxicity testing protocols, such as that for chronic toxicity or developmental toxicity (Allen *et al.*, 1994a,b; Faustman *et al.*, 1994) (see also Chap. 4 for a complete discussion of the derivation and use of NOAELs, RfDs, and benchmark doses). If chronic studies have been completed, these data are generally used for NOAEL and LOAEL estimates in preference to data from subchronic studies.

A subchronic study is usually conducted in 2 species (usually rat and dog for FDA, and mouse for EPA) by the route of intended exposure (usually oral). At least 3 doses are employed (a high dose that produces toxicity but does not cause more than 10% fatalities, a low dose that produces no apparent toxic effects, and an intermediate dose) with 10 to 20 rodents and 4 to 6 dogs of each sex per dose. Each animal should be uniquely identified with permanent markings such as ear tags, tattoos, or electronically coded microchip implants. Only healthy animals should be used, and each animal should be housed individually in an adequately controlled environment. When the test compound is administered in the diet over a prolonged period of time (subchronic and chronic studies), the concentration in the diet should be adjusted periodically (weekly for the first 12–14 weeks) to maintain a constant intake of material based on food consumption and rate of change in body weight (Wilson *et al.*, 2008). Animals should be observed once or twice daily for signs of toxicity, including changes in body weight, diet consumption, changes in fur color or texture, respiratory or cardiovascular distress, motor and behavioral abnormalities, and palpable masses. All premature deaths should be recorded and necropsied as soon as possible. Severely moribund animals should be terminated immediately to preserve tissues and reduce unnecessary suffering.

At the end of the 90-day study, all the remaining animals should be terminated and blood and tissues should be collected for further analysis. The gross and microscopic condition of the organs and tissues (about 15–20) and the weight of the major organs (about 12) are recorded and evaluated. Hematology and blood chemistry measurements are usually done before, in the middle of, and at the termination of exposure. Hematology measurements usually include hemoglobin concentration, hematocrit, erythrocyte counts, total and differential leukocyte counts, platelet count, clotting time, and prothrombin time. Clinical chemistry determinations commonly made include glucose, calcium, potassium, urea nitrogen, ALT, serum AST, gamma-glutamyltranspeptidase (GGT), sorbitol dehydrogenase, lactic dehydrogenase, alkaline phosphatase, creatinine, bilirubin, triglycerides, cholesterol, albumin, globulin, and total protein. Urinalysis is usually performed in the middle of and at the termination of the testing period and often includes determination of specific gravity or osmolarity, pH, proteins, glucose, ketones, bilirubin, and urobilinogen as well as microscopic examination of formed elements. If humans are likely to have significant exposure to the chemical by dermal contact or inhalation, subchronic dermal and/or inhalation experiments may also be required. Subchronic toxicity studies not only characterize the dose–response relationship of a test substance after repeated administration but also provide data for a more reasonable prediction of appropriate doses for chronic exposure studies.

For chemicals that are to be registered as drugs, acute and subchronic studies (and potentially additional special tests if a chemical has unusual toxic effects or therapeutic purposes) must be completed before the company can file an Investigational New Drug (IND) application with the FDA. If the application is approved, clinical trials can commence. At the same time phase I, phase II, and phase III clinical trials are performed, chronic exposure of the animals to the test compound can be carried out in laboratory animals, along with additional specialized tests.

Chronic

Long-term or chronic exposure studies are performed similarly to subchronic studies except that the period of exposure is longer than 3 months. In rodents, chronic exposures are usually for 6 months to 2 years. Chronic studies in nonrodent species are usually for 1 year but may be longer. The length of exposure is somewhat dependent on the intended period of exposure in humans. For example, for pharmaceuticals, the ICH S4 guidance calls for studies of 6 months in duration in rodents, and 9 months in nonrodents. However, if the chemical is a food additive with the potential for lifetime exposure in humans, a chronic study up to 2 years in duration is likely to be required.

Dose selection is critical in these studies to ensure that premature mortality from chronic toxicity does not limit the number of animals that survive to a normal life expectancy. Most regulatory guidelines require that the highest dose administered be the estimated maximum tolerable dose (MTD, also commonly referred to as the “minimally toxic dose”). This is generally derived from subchronic studies, but additional longer studies (eg, 6 months) may be necessary if delayed effects or extensive cumulative toxicity are indicated in the 90-day subchronic study. The MTD has had various definitions (Haseman, 1985). It has been defined by some regulatory agencies as the dose that suppresses body weight gain slightly (ie, 10%) in a 90-day subchronic study (Reno, 1997). However, regulatory agencies may also consider the use of parameters other than weight gain, such as physiological and pharmacokinetic considerations and urinary metabolite profiles, as indicators

of an appropriate MTD (Reno, 1997). Generally, 1 or 2 additional doses, usually fractions of the MTD (eg, one-half and one-quarter MTD), and a control group are tested.

Chronic toxicity tests may include a consideration of the carcinogenic potential of chemicals so that a separate lifetime feeding study that addresses carcinogenicity does not have to be performed. However, specific chronic studies designed to assess the carcinogenic potential of a substance may be required (see below).

Developmental and Reproductive Toxicity

The effects of chemicals on reproduction and development also need to be determined. *Developmental toxicology* is the study of adverse effects on the developing organism occurring anytime during the life span of the organism that may result from exposure to chemical or physical agents before conception (either parent), during prenatal development, or postnatally until the time of puberty. *Teratology* is the study of defects induced during development between conception and birth (see Chap. 10). *Reproductive toxicology* is the study of the occurrence of adverse effects on the male or female reproductive system that may result from exposure to chemical or physical agents (see Chap. 20).

Several types of animal tests are utilized to examine the potential of an agent to alter development and reproduction. (For a detailed description of reproductive and developmental toxicity testing procedures, see Christian [2008].) General fertility and reproductive performance (segment I) tests are usually performed in rats with 2 or 3 doses (20 rats per sex per dose) of the test chemical (neither produces maternal toxicity). Males are given the chemical 60 days and females 14 days before mating. The animals are given the chemical throughout gestation and lactation. Typical observations made include the percentage of females that become pregnant, the number of stillborn and live offspring, and the weight, growth, survival, and general condition of the offspring during the first 3 weeks of life.

The potential of chemicals to disrupt normal embryonic and/or fetal development (teratogenic effects) is also determined in laboratory animals. Current guidelines for these segment II studies call for the use of 2 species, including 1 nonrodent species (usually rabbits). Teratogens are most effective when administered during the first trimester, the period of organogenesis. Thus, the animals (usually 12 rabbits and 24 rats or mice per group) are usually exposed to 1 of 3 dosages during organogenesis (days 7–17 in rodents and 7–19 in rabbits), and the fetuses are removed by cesarean section a day before the estimated time of delivery (gestational days 29 for rabbit, 20 for rat, and 18 for mouse). The uterus is excised and weighed and then examined for the number of live, dead, and resorbed fetuses. Live fetuses are weighed; half of each litter is examined for skeletal abnormalities and the remaining half for soft tissue anomalies.

The perinatal and postnatal toxicities of chemicals also are often examined (segment III). This test is performed by administering the test compound to rats from the 15th day of gestation throughout delivery and lactation and determining its effect on the birth weight, survival, and growth of the offspring during the first 3 weeks of life.

In some instances a multigenerational study may be chosen, often in place of segment III studies, to determine the effects of chemicals on the reproductive system. At least 3 dosage levels are given to groups of 25 female and 25 male rats shortly after weaning (30–40 days of age). These rats are referred to as the F_0 generation. Dosing continues throughout breeding (about 140 days of age), gestation, and lactation. The offspring (F_1 generation) have

thus been exposed to the chemical in utero, via lactation, and in the feed thereafter. When the F_1 generation is about 140 days old, about 25 females and 25 males are bred to produce the F_2 generation, and administration of the chemical is continued. The F_2 generation is thus also exposed to the chemical in utero and via lactation. The F_1 and F_2 litters are examined as soon as possible after delivery. The percentage of F_0 and F_1 females that get pregnant, the number of pregnancies that go to full term, the litter size, the number of still-born, and the number of live births are recorded. Viability counts and pup weights are recorded at birth and at 4, 7, 14, and 21 days of age. The fertility index (percentage of mating resulting in pregnancy), gestation index (percentage of pregnancies resulting in live litters), viability index (percentage of animals that survive 4 days or longer), and lactation index (percentage of animals alive at 4 days that survived the 21-day lactation period) are then calculated. Gross necropsy and histopathology are performed on some of the parents (F_0 and F_1), with the greatest attention being paid to the reproductive organs, and gross necropsy is performed on all weanlings.

The International Conference on Harmonization (ICH) guidelines provide for flexible guidelines that address 6 “ICH stages” of development: premating and conception (stage A), conception to implantation (stage B), implantation to closure of the hard palate (stage C), closure of the hard palate to end of pregnancy (stage D), birth and weaning (stage E), and weaning to sexual maturity (stage F). All of these stages are covered in the segment I to segment III studies described above (Christian, 2008).

Numerous short-term tests for teratogenicity have been developed (Faustman, 1988). These tests utilize whole-embryo culture, organ culture, and primary and established cell cultures to examine developmental processes and estimate the potential teratogenic risks of chemicals. Many of these in utero test systems are under evaluation for use in screening new chemicals for teratogenic effects. These systems vary in their ability to identify specific teratogenic events and alterations in cell growth and differentiation. In general, the available assays cannot identify functional or behavioral teratogens (Faustman, 1988).

Mutagenicity

Mutagenesis is the ability of chemicals to cause changes in the genetic material in the nucleus of cells in ways that allow the changes to be transmitted during cell division. Mutations can occur in either of 2 cell types, with substantially different consequences. Germinal mutations damage DNA in sperm and ova, which can undergo meiotic division and therefore have the potential for transmission of the mutations to future generations. If mutations are present at the time of fertilization in either the egg or the sperm, the resulting combination of genetic material may not be viable, and the death may occur in the early stages of embryonic cell division. Alternatively, the mutation in the genetic material may not affect early embryogenesis but may result in the death of the fetus at a later developmental period, resulting in abortion. Congenital abnormalities may also result from mutations. Somatic mutations refer to mutations in all other cell types and are not heritable but may result in cell death or transmission of a genetic defect to other cells in the same tissue through mitotic division. Because the initiating event of chemical carcinogenesis is thought to be a mutagenic one, mutagenic tests are often used to screen for potential carcinogens.

Numerous in vivo and in vitro procedures have been devised to test chemicals for their ability to cause mutations. Some genetic alterations are visible with the light microscope. In this case, cytogenetic analysis of bone marrow smears is used after the animals have been exposed to the test agent. Because some mutations are

incompatible with normal development, the mutagenic potential of a chemical can also be evaluated by the dominant lethal test. This test is usually performed in rodents. The male is exposed to a single dose of the test compound and then is mated with 2 untreated females weekly for 8 weeks. The females are killed before term, and the number of live embryos and the number of corpora lutea are determined.

The test for mutagens that has received the widest attention is the *Salmonella*/microsome test developed by Ames *et al.* (1975). This test uses several mutant strains of *Salmonella typhimurium* that lack the enzyme phosphoribosyl ATP synthetase, which is required for histidine synthesis. These strains are unable to grow in a histidine-deficient medium unless a reverse or back mutation to the wild type has occurred. Other mutations in these bacteria have been introduced to enhance the sensitivity of the strains to mutagenesis. The 2 most significant additional mutations enhance penetration of substances into the bacteria and decrease the ability of the bacteria to repair DNA damage. Because many chemicals are not mutagenic or carcinogenic unless they are biotransformed to a toxic product by enzymes in the endoplasmic reticulum (microsomes), rat liver microsomes are usually added to the medium containing the mutant strain and the test chemical. The number of reverse mutations is then quantified by the number of bacterial colonies that grow in a histidine-deficient medium.

Strains of yeast have recently been developed that detect genetic alterations arising during cell division after exposure to nongenotoxic carcinogens as well as mutations that arise directly from genotoxic carcinogens. This test identifies deletions of genetic material that occur during recombination events in cell division that may result from oxidative damage to DNA, direct mutagenic effects, alterations in fidelity of DNA repair, and/or changes in cell cycle regulation (Galli and Schiestl, 1999). Mutagenicity is discussed in detail in Chap. 9.

With the advent of techniques that readily allow manipulation of the mouse genome, transgenic animals have been developed that allow for in vivo assessment of mutagenicity of compounds. For example, 2 commercially available mouse strains, the “MutaMouse” and “Big Blue,” contain the *lac* operon of *E. coli* that has been inserted into genomic DNA using a lambda phage to DNA to produce a recoverable shuttle vector. Stable, homozygous strains of these transgenic animals (both mice and rats have been engineered) can be exposed to potential mutagenic agents. Following in vivo exposure, the target *lac* genes can be recovered from virtually any cell type or organ and analyzed for mutations (Brusick *et al.*, 2008).

Oncogenicity Bioassays

Oncogenicity studies are both time consuming and expensive, and are usually only done when there is reason to suspect that a chemical may be carcinogenic, or when there may be wide spread, long-term exposures to humans (eg, widely used food additives, drinking water contaminants, or pharmaceuticals that are likely to be administered repeatedly for long periods of time). Chemicals that test positive in several mutagenicity assays are likely to be carcinogenic, and thus are frequent candidates for oncogenicity bioassay assessment. In the United States, the National Toxicology Program (NTP) has the primary responsibility for evaluating non-drug chemicals for carcinogenic potential. For pharmaceuticals, the FDA may require the manufacturer to conduct oncogenicity studies as part of the preclinical assessment, depending on the intended use of the drug, and the results of mutagenicity assays and other toxicological data.

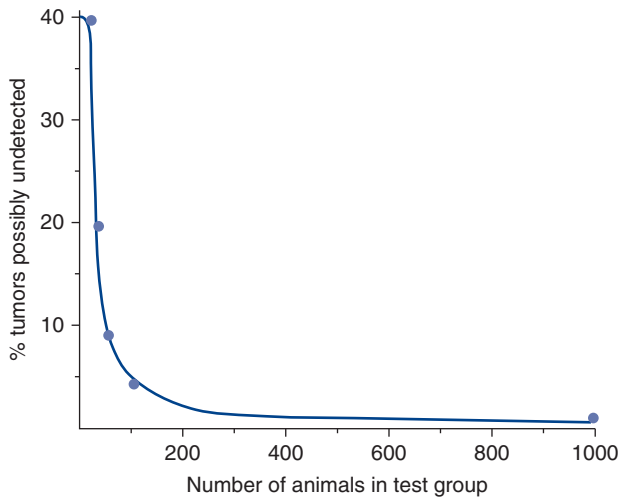

Figure 2-14. Statistical limitations in the power of experimental animal studies to detect tumorigenic effects.

Studies to evaluate the oncogenic (carcinogenic) potential of chemicals are usually performed in rats and mice and extend over the average lifetime of the species (18 months to 2 years for mice, 2–2.5 years for rats). To ensure that 30 rats per dose survive the 2-year study, 60 rats per group per sex are often started in the study. Both gross and microscopic pathological examinations are made not only on animals that survive the chronic exposure but also on those that die prematurely. The use of the MTD in carcinogenicity has been the subject of controversy. The premise that high doses are necessary for testing the carcinogenic potential of chemicals is derived from the statistical and experimental design limitations of chronic bioassays. Consider that a 0.5% increase in cancer incidence in the United States would result in over 1 million additional cancer deaths each year—clearly an unacceptably high risk. However, identifying with statistical confidence a 0.5% incidence of cancer in a group of experimental animals would require a minimum of 1000 test animals, and this assumes that no tumors were present in the absence of exposure (zero background incidence).

Fig. 2-14 shows the statistical relationship between minimum detectable tumor incidence and the number of test animals per group. This curve shows that in a chronic bioassay with 50 animals per test group, a tumor incidence of about 8% could exist even though no animals in the test group had tumors. This example assumes that there are no tumors in the control group. These statistical considerations illustrate why animals are tested at doses higher than those that occur in human exposure. Because it is impractical to use the large number of animals that would be required to test the potential carcinogenicity of a chemical at the doses usually encountered by people, the alternative is to assume that there is a relationship between the administered dose and the tumorigenic response and give animals doses of the chemical that are high enough to produce a measurable tumor response in a reasonable size test group, such as 40 to 50 animals per dose. The limitations of this approach are discussed in Chap. 4. For nonmutagenic pharmaceutical agents, ICH SIC provides the following guidance on dose selection for oncogenicity studies: “The doses selected for rodent bioassays for non-genotoxic pharmaceuticals should provide an exposure to the agent that (1) allow an adequate margin of safety over the human therapeutic exposure, (2) are tolerated without significant chronic physiological dysfunction and are compatible with good survival, (3) are guided by a comprehensive set of animal and human data that focus broadly on the properties of the agent and the suitability of the animal (4) and permit data interpretation in the context of clinical use.”

Another approach for establishing maximum doses for use in chronic animal toxicity testing of drugs is often used for substances for which basic human pharmacokinetic data are available (eg, new pharmaceutical agents that have completed phase I clinical trials). For chronic animal studies performed on drugs where single-dose human pharmacokinetic data are available, a daily dose that would provide an area under the curve (AUC) in laboratory animals equivalent to 25 times the AUC in humans given the highest (single) daily dose to be used therapeutically may be used, rather than the MTD. Based on a series of assumptions regarding allometric scaling between rodents and humans (Table 2-2), the ICH noted that it may not be necessary to exceed a dose of 1500 mg/kg per day where there is no evidence of genotoxicity, and where the maximum recommended human dose does not exceed 500 mg per day.

Most regulatory guidelines require that both benign and malignant tumors be reported in oncogenicity bioassays. Statistical increases above the control incidence of tumors (either all tumors or specific tumor types) in the treatment groups are considered indicative of carcinogenic potential of the chemical unless there are qualifying factors that suggest otherwise (lack of a dose response, unusually low incidence of tumors in the control group compared with “historic” controls, etc; Huff, 1999). Thus, the conclusion as to whether a given chronic bioassay is positive or negative for carcinogenic potential of the test substance requires careful consideration of background tumor incidence. Properly designed chronic oncogenicity studies require that a concurrent control group matched for variables such as age, diet, and housing conditions be used. For some tumor types, the “background” incidence of tumors is surprisingly high. Fig. 2-15 shows the background tumor incidence for

Figure 2-15. Most frequently occurring tumors in untreated control rats from recent NTP 2-year rodent carcinogenicity studies. The values shown represent the mean \pm SD of the percentage of animals developing the specified tumor type at the end of the 2-year study. The values were obtained from 27 different studies involving a combined total of between 1319 and 1353 animals per tumor type.

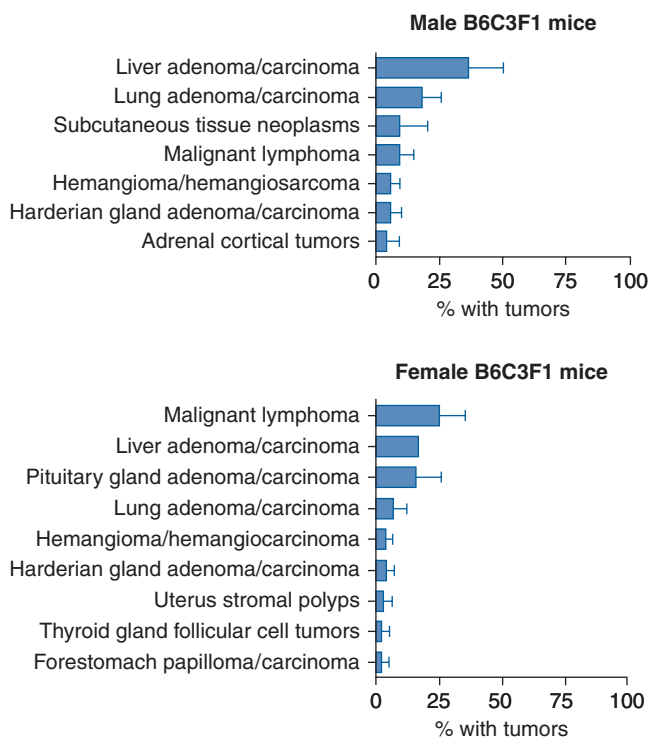

Figure 2-16. Most frequently occurring tumors in untreated control mice from recent NTP 2-year rodent carcinogenicity studies. The values shown represent the mean \pm SD of the percentage of animals developing the specified tumor type at the end of the 2-year study. The values were obtained from 30 different studies involving a total of between 1447 and 1474 animals per tumor type.

various tumors in male and female F344 rats used in 27 NTP 2-year rodent carcinogenicity studies. The data shown represent the percent of animals in control (nonexposed) groups that developed the specified tumor type by the end of the 2-year study. These studies involved more than 1300 rats of each sex. Fig. 2-16 shows similar data for control (nonexposed) male and female B6C3F1 mice from 30 recent NTP 2-year carcinogenicity studies and includes data from over 1400 mice of each sex. There are several key points that can be derived from these summary data:

1. Tumors, both benign and malignant, are not uncommon events in animals even in the absence of exposure to any known carcinogen.
2. There are numerous different tumor types that develop “spontaneously” in both sexes of both rats and mice, but at different rates.
3. Background tumors that are common in 1 species may be uncommon in another (eg, testicular interstitial cell adenomas are very common in male rats but rare in male mice; liver adenomas/carcinomas are about 10 times more prevalent in male mice than in male rats).
4. Even within the same species and strain, large gender differences in background tumor incidence are sometimes observed (eg, adrenal gland pheochromocytomas are about 7 times more prevalent in male F344 rats than in female F344 rats; lung and liver tumors are twice as prevalent in male B6C3F1 mice as in female B6C3F1 mice).
5. Even when the general protocols, diets, environment, strain and source of animals, and other variables are relatively constant, background tumor incidence can vary widely, as shown by the relatively large SDs for some tumor types in the NTP

bioassay program. For example, the range in liver adenoma/carcinoma incidence in 30 different groups of unexposed (control) male B6C3F1 mice went from a low of 10% to a high of 68%. Pituitary gland adenomas/carcinomas ranged from 12% to 60% and 30% to 76% in unexposed male and female F344 rats, respectively, and from 0% to 36% in unexposed female B6C3F1 mice.

Taken together, these data demonstrate the importance of including concurrent control animals in such studies. In addition, comparisons of the concurrent control results to “historic” controls accumulated over years of study may be important in identifying potentially spurious “false-positive” results. The relatively high variability in background tumor incidence among groups of healthy, highly inbred strains of animals maintained on nutritionally balanced and consistent diets in rather sterile environments highlights the dilemma in interpreting the significance of both positive and negative results in regard to the human population, which is genetically diverse, has tremendous variability in diet, nutritional status, and overall health, and lives in an environment full of potentially carcinogenic substances, both natural and human-made.

Finally, it should be noted that both inbred and outbred strains have distinct background tumor patterns and the NTP and most other testing programs select strains based on the particular needs of the agent under study. For example, the NTP used the Wistar rat for chemicals that may have the testis as a target organ, based on acute, subchronic, or other bioassay results. Similarly, the NTP used the Sprague–Dawley strain of rat in studies of estrogenic agents such as genistein because its mammary tumors are responsive to estrogenic stimulation, as are humans’.

Neurotoxicity Assessment

Neurotoxicity or a neurotoxic effect is defined as an adverse change in the chemistry, structure, or function of the nervous system following exposure to a chemical or physical agent. The structure, function, and development of the nervous system and its vulnerability to chemicals are examined in Chap. 16. When evaluating the potential neurological effects of a compound, effects may be on the central or peripheral nervous system or related to exposure that occurred during development or as an adult. The developing nervous system is particularly sensitive to chemical exposures (see Chap. 10).

In vitro systems often using cell culture techniques are a rapidly developing area of neurotoxicity assessment. Specific cell lines are available to examine effects on neuron or glial cells such as proliferation, migration, apoptosis, synaptogenesis, and other end points. In vitro assays have a number of potential advantages including minimizing the use of animal, lower costs, and adaptable to high-throughput screening. It is also possible to use an in vitro model to examine the interaction of chemicals, such as food additives, on neuronal cells (Lau *et al.*, 2006). The principles and challenges of in vitro neurotoxicity testing are well described (Claudio, 1992; Tiffany-Castiglioni, 2004).

Procedures for the neurobehavioral evaluation of animals were initially developed as part of the scientific investigation of behavioral motivation. Some of these procedures were then used to evaluate the neuropharmacological properties of new drugs. Now animals are commonly used to evaluate the neurotoxic properties of chemicals. A wide range of adult and developmental animal tests are used to access neurobehavioral function. In addition, neuropathological assessment is an important part of the neurotoxicity evaluation and

best practices have been developed for developmental neurotoxicity (DNT) (Bolon *et al.*, 2006). Irwin developed a basic screen for behavioral function in mice (Irwin, 1968), which was subsequently refined to the functional observational battery (FOB) (Moser, 2000). The FOB can also be used in the evaluation of drug safety (Redfern *et al.*, 2005).

The US EPA established a protocol for the evaluation of DNT in laboratory animals (US EPA 870.6300 and OECD 426) (EPA, 1998; OECD, 2004). These protocols include tests of neurobehavioral function, such as auditory startle, learning and memory function, changes in motor activity, and neuropathological examination and morphometric analysis. Methods and procedures for DNT evaluation are well established (Claudio *et al.*, 2000; Cory-Slechta *et al.*, 2001; Dorman *et al.*, 2001; Garman *et al.*, 2001; Mileson and Ferenc, 2001). Recent studies examine the neurotoxicity of multiple chemical exposures in animals (Moser *et al.*, 2006). Methods are also available to examine cognitive measures on weanling rodents in DNT studies (Ehman and Moser, 2006). Nonhuman primates have been invaluable in evaluating the effects of neurotoxicants and the risk assessment process (Burbacher and Grant, 2000). Sophisticated assessment of operant behavior, and learning and memory assessment of rodents, has been used to evaluate the effects of lead (Cory-Slechta, 1995, 1996, 2003). Monkeys can also be used to evaluate the low-level effects of neurotoxicants such as mercury on vision, auditory function, and vibration sensitivity (Burbacher *et al.*, 2005; Rice and Gilbert, 1982, 1992, 1995). There is remarkable concordance between human and animal neurotoxicity assessment, for example, in lead, mercury, and PCBs (Rice, 1995).

Human testing for the neurological effects of occupational exposures to chemicals (Anger, 2003; Farahat *et al.*, 2003; Kamel *et al.*, 2003; McCauley *et al.*, 2006), and even the neurotoxic effects of war (Binder *et al.*, 1999, 2001), is advancing rapidly. These methods have also been applied to Hispanic workers (Rohlman *et al.*, 2001b) and populations with limited education or literacy (Rohlman *et al.*, 2003). The WHO has also recommended a test battery for humans (Anger *et al.*, 2000). There are also neurobehavioral test batteries for assessing children (Rohlman *et al.*, 2001a). Evaluation of the childhood neurological effects of lead (Lanphear *et al.*, 2005; Needleman and Bellinger, 1991) and mercury (Myers *et al.*, 2000) has added enormously to our understanding of the health effects of these chemicals and to the methodology of human neurobehavioral testing.

In summary, the neurotoxicological evaluation is an important aspect of developing risk assessments for environmental chemicals and drugs.

Immunotoxicity Assessment

Under normal conditions, the immune system is responsible for host defense against pathogenic infections and certain cancers. However, environmental exposures can alter immune system development and/or function and lead to hypersensitivity, autoimmunity, or immunosuppression, the outcome of which may be expressed as a pathology in most any organ or tissue (see Chap. 12). Our understanding of the biological processes underlying immune system dysfunction remains incomplete. However, advances in molecular biology (including use of transgenic/knockout mice), analytic methods (including gene expression arrays and multiparameter flow cytometry), animal models (including adoptive transfers in immunocompromised mice and host resistance to viral, bacterial, or tumor cell challenge), and other methods are greatly advancing our knowledge.

From a toxicologist's perspective, evaluation of immune system toxicity represents special challenges. Development of hypersensitivity can take various forms, depending on the mechanism underlying the associated immune response, and standard assumptions regarding dose-response relationships may not necessarily apply. For example, a single or incidental exposure to beryllium has been associated with chronic beryllium disease in some individuals. We are only just beginning to understand the biological basis underlying such individual susceptibility. In the case of chronic beryllium disease, a genetic polymorphism in a gene involved in antigen recognition may be associated with increased susceptibility (see Bartell *et al.*, 2000). Although our ability to predict immunogenicity remains poor, research efforts are continuing to identify aspects of the chemical and the individual that confer immunogenicity and underlie hypersensitivity. For example, the increasing incidence of allergic asthma among preschool-age children in the United States since the 1980s may be associated with exposure to allergens (eg, dust mites, molds, and animal dander), genetic factors, and other factors in the in utero and postnatal environment (see Donovan and Finn, 1999; Armstrong *et al.*, 2005).

Immunosuppression is another form of immune system toxicity, which can result in a failure to respond to pathogenic infection, a prolonged infection period, or expression of a latent infection or cancer. Various chemicals have been associated with immunosuppression. Broad-spectrum and targeted immunosuppressive chemicals are designed and used therapeutically to reduce organ transplant rejection or suppress inflammation. However, a large number of chemicals have been associated with immunosuppression, including organochlorine pesticides, diethylstilbestrol, lead, and halogenated aromatic hydrocarbons (including TCDD), and exposures that occur during critical stages may present special risk to development (Holladay, 2005).

Autoimmunity is a specific immune system disorder in which components of the immune system attack normal (self) tissues. Cases of autoimmunity have been reported for a wide range of chemicals including therapeutic drugs, metals, pesticides, and solvents. As with other forms of immune system toxicity, autoimmunity can present in most any tissue.

Finally, new forms of immunotoxicity are appearing based on novel forms of clinical therapy and immunomodulation. These include the variously classified "tumor lysis syndromes" and "cytokine storms" that arise from massive cytokine dysregulation. A recent example involved 6 healthy volunteers who had enrolled in a phase I clinical trial in the United Kingdom who developed a severe cytokine response to an anti-CD28 monoclonal antibody leading to systemic organ failures (Bhagal and Combes, 2006). Such cases are stark reminders of the challenges we face in understanding how the immune system is regulated, developing reliable test systems for identifying such risks prior to human use, and developing safe means for testing these agents in humans.

As described in Chap. 12, current practice for evaluating potential toxic effects of xenobiotic exposures on the immune system involves a tiered approach to immunotoxicity screening (Luster *et al.*, 2003). This tiered approach is generally accepted worldwide in the registration of novel chemical and therapeutic products. Most recently, final guidance to the pharmaceutical industry was published in April 2006 by the ICH of Technical Requirements for Registration of Pharmaceuticals for Human Use (Table 2-3). This guidance, which applies to the nonclinical (animal) testing of human pharmaceuticals, is the accepted standard in the United States, EU, and Japan, and demonstrates the continued commitment by these regulatory bodies to understand the potential risks posed by novel therapeutics.

Tiered testing relies on the concept that standard toxicity studies can provide good evidence for immunotoxicity when considered with known biological properties of the chemical, including structural similarities to known immunomodulators, disposition, and other clinical information, such as increased occurrence of infections or tumors. Evaluation of hematological changes, including differential effects on white blood cells and immunoglobulin changes, and alterations in lymphoid organ weights or histology, can provide strong evidence of potential effects to the immune system. Should such evaluations indicate a potential effect on immune system function, more detailed evaluations may be considered, including the evaluation of functional effects (eg, T-cell-dependent antibody response or natural killer cell activity), flow cytometric immunophenotyping, or host resistance studies. Thus, as with other areas of toxicology, the evaluation of immune system toxicity requires the toxicologist to be vigilant in observing early indications from a variety of sources in developing a weight-of-evidence assessment regarding potential injury/dysfunction.

Other Descriptive Toxicity Tests

Most of the tests described above will be included in a “standard” toxicity testing protocol because they are required by the various regulatory agencies. Additional tests may be required or included in the protocol to provide information relating a special route of exposure, such as inhalation. Inhalation toxicity tests in animals usually are carried out in a dynamic (flowing) chamber rather than in static chambers to avoid particulate settling and exhaled gas complications. Such studies usually require special dispersing and analytic methodologies, depending on whether the agent to be tested is a gas, vapor, or aerosol; additional information on methods, concepts, and problems associated with inhalation toxicology is provided in Chaps. 15 and 28. The duration of exposure for inhalation toxicity tests can be acute, subchronic, or chronic, but acute studies are more common with inhalation toxicology. Other special types of animal toxicity tests include toxicokinetics (absorption, distribution, biotransformation, and excretion), the development of appropriate antidotes and treatment regimens for poisoning, and the development of analytic techniques to detect residues of chemicals in tissues and other biological materials.

TOXICOGENOMICS

In the past decade, numerous new genome-based technologies have become available that allow for the large-scale analysis of biological responses to external stimuli. Traditional scientific approaches to elucidate the biochemical and molecular effects of toxic substances focused largely on examining biochemical pathways that were logically connected to observed responses identified through gross pathology, histology, blood chemistry, or behavioral observations. Such “hypothesis-driven” research into understanding mechanism of action remains a mainstay of current scientific investigations in toxicology. However, technologies now available allow one to examine the entire “universe” of biological responses to a toxic substance (Fig. 2-17). These new “hypothesis-generating” technologies include genomics (characterization of much or all of the genome of an organism), transcriptomics (characterization of most or all of the messenger RNAs [mRNAs], or transcriptome, expressed in a given cell/tissue), proteomics (characterization of most or all of the proteins expressed in a given cell/tissue), and metabolomics (characterization of most or all of the small molecules in a cell or tissue, including substrates, products, and cofactors of enzyme reactions). Other “omics” approaches (eg, “lipidomics,”

“nutrigenomics”) are being devised to look broadly at the biological response of an organism to change. The integration of all of these levels of molecular function (genomics, transcriptomics, proteomics, metabolomics, etc) to the understanding of how a living organism functions at the cellular level is sometimes referred to as “systems biology” (Weston and Hood, 2004). Because each level of analysis generates a very large quantity of data, the collection, organization, evaluation, and statistical analysis is in itself an enormous undertaking. The field of “bioinformatics” has been developed to address the many computational and statistical challenges of “omics” data. In the field of toxicology, the term “toxicogenomics” is used to define the area of research that “combines transcript, protein and metabolite profiling with conventional toxicology to investigate the interaction between genes and environmental stress in disease causation” (Waters and Fostel, 2004). A conceptual model for how the various new “omics” technologies can be incorporated into toxicological evaluation is shown in Fig. 2-17.

Genomics

The genome of an organism represents the full complement of genes that are determined at fertilization by the combination of the parental DNA. Thus, each cell of an organism has the same genome, characterized by the nucleotide sequences inherited from its parents. The human genome consists of approximately 3 billion base pairs of deoxyribonucleotides. Within the human genome, there is, on average, about 0.1% variability in DNA sequence between any 2 individuals, and it is these differences that contribute to the uniqueness of each person. Most of this variability exists as “SNPs,” although larger segments of DNA may be variable between individuals, including the duplication or loss of entire genes. The identification of particular genetic variants, such as the GSTM1 polymorphism, which might contribute to interindividual differences in susceptibility to chemicals or other environmental factors discussed previously, represents a relatively new and growing area of study that aims to understand the complex interactions between the human genome and the environment (Costa and Eaton, 2006).

Although the genome provides the blueprint for biological function, in order for the genomic information to be utilized in a cell, it must be expressed. Expression of the genome occurs when the coding sequence of DNA is converted to mRNA. For any given cell, transcription of the genomic information contained in that cell is only partial. It is the differential expression of genes in a given cell that is largely responsible for the diverse function of the thousands of different cells, tissues, and organs that constitute an individual organism. Thus, understanding which genes are expressed in a given tissue, at what level, and how toxicants perturb the “transcriptome” is of great relevance to toxicology. In addition to coding for mRNAs that provide the blueprint for protein synthesis, genomic DNA also generates small interfering RNAs (siRNA, microRNAs) that are biologically active and can participate in the regulation of gene expression.

Epigenetics/Epigenomics

The expanding research into the relatively new field of epigenomics will have important implications for public health and toxicology. The concept of epigenetics, meaning something acting “above or in addition” to genes, was proposed many decades ago, although the application to the full genome (epigenomics) rather than to single or a few genes (epigenetics) is new. Conrad Hal Waddington first postulated in the 1930s that it was not just the genes that shaped development but also the environment that shapes the genes

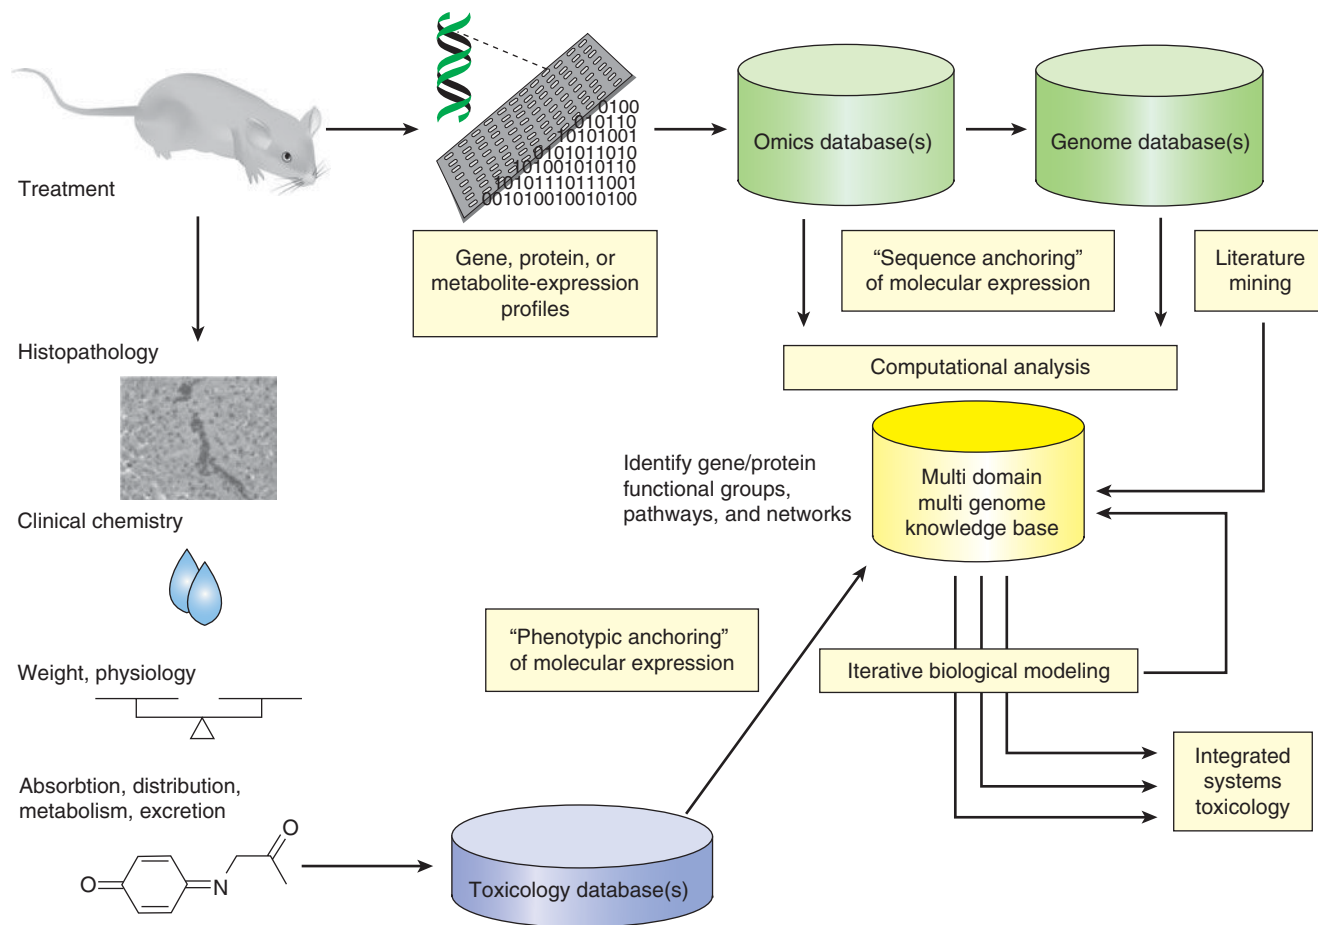

Figure 2-17. Conceptual approach for incorporating "omics" technologies and resulting large databases into toxicological evaluation. Data from experiments that evaluate the effects of a chemical on global patterns of gene expression (transcriptomics), protein content (proteomics), and small molecules/metabolites (metabonomics/metabolomics), combined with genomic information from both the test species (eg, rats, mice) and the target species of interest (eg, humans), are analyzed by computational tools (bioinformatics) for unique or potentially predictive patterns of toxicity. Essential to the use of omics data for predictive toxicology/safety assessment is the ability to reliably tie observed omics patterns to traditional measures of toxicity, such as histopathology and clinical chemistry (phenotypic anchoring). (From Waters and Fostel, 2004, with permission.)

(Holliday, 2006). Understanding a possible mechanism had to wait for a far deeper understanding of DNA and its role in development. Epigenetics has been defined in various ways, with perhaps the strictest definition being "a mitotically or meiotically heritable change in gene expression that occurs independently of an alteration in DNA sequence" (Youngson and Whitelaw, 2008). Typically gene expression is silenced or suppressed, or in some instances activated, by DNA methylation or histone deacetylation—changes that do not alter the nucleotide sequence of the silenced genes (Fig. 2-18). Epigenetic changes can potentially be transgenerational, as suggested in some animal models, which has important implications for toxicological assessment (Rosenfeld, 2010; Skinner, 2011). Given the growing recognition of epigenetics as a means by which environmental factors can alter biological responses, genomic analyses in toxicology may also include techniques to identify toxicant-induced changes in DNA methylation patterns (Watson and Goodman, 2002; LeBaron *et al.*, 2010).

Although classical approaches to toxicology have thoroughly documented the potential for a variety of environmental toxicants, such as thalidomide, alcohol, lead, mercury, and PCBs, to cause adverse effects on the developing organism, more subtle epigenetic changes, which are not associated with either cytotoxicity or mutations, can also result from environmental exposures and

thus may have important toxicological implications. Epigenetic changes have been demonstrated to occur from exposure to a variety of environmental hazards, including tobacco smoke, metals, alcohol, phthalates, and BPA (Cheng *et al.*, 2012; Perera and Herbstman, 2011; Bernal and Jirtle, 2010; Baccarelli and Bollati, 2009). Furthermore, epigenetic changes can occur through nutrition, methyl content of diet, intake of folic acid and vitamins, or even social and maternal behavior toward the offspring (Cummings *et al.*, 2010). Epigenetic changes have been causally implicated in cancer, neurodevelopment disorders, autoimmune diseases, diabetes and metabolic disorders, asthma, behavioral disorders, and endocrine disorders (Godfrey *et al.*, 2011; Nystrom and Mutanen, 2009; Zhang and Ho, 2011; Attig *et al.*, 2010). There is also concern chemicals in the environment may induce epigenetic changes in wildlife that could be an important consideration in ecotoxicology (Vandegheuchte and Janssen, 2011; Head *et al.*, 2012). Thus, epigenetic changes induced by xenobiotics, dietary factors, and maternal behavior have important implications for safety assessment and risk assessment for xenobiotics (LeBaron *et al.*, 2010; Goodman *et al.*, 2010; Szyf, 2007).

Thus, it is now evident that methylation of DNA is an important determinant of gene expression in cells and tissues, and exogenous chemicals can interfere with transcriptional function

Figure 2-18. Process and consequence of epigenetic regulation of gene expression (National Institute of Health).

via alternating DNA methylation (Watson and Goodman, 2002). Importantly, although such epigenetic changes do not result in the alteration of the genomic sequence, they theoretically can result in heritable phenotypic changes; although proof of multigenerational epigenetic changes from environmental exposures has yet to be demonstrated in humans (Baccarelli and Bollati, 2009), several animal models have demonstrated transgenerational epigenetic changes (Skinner, 2011). Thus, genomic analyses in toxicology may also include techniques to identify toxicant-induced changes in DNA methylation patterns to access epigenetic changes and the potential consequences (Watson and Goodman, 2002; Szyf, 2007).

Transcriptomics

Among the first changes that a cell will exhibit following exposure to a toxic substance is a change in gene expression. The transcriptome (all of the mature mRNA species present in a cell at a given point in time) is dynamic, and represents the steady state between the rate of synthesis (transcription) and degradation of mRNAs in a cell. Toxicologists have utilized the so-called Northern blot analysis to assess the level of expression of individual genes in cells or tissues for decades. The "reverse transcriptase polymerase chain reaction" (RT-PCR) allows one to quantitatively measure the relative number of mRNA species in a sample for specific genes. Using general primers, it is also possible to amplify the entire transcriptome quantitatively to make many complete copies of the transcriptome in a test tube. Thus, large amounts of material for analysis can be obtained from a relatively small number of cells. Finally,

using microarray technologies, where tens of thousands of unique oligonucleotides (or cDNAs) are anchored on a solid matrix, toxicologists can now quantitatively assess the expression of thousands of unique mRNAs in a single sample, thus capturing an "expression profile" of the entire transcriptome in 1 analysis.

There is great promise that gene expression profiles may be used to provide signatures of specific types of toxic responses, such as a cellular response to DNA damage or oxidative stress. There is also hope that such signature changes in gene expression could be used to facilitate more accurate cross-species extrapolation, allowing comparison of, for example, toxicant-induced changes in gene expression in rat hepatocytes with that of human hepatocytes under identical experimental conditions. However, 1 of the major challenges in toxicogenomics is the recognition that transcriptional regulation is highly dynamic, and that gene expression profiles can change dramatically with both dose and time. Because microarray experiments are relatively expensive and highly data intensive, it becomes both costly and challenging to conduct and analyze experiments with extensive dose and time course data (although costs are declining). Although changes in gene expression often contribute to, or are reflective of, phenotypic changes that occur in response to a toxic substance, the transcriptome is still somewhat far removed from the ultimate biochemical functions that dictate the actual biological function of the cell. Because the functional expression of a gene generally requires the translation of the mRNA to a protein, there is also great interest in looking at the "proteome"—the entire complement of *proteins* that are present in a cell or tissue at a given point in time.

Analysis of the proteome of a cell or tissue is much more difficult than analysis of the transcriptome, primarily because it is not yet possible to “amplify” the number of copies of proteins in a cell. Furthermore, unambiguous identification of specific proteins is much more difficult than that for individual mRNAs. Identification of specific proteins is generally done using a combination of separation techniques (eg, 2D gel electrophoresis, high-performance liquid chromatography), followed by tandem mass spectrometry for identification (Aebersold and Mann, 2003). Because of size limitations for accurate mass spectrometry, protein mixtures are usually digested to smaller peptide fragments. The mixture of peptide fragments is resolved into individual components, and the identity of the specific peptides is determined based on high-resolution mass analysis and sequential degradation (sequential loss of single amino acids) of the peptides by various means (Aebersold and Mann, 2003). The large and complex set of peptide mass fragments is then analyzed by computers and compared with a large database of mass fragments of known peptides/proteins. Because as few as 5 amino acid sequences may provide unique identification of a specific protein, the presence and relative abundance of specific proteins in a sample can then be reconstructed through bioinformatic analyses. As with transcriptomics, it is hoped that changes in protein expression can be used as specific biomarkers for particular types of toxic responses. Of course, such conceptual approaches have been used for years, for example, use of serum transaminase proteins as indicators of liver damage, or the presence of prostate-specific antigen (PSA) in serum as a potential biomarker of early stage prostate hyperplasia or cancer. The potential power of proteomics lies in the ability to identify unique patterns of protein expression, or identification of unique proteins or peptides, that are predictive of early toxic response or later development of disease.

Metabonomics/Metabolomics

These 2 terms are often used interchangeably to describe the analysis of the “universe” of small molecules that serve as substrates, products, and cofactors of the milieu of enzymatic reactions and other metabolic processes that define living cells, and thus the organism. Metabonomics has been defined as “the comprehensive and simultaneous systematic profiling of metabolite levels and their systematic and temporal change through such effects on diet, lifestyle, environment, genetic and pharmaceuticals, both beneficial and adverse, in whole organisms” (Lindon *et al.*, 2003, 2006). The term “metabolomics” has been used principally in studies in plants and in vitro or single-cell systems (Fiehn, 2002). Regardless of the specific term used (metabonomics will be used here), the concept of quantitatively analyzing toxicant-induced changes in the “metabolic profile” (the “metabonome”) of a cell, tissue, or body fluid in some ways represents the “Holy Grail” of toxicogenomics, because the changes in these small molecules must represent a biologically relevant integration of all of the molecular, biochemical, and cellular perturbations that lead to the development of toxicity (Fig. 2-17). In other words, changes in the metabonome should reflect the biologically relevant changes in gene transcription, translation, protein function, and other cellular processes, including temporal and adaptive responses, while ignoring biologically irrelevant changes in these factors. Although conceptually superior to either transcriptomics or proteomics for predictive toxicology, metabonomics lags significantly in technological development of readily accessible tools for thorough analysis of the metabonome.

Two approaches for identifying and measuring hundreds, or even thousands, of small molecules in biological samples have emerged—nuclear magnetic resonance (NMR) and mass spectrometry (Lindon *et al.*, 2003, 2006). Both have their advantages and limitations, and it is likely that the most successful approaches to applying metabonomics to toxicological problems will utilize both techniques (Pan and Raftery, 2007).

Bioinformatics

One feature in common among all of the various “omics” technologies is the ability to generate very large volumes of data (literally millions of data points from a single experiment). Both the data management and statistical evaluation of toxicogenomics studies represent an enormous challenge. The emerging field of bioinformatics has developed to address these challenges. Numerous commercial platforms for conducting microarray analysis of the transcriptome are available, and sophisticated software is available for both data management and analysis. One of the major challenges in statistical analysis of large data sets is the large number of “false positives” that will result from multiple comparisons. In a typical gene array experiment, it is not uncommon for an investigator to make >20,000 different comparisons. At the typical “95%” statistical confidence limit, one would expect more than 1000 of the noted differences to occur just by chance alone. Thus, more rigorous statistical methods have been developed to reduce the so-called false discovery rate in such experiments (Storey *et al.*, 2005; Gao, 2006).

Challenges in Using “Omics” Technologies for Predictive Toxicology and Risk Assessment

A conceptual framework for incorporating these new technologies into toxicology, sometimes referred to as “systems toxicology,” is shown in Fig. 2-18. Several key components of such an approach include: (1) large databases of treatment-specific information, such as results of transcriptomic, proteomic, and metabonomic analyses from target tissues and/or body fluids derived from toxicant-treated animals, (2) genomic databases that describe the DNA sequence information from the species of interest, (3) computational tools that extract information from these and other databases and the published literature to identify critical pathways and networks that are altered by the toxicant treatment, and (4) comparison with traditional toxicological end points to ensure that the observed “omics responses” are closely aligned with the toxicant-related pathophysiology in the animal (histopathology, clinical chemistry, etc)—a process called “phenotypic anchoring” (Waters and Fostel, 2004).

Toxicogenomics tools are becoming indispensable for research aimed at identifying the mechanisms and mode of action of toxic substances. However, the incorporation of such approaches into routine toxicity assessment presents numerous challenges. Numerous working group reports and publications have addressed the challenges of incorporating toxicogenomics data into predictive toxicology and risk assessment (Bammler *et al.*, 2005; Maggioli *et al.*, 2006; Boverhof and Zacharewski, 2006).

One of the major challenges to incorporating toxicogenomic data into risk assessment is related to the highly dynamic processes that preceded an observed toxic response. Traditional measure of toxicity, such as histopathological changes in a tissue, tends to be stable or even irreversible, whereas the myriad of molecular, biochemical, and cellular changes that give rise to the toxic response(s) are highly dynamic, frequently changing by the hour. Thus, the

profiles of mRNAs, proteins, and/or metabolites captured at a single point in time may be dramatically different, depending on the specific point in time the sample was collected. Many of the observed changes may be the result of direct effects of the toxicant on specific targets, whereas others will be compensatory or feedback mechanisms invoked in response to the initial damage. Nevertheless, patterns of change in transcript, protein, and/or metabolite profiles are likely to provide informative “signatures” of toxic response that will be of great value in predictive toxicology. Such approaches may be particularly useful in pharmaceutical development, where toxicogenomic profiles may help to accelerate preclinical evaluation of drug candidates by identifying “class prediction” profiles indicative of certain types of desirable (pharmacological efficacy) as well as adverse (eg, DNA damage, oxidative stress) responses.

Finally, it is likely that the introduction of omics technologies to toxicity testing will eventually contribute to the reduction, refinement, and replacement (the “3Rs”) of animals in toxicity testing and product safety evaluations (Kroeger, 2006).

3 chapter

Mechanisms of Toxicity

Zoltán Gregus

Step 1—Delivery: From the Site of Exposure to the Target

Absorption versus Presystemic Elimination

Absorption

Presystemic Elimination

Distribution To and Away from the Target

Mechanisms Facilitating Distribution to a Target

Mechanisms Opposing Distribution to a Target

Excretion versus Reabsorption

Excretion

Reabsorption

Toxication versus Detoxication

Toxication

Detoxication

Step 2—Reaction of the Ultimate Toxicant with the Target Molecule

Attributes of Target Molecules

Types of Reactions

Noncovalent Binding

Covalent Binding

Hydrogen Abstraction

Electron Transfer

Enzymatic Reactions

Effects of Toxicants on

Target Molecules

Dysfunction of Target Molecules

Destruction of Target Molecules

Neoantigen Formation

Toxicity Not Initiated by Reaction with Target Molecules

Step 3—Cellular Dysfunction and Resultant Toxicities

Toxicant-Induced Cellular

Dysregulation

Dysregulation of Gene Expression

Dysregulation of Ongoing

Cellular Activity

Toxic Alteration of Cellular

Maintenance

Impairment of Internal Cellular

Maintenance: Mechanisms of

Toxic Cell Death

Impairment of External Cellular

Maintenance

Step 4—Inappropriate Repair and Adaptation

Mechanisms of Repair

Molecular Repair

Cellular Repair

Tissue Repair

Mechanisms of Adaptation

Adaptation by Decreasing Delivery to the Target

Adaptation by Decreasing the Target Density or Responsiveness

Adaptation by Increasing Repair

Adaptation by Compensating

Dysfunction

When Repair and Adaptation Fail

When Repair Fails

When Adaptation Fails

Toxicity Resulting from

Inappropriate Repair and Adaptation

Tissue Necrosis

Fibrosis

Carcinogenesis

Conclusions

Depending primarily on the degree and route of exposure, chemicals may adversely affect the function and/or structure of living organisms. The qualitative and quantitative characterization of these harmful or toxic effects is essential for an evaluation of the potential hazard posed by a particular chemical. It is also valuable to understand the mechanisms responsible for the manifestation of toxicity—that is, how a toxicant enters an organism, how it interacts with target molecules, and how the organism deals with the insult.

An understanding of the mechanisms of toxicity is of both practical and theoretical importance. Such information provides a rational basis for interpreting descriptive toxicity data, estimating the probability that a chemical will cause harmful effects, establishing procedures to prevent or antagonize the toxic effects, designing drugs and industrial chemicals that are less hazardous, and developing pesticides that are more selectively toxic for their target organisms. Elucidation of the mechanisms of chemical toxicity has led to a better understanding of fundamental physiologic and biochemical processes ranging from neurotransmission (eg, curare-type arrow poisons) through deoxyribonucleic acid (DNA)

repair (eg, alkylating agents) to transcription, translation, and signal transduction pathways (eg, chemicals acting through transcription factors [TFs], such as the aryl hydrocarbon receptor [AhR]). Pathologic conditions such as cancer and Parkinson disease are better understood because of studies on the mechanism of toxicity of chemical carcinogens and 1,2,3,6-tetrahydro-1-methyl-4-phenylpyridine (MPTP), respectively. Continued research on mechanisms of toxicity will undoubtedly continue to provide such insights.

This chapter reviews the cellular mechanisms that contribute to the manifestation of toxicities. Although such mechanisms are also dealt with elsewhere in this volume, they are discussed in detail in this chapter in an integrated and comprehensive manner. We provide an overview of the mechanisms of chemical toxicity by relating a series of events that begins with exposure, involves a multitude of interactions between the invading toxicant and the organism, and culminates in a toxic effect. This chapter focuses on mechanisms that have been identified definitively or tentatively in humans or animals.

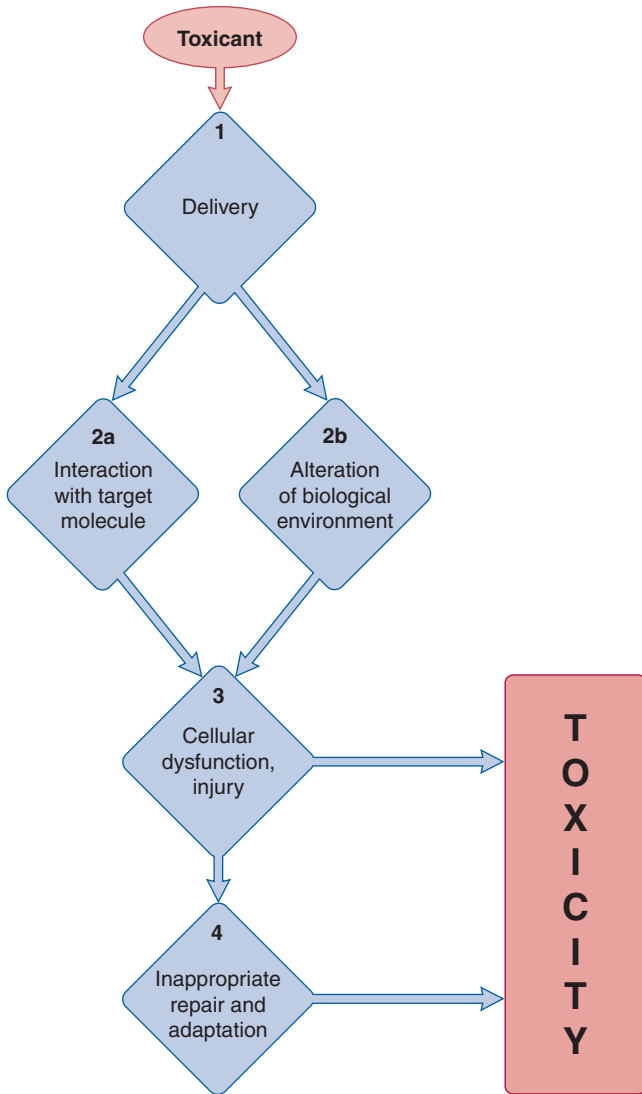

Figure 3-1. Potential stages in the development of toxicity after chemical exposure.

As a result of the huge number of potential toxicants and the multitude of biological structures and processes that can be impaired, there are a tremendous number of possible toxic effects. Correspondingly, there are various pathways that may lead to toxicity (Fig. 3-1). A common course is when a toxicant delivered to its target reacts with it, and the resultant cellular dysfunction manifests itself in toxicity. An example of this route to toxicity is that taken by the puffer fish poison, tetrodotoxin. After ingestion, this poison reaches the voltage-gated Na^+ channels of neurons (step 1). Interaction of tetrodotoxin with this target (step 2a) results in blockade of Na^+ channels, inhibition of the activity of motor neurons (step 3), and ultimately skeletal muscle paralysis. No repair mechanisms can prevent the onset of such toxicity.

Sometimes a xenobiotic does not react with a specific target molecule but rather adversely influences the biological (micro) environment, causing molecular, organellar, cellular, or organ dysfunction leading to deleterious effects. For example, 2,4-dinitrophenol, after entering the mitochondrial matrix space (step 1), collapses the outwardly directed proton gradient across the inner membrane by its mere presence there (step 2b), causing mitochondrial dysfunction (step 3), which is manifest in toxic

effects such as hyperthermia and seizures. Chemicals that precipitate in renal tubules and block urine formation represent another example for such a course (step 2b).

The most complex path to toxicity involves more steps (Fig. 3-1). First, the toxicant is delivered to its target or targets (step 1), after which the ultimate toxicant interacts with endogenous target molecules (step 2a), triggering perturbations in cell function and/or structure (step 3), which initiate repair mechanisms at the molecular, cellular, and/or tissue levels as well as adaptive mechanisms to diminish delivery, boost repair capacity, and/or compensate for dysfunction (step 4). When the perturbations induced by the toxicant exceed repair and adaptive capacity or when repair and adaptation becomes malfunctional, toxicity occurs. Tissue necrosis, cancer, and fibrosis are examples of chemically induced toxicities whose development follow this 4-step course.

STEP 1—DELIVERY: FROM THE SITE OF EXPOSURE TO THE TARGET

Theoretically, the intensity of a toxic effect depends primarily on the concentration and persistence of the ultimate toxicant at its site of action. The ultimate toxicant is the chemical species that reacts with the endogenous target molecule (eg, receptor, enzyme, DNA, microfilamental protein, lipid) or critically alters the biological (micro) environment, initiating structural and/or functional alterations that result in toxicity. Often the ultimate toxicant is the original chemical to which the organism is exposed (parent compound). In other cases, the ultimate toxicant is a metabolite of the parent compound or a reactive oxygen or nitrogen species (ROS or RNS) generated during the biotransformation of the toxicant. Occasionally, the ultimate toxicant is an unchanged or altered endogenous molecule (Table 3-1).

The concentration of the ultimate toxicant at the target molecule depends on the relative effectiveness of the processes that increase or decrease its concentration at the target site (Fig. 3-2). The accumulation of the ultimate toxicant at its target is facilitated by its absorption, distribution to the site of action, reabsorption, and toxication (metabolic activation). Conversely, presystemic elimination, distribution away from the site of action, excretion, and detoxication oppose these processes and work against the accumulation of the ultimate toxicant at the target molecule.

Absorption versus Presystemic Elimination

Absorption Absorption is the transfer of a chemical from the site of exposure, usually an external or internal body surface (eg, skin, mucosa of the alimentary and respiratory tracts), into the systemic circulation. Whereas transporters may contribute to the gastrointestinal (GI) absorption of some chemicals (eg, salicylate and valproate by monocarboxylate transporters, some β -lactam antibiotics and ACE inhibitor drugs by peptide transporters (PEPT), Fe^{2+} , Cd^{2+} , as well as some other divalent metal ions by the divalent metal ion transporter, and arsenate by phosphate transporters), the vast majority of toxicants traverse epithelial barriers and reach the blood capillaries by diffusing through cells. The rate of absorption is related to the concentration of the chemical at the absorbing surface, which depends on the rate of exposure and the dissolution of the chemical. It is also related to the area of the exposed site, the characteristics of the epithelial layer through which absorption takes place (eg, the thickness of the stratum corneum in the skin), the intensity of the subepithelial microcirculation, and the physicochemical properties of the toxicant. Lipid solubility is usually the most important

Table 3-1

Types of Ultimate Toxicants and Their Sources

Parent xenobiotics as ultimate toxicants

Pb ions
Tetrodotoxin
TCDD
Methylisocyanate
HCN
CO

Xenobiotic metabolites as ultimate toxicants

Amygdalin	→	HCN
Arsenate	→	Arsenite
Fluoroacetate	→	Fluorocitrate
Ethylene glycol	→	Oxalic acid
Hexane	→	2,5-Hexanedione
Acetaminophen	→	<i>N</i> -Acetyl- <i>p</i> -benzoquinoneimine
CCl ₄	→	CCl ₃ OO•
Benzo[<i>a</i>]pyrene (BP)	→	BP-7,8-diol-9,10-epoxide
Benzo[<i>a</i>]pyrene (BP)	→	BP-radical cation

Reactive oxygen or nitrogen species as ultimate toxicants

Hydrogen peroxide	}	→ Hydroxyl radical (HO•)
Diquat, doxorubicin, nitrofurantion		
Cr(V), Fe(II), Mn(II), Ni(II)		
Paraquat → O ₂ ⁺ + NO•		→ Peroxynitrite (ONOO ⁻)

Endogenous compounds as ultimate toxicants

Sulfonamides → albumin-bound bilirubin	→	Bilirubin
CCl ₃ OO• → unsaturated fatty acids	→	Lipid peroxy radicals
CCl ₃ OO• → unsaturated fatty acids	→	Lipid alkoxy radicals
CCl ₃ OO• → unsaturated fatty acids	→	4-Hydroxynon-2-enal
HO• → proteins	→	Protein carbonyls

property influencing absorption. In general, lipid-soluble chemicals are absorbed more readily than are water-soluble substances.

Presystemic Elimination During transfer from the site of exposure to the systemic circulation, toxicants may be eliminated. This is not unusual for chemicals absorbed from the GI tract because they must first pass through the GI mucosal cells, liver, and lung before being distributed to the rest of the body by the systemic circulation. The GI mucosa and the liver may eliminate a significant fraction of a toxicant during its passage through these tissues, decreasing its systemic availability. For example, ethanol is oxidized by alcohol dehydrogenase in the gastric mucosa (Lim *et al.*, 1993), cyclosporine is returned from the enterocyte into the intestinal lumen by multidrug resistance protein (MDR1, also known as P-glycoprotein, an ATP-dependent xenobiotic transporter) and is also hydroxylated by cytochrome P450 (CYP3A4) in these cells (Lin *et al.*, 1999), morphine is glucuronidated in intestinal mucosa and liver, and manganese is taken up from the portal blood into liver and excreted into bile. Such processes may prevent a considerable quantity of chemicals from reaching the systemic blood. Thus, presystemic or first-pass elimination reduces the toxic effects of chemicals that reach their target sites by way of the systemic circulation. In contrast, the processes involved in presystemic elimination may contribute to injury of the digestive mucosa, liver, and lungs by chemicals such as ethanol, iron salts, α -amanitin, and paraquat because these processes promote their delivery to those sites.

Distribution To and Away from the Target

Toxicants exit the blood during the distribution phase, enter the extracellular space, and may penetrate into cells. Chemicals dissolved in plasma water may diffuse through the capillary endothelium via aqueous intercellular spaces and transcellular pores called fenestrae and/or across the cell membrane. Lipid-soluble compounds move readily into cells by diffusion. In contrast, highly ionized and hydrophilic xenobiotics (eg, tubocurarine and aminoglycosides) are largely restricted to the extracellular space unless specialized membrane carrier systems are available to transport them.

During distribution, toxicants reach their site or sites of action, usually a macromolecule on either the surface or the interior of a particular type of cell. Chemicals also may be distributed to the site or sites of toxication, usually an intracellular enzyme, where the ultimate toxicant is formed. Some mechanisms facilitate, whereas others delay, the distribution of toxicants to their targets.

Mechanisms Facilitating Distribution to a Target Distribution of toxicants to specific target sites may be enhanced by (1) the porosity of the capillary endothelium, (2) specialized membrane transport, (3) accumulation in cell organelles, and (4) reversible intracellular binding.

Porosity of the Capillary Endothelium Endothelial cells in the hepatic sinusoids and in the renal peritubular capillaries have larger

Figure 3-2. The process of toxicant delivery is the first step in the development of toxicity.

fenestrae (50–150 nm in diameter) that permit passage of even protein-bound xenobiotics. This favors the accumulation of chemicals in the liver and kidneys.

Specialized Transport Across the Plasma Membrane

Specialized ion channels and membrane transporters can contribute to the delivery of toxicants to intracellular targets. For example, aquaglyceroporin channels may mediate influx of arsenite, which is present at physiologic pH as uncharged $\text{As}(\text{OH})_3$, voltage-gated Ca^{2+} channels permit the entry of cations such as lead or barium ions into excitable cells, and Na^+, K^+ -ATPase promotes intracellular accumulation of thallosium ion. By mimicking Na^+ , Li^+ may enter excitable cells through voltage-gated Na^+ channels and, from the tubular fluid, into the principal cells of the renal collecting duct via the epithelial Na^+ channels. Paraquat enters into pneumocytes via hitherto unspecified transporters and an MPTP metabolite (MPP^+) is taken up into extrapyramidal dopaminergic neurons by the dopamine transporter. Organic cation transporters (OCT) mediate the uptake of small-molecular-weight organic cations (eg, metformin, cimetidine, and cisplatin) from blood into liver cells (by OCT1) and into renal proximal tubular cells (by OCT2). The hepatocellular uptake of α -amanitin is mediated by the Na-dependent bile acid transporter (NTCP). Specific organic anion-transporting polypeptide (OATP) transporters mediate the hepatic uptake and hepatotoxicity of microcystin, a cyclic heptapeptide toxin produced by blue-green algae. In mice, *Oatp1b2* (the rodent ortholog of OATP1B1/1B3) is essential, as *Oatp1b2*-null mice are resistant to microcystin-induced liver injury (Lu *et al.*, 2008). Organic anion transporters such as human OAT1 and OAT3 mediate renal tubular uptake of ochratoxin and mercuric ion (the latter as the

dicysteine conjugate Cys-Hg-Cys), whereas both OAT1 and amino acid transporters can carry methylmercury as its cysteine conjugate $\text{CH}_3\text{-Hg-Cys}$, and an MPTP metabolite (MPP^+) enters into extrapyramidal dopaminergic neurons by means of the dopamine transporter. Endocytosis of some toxicant-protein complexes, such as Cd-metallothionein (MT) or hydrocarbons bound to the male rat-specific α_{2u} -globulin, by renal proximal tubular cells can also occur. Particles, such as asbestos and manufactured nanomaterial, may also enter cells by endocytosis, depending on their size and shape. Lipoprotein receptor-mediated endocytosis contributes to entry of lipoprotein-bound toxicants into cells equipped with such transporters. Membrane recycling can internalize cationic aminoglycosides associated with anionic phospholipids in the brush border membrane of renal tubular cells (Laurent *et al.*, 1990). This process may also contribute to cellular uptake of heavy metal ions. Such uptake mechanisms facilitate the entry of toxicants into specific cells, rendering those cells targets. Thus, carrier-mediated uptake of paraquat by pneumocytes and internalization of aminoglycosides by renal proximal tubular cells expose those cells to toxic concentrations of those chemicals.

Accumulation in Cell Organelles Amphipathic xenobiotics with a protonable amine group and lipophilic character accumulate in lysosomes as well as mitochondria and cause adverse effects there. Lysosomal accumulation occurs by pH trapping, that is, diffusion of the amine (eg, amiodarone, amitriptyline, fluoxetine) in unprotonated form into the acidic interior of the organelle, where the amine is protonated, preventing its efflux. The entrapped amine inhibits lysosomal phospholipases, impairing degradation of lysosomal phospholipids and causing phospholipidosis. Mitochondrial accumulation takes place electrophoretically. The amine is protonated in the intermembrane space (to where the mitochondria eject protons). The cation thus formed will then be sucked into the matrix space by the strong negative potential there (-220 mV), where it may impair β -oxidation and oxidative phosphorylation. By such mechanisms, the valued antiarrhythmic drug amiodarone is entrapped in the hepatic lysosomes and mitochondria, causing phospholipidosis (Kodavanti and Mehendale, 1990) and microvesicular steatosis with other liver lesions (Fromenty and Pessayre, 1997), respectively. The cationic metabolite of MPTP (MPP^+) also electrophoretically accumulates in the mitochondria of dopaminergic neurons, causing mitochondrial dysfunction and cell death, whereas highly lipophilic local anesthetics (eg, tetracaine, bupivacaine), when overdosed or inadvertently injected into a blood vessel, accumulate in cardiac mitochondria, compromising mitochondrial energy production and causing cardiac failure. Human equilibrative nucleoside transporter 1 (ENT1) in the mitochondrial inner membrane appears responsible for targeting fialuridine (an already withdrawn thymidine nucleoside analogue antiviral drug) into human mitochondria, where it inhibits mitochondrial DNA synthesis, thereby inducing hepatotoxicity. The fact that ENT1 is not localized in rodent mitochondria may account for the dramatic difference in mitochondrial toxicity of fialuridine between humans and rodents (Lee *et al.*, 2006).

Reversible Intracellular Binding Binding to the pigment melanin, an intracellular polyanionic aromatic polymer, is a mechanism by which chemicals, such as organic and inorganic cations and polycyclic aromatic hydrocarbons, can accumulate in melanin-containing cells in retina, substantia nigra, and skin (Larsson, 1993). The release of melanin-bound toxicants is thought to contribute to the retinal toxicity associated with chlorpromazine and chloroquine, injury to substantia nigra neurons by MPTP and manganese, and the induction of melanoma by polycyclic aromatics.

Keratins are the major structural proteins in the epidermis and its appendages (nail and hair), constituting up to 85% of fully differentiated keratinocytes (skin cells). As keratins are abundant in cysteine residues, they can sequester thiol-reactive metal ions and metalloids, whose nail and hair contents are indicative of exposure. Release of keratin-bound arsenic in keratinocytes may adversely affect these cells, leading to dermal lesions common in arsenicism.

Mechanisms Opposing Distribution to a Target Distribution of toxicants to specific sites may be hindered by several processes. The processes include (1) binding to plasma proteins, (2) specialized barriers, (3) distribution to storage sites such as adipose tissue, (4) association with intracellular binding proteins, and (5) export from cells.

Binding to Plasma Proteins As long as xenobiotics such as DDT (an insecticide) and TCDD (often called dioxin, an environmental pollutant) are bound to high-molecular-weight proteins or lipoproteins in plasma, they cannot leave the capillaries by diffusion. Even if they exit the bloodstream through fenestrae, they have difficulty permeating cell membranes. Dissociation from proteins is required for most xenobiotics to leave the blood and enter cells. Therefore, strong binding to plasma proteins delays and prolongs the effects and elimination of toxicants.

Specialized Barriers Brain capillaries have very low aqueous porosity because their endothelial cells lack fenestrae and are joined by extremely tight junctions. This blood–brain barrier prevents the access of hydrophilic chemicals to the brain except for those that can be actively transported. In the choroid plexus, where the capillaries are fenestrated, the choroidal epithelial cells are sealed together by tight junctions, forming the blood–cerebrospinal fluid barrier. Water-soluble toxicants also have restricted access to reproductive cells, which are separated from capillaries by other cells. The oocyte in the ovary is surrounded by multiple layers of granulosa cells, and the spermatogenic cells are supported by Sertoli cells that are tightly joined in the seminiferous tubules to form the blood–testis barrier (see Chap. 20). Transfer of hydrophilic toxicants across the placenta is also restricted. However, none of these barriers are effective against lipophilic substances.

Distribution to Storage Sites Some chemicals accumulate in tissues (ie, storage sites) where they do not exert significant effects. For example, highly lipophilic substances such as chlorinated hydrocarbon insecticides concentrate in adipocytes, whereas lead is deposited in bone by substituting for Ca^{2+} in hydroxyapatite. Such storage decreases the availability of these toxicants for their target sites and acts as a temporary protective mechanism. However, insecticides may return to the circulation and be distributed to their target site, the nervous tissue, when there is a rapid lipid loss as a result of fasting. This contributes to the lethality of pesticide-exposed birds during migration or during the winter months, when food is restricted. The possibility that lead is mobilized from the bone during pregnancy is of concern.

Association with Intracellular Binding Proteins Binding to nontarget intracellular sites also reduces the concentration of toxicants at the target site, at least temporarily. MT, a cysteine-rich cytoplasmic protein, serves such a function in acute cadmium intoxication (Klaassen *et al.*, 1999).

Export from Cells Intracellular toxicants may be transported back into the extracellular space. This occurs in brain capillary endothelial cells. In their luminal membrane, these cells contain

ATP-dependent membrane transporters (ATP-binding cassette [ABC] transporters) such as the MDR1, or P-glycoprotein, which extrudes chemicals and contributes to the blood–brain barrier (Schinkel, 1999). Compared with normal mice, mice with disrupted *mdr1a* gene exhibit 100-fold higher brain levels of and sensitivity to ivermectin, a neurotoxic pesticide and human antihelmintic drug that is one of many P-glycoprotein substrates (Schinkel, 1999). The oocyte is also equipped with P-glycoprotein that provides protection against chemicals that are substrates for this efflux pump (Elbling *et al.*, 1993). Hematopoietic stem cells (and perhaps other stem cells) are also protected by ABC transporters, such as MDR1, MRP1, and breast cancer resistance protein (BCRP), of which the latter confers these cells resistance to mitoxantrone. ABC transporters that export drugs were first identified in tumor cells that often overexpress them, thereby making these cells resistant to antitumor drugs these transporters pump out (see Chap. 5).

Excretion versus Reabsorption

Excretion Excretion is the removal of xenobiotics from the blood and their return to the external environment. It is a physical mechanism, whereas biotransformation is a chemical mechanism for eliminating the toxicant.

For nonvolatile chemicals, the major excretory structures in the body are the renal glomeruli, which hydrostatically filter small molecules (<60 kDa) through their pores, and the proximal renal tubular cells and hepatocytes, which actively transport chemicals from the blood into the renal tubules and bile canaliculi, respectively. These cells are readily exposed to blood-borne chemicals through the large endothelial fenestrae; they have transporters of the solute carrier (SLC) family (eg, OAT, OCT, and OATP type) that mediate the basolateral uptake of particular chemicals and transporters of the ABC carrier family (eg, MRP and MDR type) that mediate the luminal export of certain chemicals (see Chap. 5). Renal transporters have a preferential affinity for smaller (<300 Da), and hepatic transporters for larger (>400 Da) amphiphilic molecules. A less common “excretory” mechanism consists of diffusion and partition into the excreta on the basis of their lipid content (see below) or acidity. For example, morphine is transferred into milk and amphetamine is transferred into gastric juice by nonionic diffusion. This is facilitated by pH trapping of those organic bases in those fluids, which are acidic relative to plasma (see Chap. 5).

The route and speed of excretion depend largely on the physicochemical properties of the toxicant. The major excretory organs—kidney and liver—can efficiently remove only highly hydrophilic, usually ionized chemicals such as organic acids and bases. The reasons for this are as follows: (1) in the renal glomeruli, only compounds dissolved in plasma water can be filtered; (2) transporters in hepatocytes and renal proximal tubular cells are specialized for secretion of highly hydrophilic organic acids and bases; (3) only hydrophilic chemicals are freely soluble in the aqueous urine and bile; and (4) lipid-soluble compounds are readily reabsorbed by transcellular diffusion.

There are no efficient elimination mechanisms for nonvolatile, highly lipophilic chemicals such as polyhalogenated biphenyls and chlorinated hydrocarbon insecticides. If they are resistant to biotransformation, such chemicals are eliminated very slowly and tend to accumulate in the body on repeated exposure. Three rather inefficient processes are available for the elimination of such chemicals: (1) excretion by the mammary gland after the chemical is dissolved in milk lipids; (2) excretion in bile in association with biliary micelles and/or phospholipid vesicles; and (3) intestinal excretion, an incompletely understood transport from blood into the

intestinal lumen. Volatile, nonreactive toxicants such as gases and volatile liquids diffuse from pulmonary capillaries into the alveoli and are exhaled.

Reabsorption Toxicants delivered into the renal tubules may diffuse back across the tubular cells into the peritubular capillaries. This process is facilitated by tubular fluid reabsorption, which increases the intratubular concentration as well as the residence time of the chemical by slowing urine flow. Reabsorption by diffusion is dependent on the lipid solubility of the chemical. For organic acids and bases, diffusion is inversely related to the extent of ionization, because the nonionized molecule is more lipid-soluble. The ionization of weak organic acids, such as salicylic acid and phenobarbital, and bases, such as amphetamine, procainamide, and quinidine, is strongly pH-dependent in the physiologic range. Therefore, their reabsorption is influenced significantly by the pH of the tubular fluid. Acidification of urine favors the excretion of weak organic bases, whereas alkalization favors the elimination of weak organic acids. Some organic compounds may be reabsorbed from the renal tubules by transporters. For example, PEPT can move peptidomimetic drugs, such as some β -lactam antibiotics and angiotensin-converting enzyme inhibitors, across the brush border membrane. Carriers for the physiologic oxyanions mediate the reabsorption of some toxic metal oxyanions in the kidney. Thus, chromate and molybdate are reabsorbed by the sulfate transporter, whereas arsenate is reabsorbed by the phosphate transporter.

Toxicants delivered to the GI tract by biliary, gastric, and intestinal excretion and secretion by salivary glands and the exocrine pancreas may be reabsorbed by diffusion across the intestinal mucosa. Because compounds secreted into bile are usually organic acids, their reabsorption is possible only if they are sufficiently lipophilic or are converted to more lipid-soluble forms in the intestinal lumen. For example, glucuronides of toxicants such as diethylstilbestrol (DES) and glucuronides of the hydroxylated metabolites of polycyclic aromatic hydrocarbons, chlordecone, and halogenated biphenyls are hydrolyzed by the β -glucuronidase of intestinal microorganisms, and the released aglycones are reabsorbed (Gregus and Klaassen, 1986). Glutathione conjugates of hexachlorobutadiene and trichloroethylene are hydrolyzed by intestinal and pancreatic peptidases, yielding the cysteine conjugates, which are reabsorbed and serve as precursors of some nephrotoxic metabolites (Anders, 2004).

Toxication versus Detoxication

Toxication A number of xenobiotics (eg, strong acids and bases, nicotine, aminoglycosides, ethylene oxide, methylisocyanate, heavy metal ions, HCN, CO) are directly toxic, whereas the toxicity of others is due primarily to metabolites. Biotransformation to harmful products is called *toxication or metabolic activation*. With some xenobiotics, toxication confers physicochemical properties that adversely alter the microenvironment of biological processes or structures. For example, oxalic acid formed from ethylene glycol may cause acidosis and hypocalcaemia as well as obstruction of renal tubules by precipitation as calcium oxalate. Occasionally, chemicals acquire structural features and reactivity by biotransformation that allows for a more efficient interaction with specific receptors or enzymes. For example, the organophosphate insecticide parathion is biotransformed to paraoxon, an active cholinesterase inhibitor; the rodenticide fluoroacetate is converted in the citric acid cycle to fluorocitrate, a false substrate that inhibits aconitase; as a result of its CYP2E1-catalyzed oxidation, the general anesthetic methoxyflurane releases fluoride ion that inhibits several enzymes (including enolase in the glycolytic pathway) and that

contributes to renal injury after prolonged anesthesia; some cephalosporin antibiotics (eg, cephoperazone) may cause hemorrhage because they undergo biotransformation with release of 1-methyltetrazole-5-thiol that inhibits vitamin K epoxide reductase and thus impairs activation of clotting factors; and fialuridine, an antiviral drug withdrawn from development because it produced lethal hepatotoxicity in patients involved in the clinical trial, is phosphorylated to the triphosphate, which inhibits DNA polymerase- γ and thus impairs synthesis of mitochondrial DNA (Lewis *et al.*, 1996). Most often, however, toxication renders xenobiotics and occasionally other molecules in the body, such as oxygen and nitric oxide (*NO), indiscriminately reactive toward endogenous molecules with susceptible functional groups. This increased reactivity may be due to conversion into (1) electrophiles, (2) free radicals, (3) nucleophiles, or (4) redox-active reactants.

Formation of Electrophiles Electrophiles are molecules containing an electron-deficient atom with a partial or full positive charge that allows it to react by sharing electron pairs with electron-rich atoms in nucleophiles. The formation of electrophiles is involved in the toxication of numerous chemicals (Table 3-2) (see Chap. 6). Such reactants are often produced by insertion of an oxygen atom, which withdraws electrons from the atom it is attached to, making that electrophilic. This is the case when aldehydes, ketones, epoxides, arene oxides, sulfoxides, nitroso compounds, phosphonates, and acyl halides are formed (Table 3-2). In other instances, conjugated double bonds are formed, which become polarized by the electron-withdrawing effect of an oxygen, making one of the double-bonded carbons electron-deficient (ie, electrophilic). This occurs when α,β -unsaturated aldehydes and ketones as well as quinones, quinoneimines, and quinone methides are produced (Table 3-2). Formation of many of these electrophilic metabolites is catalyzed by cytochrome P450s (Leung *et al.*, 2012).

Cationic electrophiles may be produced as a result of heterolytic bond cleavage. For example, methyl-substituted aromatics, such as 7,12-dimethylbenzanthracene, and aromatic amines (amides), such as 2-acetylaminofluorene, are hydroxylated to form benzylic alcohols and *N*-hydroxy arylamines (amides), respectively (Miller and Surh, 1994). These metabolites are then esterified, typically by sulfotransferases. Heterolytic cleavage of the C–O or N–O bonds of these esters results in a hydrosulfate anion and the concomitant formation of a benzylic carbonium ion or arylnitrenium ion, respectively (see Chap. 6). The antiestrogen tamoxifen undergoes similar activation by hydroxylation and sulfation to form a carbocationic metabolite (Kim *et al.*, 2004). After being C-hydroxylated by CYP2E1, the hepatocarcinogen dimethylnitrosamine undergoes spontaneous decomposition, finally a heterolytic cleavage of the C–N bond to form methyl carbonium cation ($^+CH_3$) (see Chap. 6). In a similar process, the tobacco-specific nicotine-derived nitrosamine ketone (NNK), the most potent carcinogen in tobacco, may generate either methyl carbonium cation or piridylxobutyl carbonium cation, depending on the site of C-hydroxylation that initiates its decomposition. Formally, spontaneous heterolytic cleavage of the C–Cl bond results in formation of reactive episulfonium ion from the vesicant chemical warfare agent sulfur mustard (2,2'-bis-chloroethylsulfide). An episulfonium ion metabolite is also the ultimate toxicant produced from the fumigant 1,2-dibromoethane following its conjugation with glutathione to form *S*-(2-bromoethyl) glutathione conjugate, a so-called half-sulfur mustard (Anders, 2004). The oxidation of mercury (Hg^0) to Hg^{2+} by catalase and reduction of CrO_4^{2-} into DNA-reactive Cr^{3+} by ascorbate (Quievryn *et al.*, 2002) are examples for formation of electrophilic toxicants from inorganic chemicals. Reduction of arsenate (containing As^V)

Table 3-2

Toxication by Formation of Electrophilic Metabolites

ELECTROPHILIC METABOLITE	PARENT TOXICANT	ENZYMES CATALYZING TOXICATION	TOXIC EFFECT
Nonionic electrophiles			
Aldehydes, ketones			
Acetaldehyde	Ethanol	ADH	Hepatic fibrosis (?)
Zomepirac glucuronide	Zomepirac	GT → isomerization	Immune reaction (?)
2,5-Hexanedione	Hexane	CYP	Axonopathy
α,β-Unsaturated aldehydes, ketones			
Acrolein	Allyl alcohol	ADH	Hepatic necrosis
Acrolein	Allyl amine	MAO	Vascular injury
Acrolein	Cyclophosphamide	CYP → sp. cl.	Hemorrhagic cystitis
Muconic aldehyde	Benzene	Multiple	Bone marrow injury
Atropaldehyde (2-phenylacrolein)	Felbamate	Esterase → ADH → sp. cl.	Bone marrow and liver injury
4-Hydroxynon-2-enal	Fatty acids	Lipid peroxidation	Cellular injury (?)
Quinones, quinoneimines			
DES-4,4'-quinone	DES	Peroxidases	Carcinogenesis (?)
<i>N</i> -Acetyl- <i>p</i> -benzoquinoneimine	Acetaminophen	CYP, peroxidases	Hepatic necrosis
Epoxides, arene oxides			
Aflatoxin B ₁ 8,9-epoxide	Aflatoxin B ₁	CYP	Carcinogenesis
2-Chlorooxirane	Vinyl chloride	CYP	Carcinogenesis
Bromobenzene 3,4-oxide	Bromobenzene	CYP	Hepatic necrosis

KEY: AAF, 2-acetylaminofluorene; ADH, alcohol dehydrogenase; CCβL, cysteine conjugate β-lyase; ChE, cholinesterase; CYP, cytochrome P450; DENA, diethylnitrosamine; DMAB, *N,N*-dimethyl-4-aminoazobenzene; 7,12-DMBA, 7,12-dimethylbenzanthracene; DES, diethylstilbestrol; DP, dipeptidase; FMO, flavin-containing monooxygenase; GT, UDP-glucuronosyltransferase; GGT, gamma-glutamyltransferase; GST, glutathione *S*-transferase; HAPP, heterocyclic arylamine pyrolysis products; HCBD, hexachlorobutadiene; ST, sulfotransferase; sp. cl., spontaneous cleavage; sp. ra., spontaneous rearrangement.

Figure 3-3. Production of superoxide anion radical ($\text{O}_2^{\bullet -}$) by paraquat (PQ^{2+}), doxorubicin (DR), and nitrofurantoin (NF). Note that formation of $\text{O}_2^{\bullet -}$ is not the final step in the toxication of these xenobiotics, because $\text{O}_2^{\bullet -}$ can yield the much more reactive hydroxyl radical, as depicted in Fig. 3-4.

to arsenite (containing As^{III}) by glutathione is greatly accelerated via incorporation of arsenate into arsenate esters or anhydrides. These arsenylated metabolites (eg, ribose-1-arsenate, glucose-1-arsenate, ADP-arsenate) can be formed by phosphorylating enzymes (eg, purine nucleoside phosphorylase and glycogen phosphorylase) and by ATP synthase, which accept arsenate instead of phosphate as their substrate. This is how such enzymes promote reduction of arsenate into the more toxic thiol-reactive arsenite (Gregus *et al.*, 2009; Némethi *et al.*, 2010).

Formation of Free Radicals A free radical is a molecule or molecular fragment that contains one or more unpaired electrons in its outer orbital. Radicals are formed by (1) accepting an electron, (2) losing an electron, or (3) homolytic fission of a covalent bond.

1. Xenobiotics such as paraquat, doxorubicin, and nitrofurantoin can accept an electron from reductases to give rise to radicals (Fig. 3-3). These radicals typically transfer the extra electron to molecular oxygen, forming a superoxide anion radical ($\text{O}_2^{\bullet -}$) and regenerating the parent xenobiotic, which is ready to gain a new electron (Kappus, 1986). Through this “redox cycling,”

one electron acceptor xenobiotic molecule can generate many $\text{O}_2^{\bullet -}$ molecules. There are also endogenous sources of $\text{O}_2^{\bullet -}$. This radical is generated in large quantities by NADPH oxidase (Nox) in activated macrophages and granulocytes during “respiratory burst,” and in smaller quantities by many other cells, such as endothelial cells and vascular smooth muscle cells, which also express Nox in the plasma membrane (Bokoch and Knaus, 2003). Growth factor receptor stimulation in these non-phagocytotic cells is coupled to Nox activation. $\text{O}_2^{\bullet -}$ is also produced by the mitochondrial electron transport chain, especially by complexes I and III. The significance of $\text{O}_2^{\bullet -}$ stems to a large extent from the fact that $\text{O}_2^{\bullet -}$ is a starting compound in two toxication pathways (Fig. 3-4); one leads to formation of hydrogen peroxide (HOOH) and then hydroxyl radical (HO^{\bullet}), whereas the other produces peroxynitrite (ONOO^-) and ultimately nitrogen dioxide ($^{\bullet}\text{NO}_2$), and carbonate anion radical ($\text{CO}_3^{\bullet -}$).

2. Nucleophilic xenobiotics such as phenols, hydroquinones, aminophenols, aromatic amines (eg, benzidine), hydrazines, phenothiazines (eg, chlorpromazine; see Fig. 3-6), and thiols are prone to lose an electron and form free radicals in a reaction catalyzed by peroxidases (Aust *et al.*, 1993). Some of these chemicals, such as catechols and hydroquinones, may undergo two sequential one-electron oxidations, producing first semiquinone radicals and then quinones. Quinones are not only reactive electrophiles (Table 3-2) but also electron acceptors with the capacity to initiate redox cycling or oxidation of thiols and NAD(P)H. Polycyclic aromatic hydrocarbons with sufficiently low ionization potential, such as benzo[*a*]pyrene and 7,12-dimethylbenzanthracene, can be converted via one-electron oxidation by peroxidases or cytochrome P450 to radical cations, which may be the ultimate toxicants for these carcinogens (Cavalieri and Rogan, 1992). Like peroxidases, oxyhemoglobin (Hb-FeII-O_2) can catalyze the oxidation of aminophenols to semiquinone radicals and quinoneimines. This is another example of toxication, because these products, in turn, oxidize ferrohemeoglobin (Hb-FeII) to methemoglobin (Hb-FeIII), which cannot carry oxygen.

Figure 3-4. Two pathways for toxication of superoxide anion radical $\text{O}_2^{\bullet -}$ via nonradical products (ONOO^- and HOOH) to radical products ($^{\bullet}\text{NO}_2$, $\text{CO}_3^{\bullet -}$, and HO^{\bullet}). In one pathway, conversion of $\text{O}_2^{\bullet -}$ to HOOH is spontaneous or is catalyzed by SOD. Homolytic cleavage of HOOH to hydroxyl radical and hydroxyl ion is called the Fenton reaction and is catalyzed by the transition metal ions shown. Hydroxyl radical formation is the ultimate toxication for xenobiotics that form $\text{O}_2^{\bullet -}$ (see Fig. 3-3) or for HOOH , the transition metal ions listed, and some chemicals that form complexes with these transition metal ions. In the other pathway, $\text{O}_2^{\bullet -}$ reacts avidly with nitric oxide ($^{\bullet}\text{NO}$), the product of $^{\bullet}\text{NO}$ synthase (NOS), forming peroxynitrite (ONOO^-). Spontaneous reaction of ONOO^- with carbon dioxide (CO_2) yields nitrosoperoxy carbonate that is homolytically cleaved to nitrogen dioxide ($^{\bullet}\text{NO}_2$) and carbonate anion radical ($\text{CO}_3^{\bullet -}$). All 3 radical products indicated in this figure are oxidants, whereas $^{\bullet}\text{NO}_2$ is also a nitrating agent (see Fig. 3-8).

- Free radicals are also formed by homolytic bond fission, which can be induced by electron transfer to the molecule (reductive fission). This mechanism is involved in the conversion of CCl_4 to the trichloromethyl free radical ($\text{Cl}_3\text{C}^\bullet$) by an electron transfer from cytochrome P450 or the mitochondrial electron transport chain (reductive dehalogenation) (Recknagel *et al.*, 1989). The $\text{Cl}_3\text{C}^\bullet$ reacts with O_2 to form the even more reactive trichloromethylperoxy radical ($\text{Cl}_3\text{COO}^\bullet$) (Hippeli and Elstner, 1999).

The hydroxyl radical (HO^\bullet), a free radical of paramount toxicological significance, is also generated by homolytic fission. Such a process yields large amounts of HO^\bullet from water on ionizing radiation. Reductive homolytic fission of HOOH to the harmful HO^\bullet and the harmless HO^- (hydroxide anion) is called the Fenton reaction (Fig. 3-4). This is catalyzed by transition metal ions, typically Fe(II) , Cu(I) , Cr(V) , Ni(II) , or Mn(II) , and is a major toxication mechanism for HOOH and its precursor O_2^\bullet , as well as for transition metals. Moreover, the toxicity of chemicals, such as nitrotriacetic acid, bleomycin, and orellanin (Hippeli and Elstner, 1999), which chelate transition metal ions is also based on Fenton chemistry, because chelation increases the catalytic efficiency of some transition metal ions. Complexation with some endogenous oligopeptides also increases the catalytic efficiency of weakly Fenton-active metal ions, such as Ni(II) . The pulmonary toxicity of inhaled mineral particles such as asbestos and silica is caused, at least in part, by the formation of HO^\bullet triggered by Fe ions on the particle surface (Vallyathan *et al.*, 1998; Castranova, 2004). HOOH is a direct or indirect by-product of several enzymatic reactions, including monoamine oxidase, acyl-coenzyme A oxidase, xanthine oxidase (Harrison, 2002), aldehyde oxidase, and CYP2E1 (Caro and Cederbaum, 2004). It is produced in large quantities by spontaneous or superoxide dismutase (SOD)-catalyzed dismutation of O_2^\bullet .

Homolytic cleavage is also involved in free radical generation from ONOO^- (Squadrito and Pryor, 1998) (Fig. 3-4). The facile reaction of ONOO^- with the ubiquitous CO_2 yields nitrosoperoxy-carbonate (ONOOCO_2^-), which can spontaneously homolyze into 2 radicals, the oxidant and nitrating agent nitrogen dioxide ($\bullet\text{NO}_2$) and the oxidant carbonate anion radical (CO_2^\bullet). Thus, formation of ONOO^- and the latter radicals represents a toxication mechanism for O_2^\bullet and $\bullet\text{NO}$. As $\bullet\text{NO}$ is the product of nitric oxide synthase (NOS), this mechanism is especially relevant in and around cells that express NOS constitutively (ie, neurons and endothelial cells) as well as in and around cells that express the inducible form of NOS in response to cytokines. Inside the cell, a predominant site for formation of ONOO^- as well as its products CO_3^\bullet and $\bullet\text{NO}_2$ is the mitochondria, wherein the lipophilic $\bullet\text{NO}$ can readily diffuse and where the electron transport chain and the citric acid cycle produce O_2^\bullet and CO_2 , respectively (Denicola and Radi, 2005).

Formation of Nucleophiles The formation of nucleophiles is a relatively uncommon mechanism for activating toxicants. Examples include the formation of cyanide from amygdalin, which is catalyzed by bacterial β -glucosidase in the intestine; from acrylonitrile after epoxidation and subsequent glutathione conjugation; and from sodium nitroprusside by thiol-induced decomposition. Carbon monoxide is a toxic metabolite of dihalomethanes that undergo oxidative dehalogenation. Hydrogen selenide, a strong nucleophile and reductant, is formed from selenite by reaction with glutathione or other thiols.

Formation of Redox-Active Reactants There are specific mechanisms for the creation of redox-active reactants other than those already mentioned. Examples include the formation of the methemoglobin-producing nitrite from nitrate by bacterial

reduction in the intestine or from esters of nitrous or nitric acids in reaction with glutathione. Dapsone hydroxylamine and 5-hydroxyprimaquine, hydroxylated metabolites of the respective drugs, produce methemoglobin by cooxidation (Fletcher *et al.*, 1988). Reductants such as ascorbic acid and reductases such as NADPH-dependent flavoenzymes reduce Cr(VI) to Cr(V) (Shi and Dalal, 1990). Xenobiotic radicals formed in redox cycling (eg, those depicted in Fig. 3-3) as well as O_2^\bullet can reduce Fe(III) bound to ferritin and consequently release it as Fe(II) . Cr(V) and Fe(II) thus formed catalyze HO^\bullet formation (Fig. 3-4).

In summary, the most reactive metabolites are electron-deficient molecules and molecular fragments such as electrophiles and neutral or cationic free radicals. Although some nucleophiles are reactive (eg, HCN , CO), many (eg, hydroquinones) are activated by conversion to electrophiles. Similarly, free radicals with an extra electron (eg, those shown in Fig. 3-3) cause damage by giving rise to the neutral HO^\bullet radical after the formation and subsequent homolytic cleavage of HOOH .

Detoxication Biotransformation that eliminates an ultimate toxicant or prevents its formation is called detoxication. In some cases, detoxication may compete with toxication for a chemical. Detoxication can take several pathways, depending on the chemical nature of the toxic substance.

Detoxication of Toxicants with No Functional Groups In general, chemicals without functional groups, such as benzene and toluene, are detoxicated in 2 phases. Initially, a functional group such as hydroxyl or carboxyl is introduced into the molecule, most often by cytochrome P450 enzymes. Subsequently, an endogenous acid, such as glucuronic acid, sulfuric acid, or an amino acid, is added to the functional group by a transferase. With some exceptions, the final products are inactive, highly hydrophilic organic acids that are readily excreted. Carbonyl reduction, catalyzed by at least 5 enzymes (eg, 11- β -hydroxysteroid dehydrogenase-1, carbonyl reductase, and 3 members of aldo-keto reductase superfamily), initiates detoxication of the potent carcinogen NNK (4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone). The formed nicotine-derived nitrosamine alcohol is then readily glucuronidated at its hydroxyl moiety and is excreted into urine (Maser, 2004).

Detoxication of Nucleophiles Nucleophiles are generally detoxicated by conjugation at the nucleophilic functional group. Hydroxylated compounds are conjugated by sulfation, glucuronidation, or rarely by methylation, whereas thiols are methylated or glucuronidated and amines and hydrazines are acetylated. These reactions prevent peroxidase-catalyzed conversion of the nucleophiles to free radicals and biotransformation of phenols, aminophenols, catechols, and hydroquinones to electrophilic quinones and quinoneimines. An alternative mechanism for the elimination of thiols, amines, and hydrazines is oxidation by flavin-containing monooxygenases (Krueger and Williams, 2005). Some alcohols, such as ethanol, are detoxicated by oxidation to carboxylic acids by alcohol and aldehyde dehydrogenases. A specific detoxication mechanism is the biotransformation of cyanide to thiocyanate by rhodanese or mercaptopyruvate sulfurtransferase.

Detoxication of Electrophiles A general mechanism for the detoxication of electrophilic toxicants is conjugation with the thiol nucleophile glutathione (Ketterer, 1988). This reaction may occur spontaneously or can be facilitated by glutathione *S*-transferases. Metal ions—such as Ag^+ , Cd^{2+} , Hg^{2+} , and CH_3Hg^+ ions—readily react with and are detoxicated by glutathione. Specific mechanisms for the detoxication of electrophilic chemicals include epoxide hydrolase-catalyzed biotransformation of epoxides and arene

oxides to diols and dihydrodiols, respectively, and carboxylesterase-catalyzed hydrolysis of organophosphate ester pesticides. Others are two-electron reduction of quinones to hydroquinones by NAD(P)H:quinone oxidoreductase (NQO1) and NRH:quinone oxidoreductase (NQO2), reduction of α,β -unsaturated aldehydes (eg, the lipid peroxidation product 4-oxonon-2-enal) to alcohols or to their saturated derivative by carbonyl reductase (Maser, 2006), or oxidation of α,β -unsaturated aldehydes to acids by aldehyde dehydrogenases. Complex formation of thiol-reactive metal ions by MT and the redox-active ferrous iron by ferritin are special types of detoxications. Covalent binding of electrophiles to proteins can also be regarded as detoxication provided that the protein has no critical function and does not become a neoantigen or otherwise harmful. Carboxylesterases, for example, inactivate organophosphates not only by hydrolysis but also by covalent binding.

Detoxication of Free Radicals Because $O_2^{\cdot-}$ can be converted into much more reactive compounds (Fig. 3-4), its elimination is an important detoxication mechanism. This is carried out by SOD, high-capacity enzymes located in the cytosol (Cu, Zn-SOD) and the mitochondria (Mn-SOD), which convert $O_2^{\cdot-}$ to HOOH (Fig. 3-5). Subsequently, HOOH is reduced to water by catalase in the peroxisomes (also in the mitochondria in cardiac muscle), by the selenocysteine-containing glutathione peroxidases in the cytosol and mitochondria, and by peroxiredoxins in the cytosol, mitochondria, and endoplasmic reticulum (EPR) (Fig. 3-5) (Rhee *et al.*, 2005).

No enzyme eliminates HO^{\cdot} . Whereas some relatively stable radicals, such as peroxy radicals (see Fig. 3-9), can readily abstract a hydrogen atom from glutathione, α -tocopherol (vitamin E), or ascorbic acid (vitamin C), thus becoming nonradicals, these antioxidants are generally ineffective in detoxifying HO^{\cdot} (Sies, 1993). This is due to its extreme reactivity and thus short half-life (10^{-9} seconds), which provides little time for the HO^{\cdot} to reach and react with antioxidants. Therefore, the only effective protection against HO^{\cdot} is to prevent its formation by elimination of its precursor, HOOH, via conversion to water (Fig. 3-5).

ONOO⁻ (which is not a free radical oxidant) is significantly more stable than HO^{\cdot} (half-life of about 1 second). Nevertheless, the small biological antioxidant molecules (glutathione, uric acid, ascorbic acid, α -tocopherol) are relatively inefficient in intercepting it, because ONOO⁻ rapidly reacts with CO₂ (Squadrito and Pryor, 1998) to form reactive free radicals (Fig. 3-4). More efficient are the selenocysteine-containing glutathione peroxidase and peroxiredoxins, which can reduce ONOO⁻ to nitrite (ONO⁻) the same way they reduce HOOH to water (Fig. 3-5). Selenoprotein P, which contains 10 selenocysteine residues and coats the surface of endothelial cells, also reduces ONOO⁻ and may serve as a protectant against this oxidant in blood. In addition, ONOO⁻ reacts with oxyhemoglobin, heme-containing peroxidases, and albumin, all of which

Figure 3-5. Detoxication of superoxide anion radical ($O_2^{\cdot-}$) by superoxide dismutase (SOD), and of HOOH by glutathione peroxidase (GPX), peroxiredoxin ($Prx-(SH)_2$), and catalase (CAT). When GPX reduces HOOH, it forms glutathione disulfide (GSSG) as a by-product, which is reduced back to GSH by glutathione reductase using NADPH. When $Prx-(SH)_2$ reduces HOOH, its catalytic thiol group ($-R-S-H$) becomes first oxidized into a sulfenic acid group ($-R-S-OH$), which in turn reacts with another SH group of Prx, forming HOH and Prx disulfide ($PrxS_2$). The latter can be reduced back into $Prx-(SH)_2$ by the thioredoxin–thioredoxin reductase–NADPH system, as shown in Fig. 3-22. When HOOH is produced in large excess, the sulfenic acid group ($-R-S-OH$) in Prx may react with a second molecule of HOOH, causing its overoxidation into a sulfonic acid group ($-R-S(O)-OH$). This can be reduced back into $-R-S-OH$ group by the ATP-dependent sulfiredoxins, thus reactivating $Prx-(SH)_2$ (Lowther and Haynes, 2011). Further oxidation into a sulfonic acid form ($-R-S(O)-(OH)_2$) is irreversible and results in the loss of the peroxidase function of Prx; however, in this form Prx functions as a molecular chaperone (see later). Thus, out of the 3 enzymes eliminating HOOH, the capacity of Prx becomes limited at moderate overload of HOOH, whereas catalase activity is not capacity-limited even at high HOOH overload (Neumann *et al.*, 2009).

could be important sinks for ONOO⁻. Furthermore, elimination of the 2 ONOO⁻ precursors—that is, $^{\cdot}NO$ by reaction with oxyhemoglobin (to yield methemoglobin and nitrate) and $O_2^{\cdot-}$ by SODs (see above)—is a significant mechanism in preventing ONOO⁻ buildup (Squadrito and Pryor, 1998).

Peroxidase-generated free radicals are eliminated by electron transfer from glutathione. This results in the oxidation of glutathione, which is reversed by NADPH-dependent glutathione reductase (Fig. 3-6). Thus, glutathione plays an important role in the detoxication of both electrophiles and free radicals.

Detoxication of Protein Toxins Presumably, extracellular and intracellular proteases are involved in the inactivation of toxic polypeptides. Several toxins found in venoms, such as α - and β -bungarotoxin, erabutoxin, and phospholipase, contain intramolecular disulfide bonds that are required for their activity. These proteins are inactivated by thioredoxin, an endogenous dithiol protein that reduces the essential disulfide bond (Lozano *et al.*, 1994).

Figure 3-6. Detoxication of peroxidase (POD)-generated free radicals such as chlorpromazine free radical ($CPZ^{\cdot+}$) by glutathione (GSH). The by-products are glutathione thiol radical (GS^{\cdot}) and glutathione disulfide (GSSG), from which GSH is regenerated by glutathione reductase (GR).

When Detoxication Fails Detoxication may be insufficient for several reasons:

1. Toxicants may overwhelm detoxication processes, leading to saturation of the detoxication enzymes, consumption of the cosubstrates, or depletion of cellular antioxidants such as glutathione, ascorbic acid, and α -tocopherol. This results in the accumulation of the ultimate toxicant.
2. Occasionally, a reactive toxicant inactivates a detoxicating enzyme. For example, ONOO⁻ incapacitates Mn-SOD, which normally would counteract ONOO⁻ formation (Murphy, 1999) (see Fig. 3-4).
3. Some conjugation reactions can be reversed. For example, 2-naphthylamine, a bladder carcinogen, is *N*-hydroxylated and glucuronidated in liver, with the glucuronide excreted into urine. While in the bladder, the glucuronide is hydrolyzed, and the released arylhydroxylamine is converted by protonation and dehydration to the reactive electrophilic arylnitrenium ion (Bock and Lilenblum, 1994). Isocyanates and isothiocyanates form labile glutathione conjugates from which they can be released. Thus, methylisocyanate readily forms a glutathione conjugate in the lung after inhalation. From there, the conjugate is distributed to other tissues, where the reactive electrophilic parent compound may be regenerated (Baillie and Kassahun, 1994). Such conjugates are considered transport forms of toxicants.
4. Sometimes detoxication generates potentially harmful by-products, such as the glutathione thiol radical and glutathione disulfide, which are produced during the detoxication of free radicals (Fig. 3-6). Glutathione disulfide can form mixed disulfides with protein thiols, whereas the thiol radical (GS[•]), after reacting with thiolate (GS⁻), forms glutathione disulfide radical anion (GSSG₂^{•-}), which can reduce O₂ to O₂^{•-}. Conjugation with glutathione may lead to HCN generation in the course of acrylonitrile biotransformation, the first step of which is epoxidation of acrylonitrile (H₂C=CH-CN). Whereas glutathione conjugation detoxifies this epoxide if it takes place at the carbon adjacent to the nitrile group (-CN), it causes release of this group as HCN if glutathione conjugates with the epoxide at the carbon not linked to the nitrile moiety.

STEP 2—REACTION OF THE ULTIMATE TOXICANT WITH THE TARGET MOLECULE

Toxicity is typically mediated by a reaction of the ultimate toxicant with a target molecule (step 2a in Fig. 3-1). Subsequently, a series of secondary biochemical events occur, leading to dysfunction or injury that is manifest at various levels of biological organization, such as at the target molecule itself, cell organelles, cells, tissues and organs, and even the whole organism. Because interaction of the ultimate toxicant with the target molecule triggers the toxic effect, consideration is given to (1) the attributes of target molecules, (2) the types of reactions between ultimate toxicants and target molecules, and (3) the effects of toxicants on the target molecules (Fig. 3-7). Finally, consideration is given to toxicities that are initiated not by reaction of the ultimate toxicant with target molecules, but rather by alteration of the biological (micro)environment (step 2b in Fig. 3-1) in which critical endogenous molecules, cell organelles, cells, and organs function.

Attributes of Target Molecules

Practically all endogenous compounds are potential targets for toxicants. The identification and characteristics of the target molecules

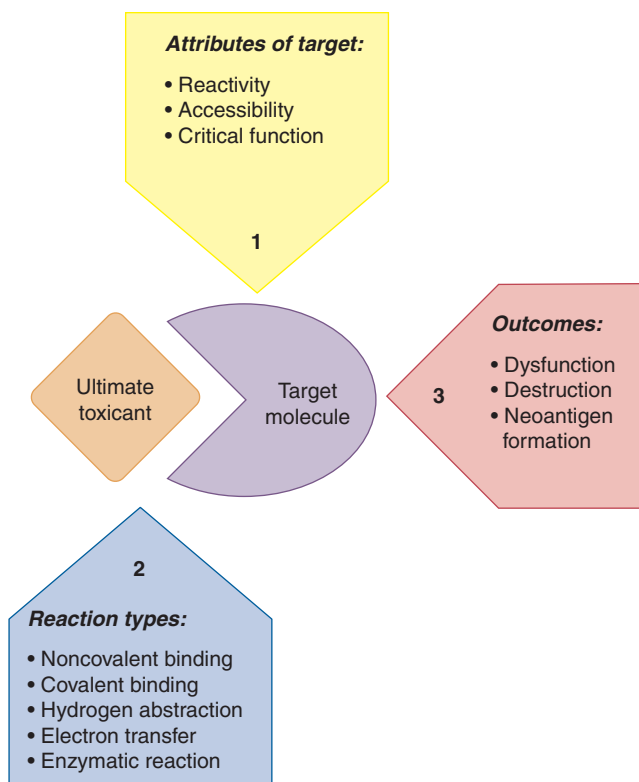

Figure 3-7. Reaction of the ultimate toxicant with the target molecule: the second step in the development of toxicity.

involved in toxicity constitute a major research priority, but a comprehensive inventory of potential target molecules is impossible. Nevertheless, the most prevalent and toxicologically relevant targets are macromolecules such as nucleic acids (especially DNA) and proteins. Among the small molecules, membrane lipids are frequently involved, whereas cofactors such as coenzyme A and pyridoxal rarely are involved.

To be a target, an endogenous molecule must possess the appropriate reactivity and/or steric configuration to allow the ultimate toxicant to enter into covalent or noncovalent reactions. For these reactions to occur, the target molecule must be accessible to a sufficiently high concentration of the ultimate toxicant. Thus, endogenous molecules that are exposed to reactive chemicals or are adjacent to sites where reactive metabolites are formed are frequently targets. Technical advances in the field of proteomics make it increasingly possible to identify potential protein targets of reactive chemicals as chemical-protein adducts. A compendium of proteins adducted by reactive toxicant metabolites has been established at the University of Kansas (<http://tpdb.medchem.ku.edu/tpdb.html>). The first target for reactive metabolites is often the enzyme that catalyzes their production or the adjacent intracellular structures. For example, thyroperoxidase, the enzyme involved in thyroid hormone synthesis, converts some nucleophilic xenobiotics (such as methimazole, amitrole, and resorcinol) into reactive free radicals that inactivate thyroperoxidase (Engler *et al.*, 1982). This is the basis for the antithyroid as well as the thyroid tumor-inducing effect of these chemicals. Carbon tetrachloride, which is activated by cytochrome P450, destroys this enzyme as well as the neighboring microsomal membranes (Osawa *et al.*, 1995). Several mitochondrial enzymes are convenient targets for nephrotoxic cysteine conjugates such as dichlorovinyl cysteine, because these conjugates are converted to electrophiles by mitochondrial enzymes with cysteine conjugate

β -lyase activity (eg, aspartate aminotransferase and branched chain amino acid aminotransferase) that can readily channel their reactive products to neighboring enzymes such as α -ketoglutarate dehydrogenase (Anders, 2004). Reactive metabolites that are unable to find appropriate endogenous reaction partners in close proximity to their site of formation may diffuse until they encounter such reactants. For example, hard electrophiles such as the arylnitrenium ion metabolite of *N*-methyl-4-aminoazobenzene react readily with hard nucleophilic atoms in nucleic acids, and thus target DNA in the nucleus, even though the electrophiles are produced in the cytoplasm. Vinyl chloride epoxide, formed in the hepatocytes from vinyl chloride, reaches its DNA targets in the neighboring endothelial cells (which are more sensitive to this genotoxin than the liver cells), initiating hepatic hemangiosarcoma.

Not all targets for chemicals contribute to the harmful effects. Thus, while carbon monoxide causes toxicity by binding to ferrohemoglobin, it also associates with the iron in cytochrome P450 with little or no consequence. Covalent binding of toxicants to various intracellular proteins, including enzymes and structural proteins, has been demonstrated, yet it is often uncertain which protein(s) is/are involved in binding that is toxicologically relevant (Cohen *et al.*, 1997; Pumford and Halmes, 1997; Rombach and Hanzlik, 1999). Arylation of some hepatic mitochondrial proteins by acetaminophen (4'-hydroxyacetanilide) is thought to be causally related to the liver injury induced by this drug because the nonhepatotoxic regioisomer of acetaminophen (3'-hydroxyacetanilide) does not readily bind covalently to these proteins (Cohen *et al.*, 1997; Jaeschke and Bajt, 2006). In contrast, arylation of a number of hepatic cytoplasmic proteins by acetaminophen is likely to be inconsequential because the nonhepatotoxic regioisomer of this drug also arylates those proteins (Nelson and Pearson, 1990). Covalent binding to proteins without adverse consequences may even represent a form of detoxication by sparing toxicologically relevant targets. This principle is best exemplified by covalent binding of organophosphate insecticides to plasma cholinesterase, which is a significant protective mechanism, as it counteracts phosphorylation of acetylcholinesterase, the target molecule. Thus, to conclusively identify a target molecule as being responsible for toxicity, it should be demonstrated that the ultimate toxicant (1) reacts with the target and adversely affects its function, (2) reaches an effective concentration at the target site, and (3) alters the target in a way that is mechanistically related to the observed toxicity.

Types of Reactions

The ultimate toxicant may bind to the target molecules noncovalently or covalently and may alter it by hydrogen abstraction, electron transfer, or enzymatically.

Noncovalent Binding This type of binding can be due to apolar interactions or the formation of hydrogen and ionic bonds and is typically involved in the interaction of toxicants with targets such as membrane receptors, intracellular receptors, ion channels, and some enzymes. For example, such interactions are responsible for the binding of strychnine to the glycine receptor on motor neurons in the spinal cord, TCDD to the AhR, saxitoxin to sodium channels, phorbol esters to protein kinase C (PKC), and warfarin to vitamin K 2,3-epoxide reductase. Such forces also are responsible for the intercalation of chemicals such as acridine yellow and doxorubicin into the double helix of DNA. These chemicals are toxic because the steric arrangement of their atoms allows them to combine with complementary sites on the endogenous molecule more or less as a key fits into a lock. Noncovalent binding usually is reversible because of the comparatively low bonding energy.

Covalent Binding Being practically irreversible, covalent binding is of great toxicological importance because it permanently alters endogenous molecules (Boelsterli, 1993). Covalent adduct formation is common with electrophilic toxicants such as nonionic and cationic electrophiles and radical cations. These toxicants react with nucleophilic atoms that are abundant in biological macromolecules, such as proteins and nucleic acids. Electrophilic atoms exhibit some selectivity toward nucleophilic atoms, depending on their charge-to-radius ratio. In general, soft electrophiles prefer to react with soft nucleophiles (low charge-to-radius ratio in both), whereas hard electrophiles react more readily with hard nucleophiles (high charge-to-radius ratio in both). Examples are presented in Table 3-3. Metal ions such as silver and mercury are also classified as soft electrophiles. These prefer to react covalently with soft nucleophiles (especially thiol groups). Conversely, hard electrophiles such as lithium, calcium, and barium react preferentially as cations with hard nucleophiles (eg, carboxylate and phosphate anions). Metals falling between these 2 extremes, such as chromium, zinc, and lead, exhibit universal reactivity with nucleophiles. The reactivity of an electrophile determines which endogenous nucleophiles can react with it and become a target.

Table 3-3

Examples of Soft and Hard Electrophiles and Nucleophiles

ELECTROPHILES		NUCLEOPHILES
Carbon in polarized double bonds (eg, quinones, α,β -unsaturated ketones)	Soft	Sulfur in thiols (eg, cysteinyl residues in proteins and glutathione)
Carbon in epoxides, strained-ring lactones, aryl halides	↑ ↓	Sulfur in methionine
Aryl carbonium ions		Nitrogen in primary and secondary amino groups of proteins (eg, lysine ϵ -amino group)
Benzylic carbonium ions, nitrenium ions		Nitrogen in amino groups in purine bases in nucleic acids
Alkyl carbonium ions		Oxygen of purines and pyrimidines in nucleic acids
		Hard

SOURCE: Based on Coles (1984).

A covalent reaction of special biological significance can take place between HOOH (a soft electrophile) and protein thiol groups, preferentially those with low pK_a value, that is, with a propensity of being in the strongly nucleophilic thiolate anion form (Prot-S⁻) at physiologic pH. This reaction produces protein sulfenic acid (Prot-S-OH):

The S atom in a sulfenic acid is electrophilic as it is made electron-deficient by the electron-withdrawing effect of O. Therefore, a protein-sulfenic acid can react with another thiol group of the same or a different protein or of glutathione (GSH), resulting in, respectively, formation of an intramolecular disulfide, intermolecular disulfide, or a mixed disulfide of the protein and glutathione (ie, glutathionylation of the protein):

Not only HOOH but also hydroperoxides (eg, lipid hydroperoxides, LOOH; see Fig. 3-9) may enter into such reactions, producing protein-sulfenic acids, protein-disulfides, and glutathionylated proteins, which can be considered as posttranslational modifications with a role in redox signaling (Forman *et al.*, 2004).

Neutral free radicals such as HO•, •NO₂, and Cl₃C• can also bind covalently to biomolecules. The addition of Cl₃C• to double-bonded carbons in lipids or to lipid radicals yields lipids containing chloromethylated fatty acids. The addition of hydroxyl radicals to DNA bases results in the formation of numerous products, including 8-hydroxypurines, 5-hydroxymethylpyrimidines, and thymine and cytosine glycols (Breen and Murphy, 1995).

Nucleophilic toxicants are in principle reactive toward electrophilic endogenous compounds. Such reactions occur infrequently because electrophiles are rare among biomolecules. Examples include the covalent reactions of amines and hydrazides with the aldehyde pyridoxal, a cosubstrate for several enzymes, including glutamate decarboxylase. Carbon monoxide, cyanide, hydrogen sulfide, and azide form coordinate covalent bonds with iron in various heme proteins. Other nucleophiles react with hemoglobin in an electron transfer reaction (see below).

Hydrogen Abstraction Neutral free radicals, such as those generated in reactions depicted in Fig. 3-4, can readily abstract H atoms from endogenous compounds, converting those compounds into radicals. Abstraction of hydrogen from thiols (R-SH) creates thiyl radicals (R-S•), which on radical recombination with HO• form sulfenic acids (R-S-OH) that are precursors of disulfides (R-S-S-R) (see above). Radicals can remove hydrogen from CH₂ groups of free amino acids or from amino acid residues in proteins and convert them to carbonyls. These carbonyls react covalently with amines, forming cross-links with DNA or other proteins. Hydrogen abstraction from deoxyribose in DNA yields the C-4' radical, the first step to DNA cleavage (Breen and Murphy, 1995). Abstraction of hydrogen from fatty acids produces lipid radicals and initiates lipid peroxidation. As depicted in Fig. 3-8, nitration of tyrosine residues in proteins purportedly involves H abstraction followed by radical recombination, that is, covalent binding between the resultant tyrosyl radical and •NO₂ (Squadrito and Pryor, 1998).

Electron Transfer Chemicals can oxidize Fe(II) in hemoglobin to Fe(III), producing methemoglobinemia. Nitrite can oxidize hemoglobin, whereas *N*-hydroxyl arylamines (such as dapsone hydroxylamine), phenolic compounds (such as 5-hydroxy

Figure 3-8. Formation of 3-nitrotyrosine residues in proteins by reaction with nitrogen dioxide (•NO₂). •NO₂ is an oxidizing and nitrating species generated from ONOO⁻ (Fig. 3-4). In addition, •NO₂ is a contaminant in cigarette smoke, exhaust of gas engines and stoves, as well as the causative agent of “silo-filler’s disease.”

primaquine), and hydrazines (such as phenylhydrazine) are cooxidized with oxyhemoglobin, forming methemoglobin and HOOH (Coleman and Jacobus, 1993).

Enzymatic Reactions A few toxins act enzymatically on specific target proteins. For example, the plant toxins ricin and abrin are *N*-glycosidases; they hydrolyze a specific glycosidic bond in ribosomal RNA, blocking protein synthesis. Botulinum toxin acts as a Zn-protease; it hydrolyzes the fusion proteins that assist in exocytosis of the neurotransmitter acetylcholine in cholinergic neurons, most importantly motor neurons, causing paralysis. The lethal factor component of anthrax toxin is also a Zn-protease, which inactivates mitogen-activated protein kinase kinase (MAPKK), inducing cell death. Other bacterial toxins catalyze the transfer of ADP-ribose from NAD⁺ to specific proteins. Through such a mechanism, diphtheria toxin blocks the function of elongation factor 2 in protein synthesis and cholera toxin activates a G protein. Snake venoms contain hydrolytic enzymes that destroy biomolecules.

In summary, most ultimate toxicants act on endogenous molecules on the basis of their chemical reactivity. Those with more than one type of reactivity may react by different mechanisms with various target molecules. For example, quinones may act as electron acceptors and initiate thiol oxidation or free radical reactions that lead to lipid peroxidation, but they may also act as soft electrophiles and bind covalently to protein thiols. The lead ion acts as a soft electrophile when it forms coordinate covalent bonds with critical thiol groups in δ -aminolevulinic acid dehydratase, its major target enzyme in heme synthesis (Goering, 1993). However, it behaves like a hard electrophile or an ion when it binds to PKC or blocks calcium channels, substituting for the natural ligand Ca²⁺ at those target sites.

Effects of Toxicants on Target Molecules

Reaction of the ultimate toxicant with endogenous molecules may cause dysfunction or destruction; in the case of proteins, it may render them foreign (ie, an antigen) to the immune system.

Dysfunction of Target Molecules Some toxicants activate protein target molecules, mimicking endogenous ligands. For example, morphine activates opioid receptors, clofibrate is an agonist on the peroxisome proliferator-activated receptor, and phorbol esters and lead ions stimulate PKC.

More commonly, chemicals inhibit the function of target molecules. Several xenobiotics—such as atropine, curare, and strychnine—block neurotransmitter receptors by attaching to the ligand-binding sites, whereas others interfere with the function of ion channels. Tetrodotoxin and saxitoxin, for example, inhibit opening of the voltage-activated sodium channels in the neuronal membrane, whereas DDT and the pyrethroid insecticides inhibit their closure. Some toxicants block ion transporters, others inhibit mitochondrial electron transport complexes, and many inhibit enzymes. Chemicals that bind to tubulin (eg, vinblastine, colchicine, paclitaxel, trivalent arsenic) or actin (eg, cytochalasin B, phalloidin) impair the assembly (polymerization) and/or disassembly (depolymerization) of these cytoskeletal proteins.

Protein function is impaired when conformation or structure is altered by interaction with the toxicant. Many proteins possess critical moieties, especially thiol groups, which are essential for catalytic activity or assembly to macromolecular complexes. Proteins that are sensitive to covalent and/or oxidative modification of their thiol groups include the enzymes glyceraldehyde 3-phosphate dehydrogenase (see Table 3-6) and pyruvate dehydrogenase (see Fig. 3-16), the Ca^{2+} pumps (see Fig. 3-17, Table 3-7), the DNA repair enzyme *O*⁶-methylguanine-DNA-methyltransferase, the DNA-methylating enzyme *C*⁵-cytosine-DNA-methyltransferase, ubiquitin-activating and -conjugating enzymes (E1 and E2), peroxiredoxins, protein tyrosine phosphatases (PTP, eg, *cdc25*), the lipid phosphatase PTEN (phosphatase and tensin homologue; see Fig. 3-12) (Rhee *et al.*, 2005), caspases (see Fig. 3-19), the TF AP-1, and the electrophile sensor protein Keap1 (see Fig. 3-27), just to name a few. These and many other proteins are inactivated by thiol-reactive chemicals, causing impaired maintenance of the cell's energy and metabolic homeostasis.

Binding of thiol-reactive chemicals to specific proteins may also initiate a signal. For example, thiol-reactive and oxidant chemicals, such as acrolein, methyl isocyanate, the lacrimator chloroacetophenone, and corrosive gases (eg, phosgene, chloropicrin, and chlorine), react with cysteine thiol groups of the TRPA1 receptor (a cation channel) in the membrane of sensory neurons. Excitation of these neurons located in the cornea and the mucous membranes of the eye and the respiratory tract elicits irritation, pain, lacrimation, bronchial secretion, sneezing, coughing, and bronchospasm (Bessac and Jordt, 2010). If moderate, these responses are alerting and protective, but are incapacitating and detrimental when exaggerated at high exposure. Keap1 may be regarded as an intracellular sensor of similar chemicals, as covalent and/or oxidative modification of thiol groups in Keap1 triggers the adaptive electrophile stress response, which is cytoprotective (see Fig. 3-27; Klaassen and Reisman, 2010). Conversion of the catalytic thiol group (-SH) in PTP and the lipid phosphatase PTEN to sulfenic acid group (-S-OH) on reaction with HOOH or lipid hydroperoxides (see reaction scheme above) inactivates these enzymes. PTPs keep protein kinase-mediated signal transduction pathways under control and PTEN controls the phosphatidylinositol-3-kinase (PI3K)–Akt pathway, both activated by growth factors (see Fig. 3-12). Therefore, inactivation of PTPs and PTEN permits these signalings to surge, thereby initiating, for example, a proliferative response. However, this concept may be an oversimplification because similar inactivation of *cdc25* (another PTP) may compromise mitosis, as *cdc25* normally dephosphorylates and activates cyclins 1 and 2, which are positive regulators of cell division (see Fig. 3-25). Formation of protein sulfenic acids by the oxidative stress product HOOH is thus considered as an initiating event of redox signaling (Forman *et al.*, 2004). Redox signaling is controlled by the production of HOOH (eg, by Nox activated on growth factor receptor stimulation) and its

enzymatic elimination. At low level, HOOH is removed effectively by peroxiredoxins (Fig. 3-5); however, these enzymes are incapacitated by overoxidation of their catalytic thiol groups at high HOOH levels (see Fig. 3-5). This modification can be reversed by sulfiredoxins (Lowther and Haynes, 2011). Furthermore, protein sulfenic acid formation is readily reversed by reaction of the sulfenic acid with a thiol (eg, glutathione), resulting in a protein disulfide (eg, protein-S-SG; see the scheme above), which in turn is reduced by thioredoxin or glutaredoxin as shown in Fig. 3-22, thereby regenerating PTPs and PTEN in their active thiol form. Therefore, peroxiredoxins, sulfiredoxins, thioredoxin, thioredoxin reductase, glutaredoxin, glutathione, and NADPH are all important negative regulators of oxidative signaling (Neumann *et al.*, 2009). Protein tyrosine nitration (see Fig. 3-8) may also alter protein function or may interfere with signaling pathways that involve tyrosine kinases and phosphatases.

Toxicants may interfere with the template function of DNA. The covalent binding of chemicals to DNA causes nucleotide mispairing during replication. For example, covalent binding of aflatoxin 8,9-oxide to *N*-7 of guanine results in pairing of the adduct-bearing guanine with adenine rather than cytosine, leading to the formation of an incorrect codon and the insertion of an incorrect amino acid into the protein. Such events are involved in the aflatoxin-induced mutation of the Ras proto-oncogene and the p53 tumor suppressor gene (Eaton and Gallagher, 1994). 8-Hydroxyguanine (8-OH-Gua) and 8-hydroxyadenine are mutagenic bases produced by HO• that can cause mispairing with themselves as well as with neighboring pyrimidines, producing multiple amino acid substitutions (Breen and Murphy, 1995). Cr(III) produced from chromate (Cr(VI)) via reduction by ascorbate, alone or complexed to ascorbate, forms a coordinate covalent bond with phosphate in DNA, thereby inducing a mutation (Queivryn *et al.*, 2002). Chemicals such as doxorubicin, which intercalate between stacked bases in the double-helical DNA, push adjacent base pairs apart, causing an even greater error in the template function of DNA by shifting the reading frame.

Destruction of Target Molecules In addition to adduct formation, toxicants alter the primary structure of endogenous molecules by means of cross-linking and fragmentation. Bifunctional electrophiles, such as 2,5-hexanedione, carbon disulfide, acrolein, 4-oxonon-2-enal, 4-hydroxynon-2-enal, and nitrogen mustard alkylating agents, cross-link cytoskeletal proteins, DNA, or DNA with proteins. HOOH and hydroxyl radicals can also induce cross-linking by converting proteins into either reactive electrophiles (eg, protein sulfenic acids and protein carbonyls, respectively), which react with a nucleophilic group (eg, thiol, amine) in another macromolecule. Radicals (eg, those shown in Fig. 3-4) may induce cross-linking of macromolecules by converting them into radicals, which react with each other by radical recombination. Cross-linking imposes both structural and functional constraints on the linked molecules.

Some target molecules are susceptible to spontaneous degradation after chemical attack. Free radicals such as $\text{Cl}_3\text{COO}^\bullet$ and HO• can initiate peroxidative degradation of lipids by hydrogen abstraction from fatty acids (Recknagel *et al.*, 1989). The lipid radical (L•) formed is converted successively to lipid peroxy radical (LOO•) by oxygen fixation, lipid hydroperoxide (LOOH) by hydrogen abstraction, and lipid alkoxy radical (LO•) by the Fe²⁺-catalyzed Fenton reaction. Subsequent fragmentation gives rise to hydrocarbons such as ethane and reactive aldehydes such as 4-hydroxynon-2-enal and malondialdehyde (Fig. 3-9). Thus, lipid peroxidation not only destroys lipids in cellular membranes but also generates endogenous toxicants, both free radicals (eg, LOO•, LO•) and electrophiles (eg, 4-oxonon-2-enal, 4-hydroxynon-2-enal). These substances can

Figure 3-9. Lipid peroxidation initiated by the hydroxyl radical (HO•). Many of the products, such as the radicals and the α,β -unsaturated aldehydes, are reactive, whereas others, such as ethane, are nonreactive but are indicators of lipid peroxidation.

readily react with adjacent molecules, such as membrane proteins, or diffuse to more distant molecules such as DNA. F₂-isoprostanes are stable peroxidation products of arachidonic acid; these are not only sensitive markers of lipid peroxidation but also potent pulmonary and renal vasoconstrictors (Basu, 2004).

Apart from hydrolytic degradation by toxins and radiolysis, toxicant-induced fragmentation of proteins is not well documented. There are, however, examples for destruction of the prosthetic group in enzymes. For instance, cytochrome P450 converts allyl isopropyl acetamide into a reactive metabolite, which alkylates the heme moiety of the enzyme. This leads to loss of the altered heme and to porphyria (De Matteis, 1987). Arsine (AsH₃) acutely induces heme release from oxyhemoglobin, which may underlie its hemolytic effect. Aconitase is attacked by ONOO⁻ at its [4Fe-4S]²⁺ cluster, in which one of the Fe atoms is genuinely labile (as is complexed to inorganic sulfur and not to enzyme-bound cysteines like the others). As a result of the oxidant action of ONOO⁻, the labile Fe is lost, inactivating the enzyme (Castro *et al.*, 1994) and compromising the citric acid cycle where aconitase functions.

Several forms of DNA fragmentation are caused by toxicants. For instance, attack of DNA bases by HO• can result in the formation of imidazole ring-opened purines or imidazole ring-contracted pyrimidines, which block DNA replication. Formation of a bulky

adduct at guanine N-7 destabilizes the N-glycosylic bond, inducing depurination. Depurination results in apurinic sites that are mutagenic. Single-strand breaks (SSB) typically are caused by hydroxyl radicals via abstraction of H from desoxyribose in DNA yielding the C-4' radical, followed by O₂[•] addition, Criegee rearrangement, and cleavage of the phosphodiester bond (Breen and Murphy, 1995). Multiple hydroxyl radical attacks on a short length of DNA, which occur after ionizing radiation, cause double-strand breaks (DSB) that are typically lethal to the affected cell.

Neoantigen Formation Whereas the covalent binding of xenobiotics or their metabolites is often inconsequential with respect to the function of the immune system, in some individuals these altered proteins, which carry the xenobiotic adduct as a hapten, evoke an immune response. Some chemicals (eg, dinitrochlorobenzene, penicillin, and nickel ion) are sufficiently reactive to bind to proteins spontaneously. Others may obtain reactivity by auto-oxidation to quinones (eg, urushiols, the allergens in poison ivy) or by enzymatic biotransformation (Park *et al.*, 2005). For example, CYP2E1 biotransforms halothane to an electrophile, trifluoroacetyl chloride, which binds as a hapten to microsomal and cell surface proteins in the liver, inducing a hepatitis-like immune reaction in sensitive patients.

Haptenized proteins released from cells may evoke antibody-mediated (humoral) and/or T-cell-mediated (cellular) immune response. In the humoral response, B cells play the leading role: they bind the complete antigen through their B-cell receptors and associate with T-helper cells (CD4⁺). Antigen binding (as signal #1) and cell surface costimulatory molecules on T-helper cells (as signal #2) induce differentiation of B cells into plasma B cells that manufacture and secrete antibody. By binding to the antigen, the antibody assists in destruction of the antigen by phagocytosis; however, harmful consequences may also result. For example, when penicillin-bound proteins as antigens react with IgE-type antibodies on the surface of mast cells, the reaction triggers release of mast cell mediators (eg, histamine, leukotrienes), which in turn may cause bronchoconstriction (asthma), vasodilatation, and plasma exudation (wheal, anaphylactic shock).

In cellular immune response, T cells are the main mediators. In the sensitization phase, T-helper cells become activated by two signals coming from antigen-presenting cells, such as macrophages in internal tissues and dendritic cells in tissues that are in contact with external environment (ie, skin and mucosal lining of the respiratory and GI tract). The APC phagocytoses the haptenized protein and migrates to lymph nodes where most T cells are located. Meanwhile, the APC processes the antigen into appropriate peptides, externalizes, and transfers the processed antigen to the major histocompatibility complex (MHC) on its surface. On reaching the lymph node, the APC presents the MHC-bound peptide to the T-cell receptor (TCR) of T-helper cells (signal #1). In addition, cell surface coactivator molecules (eg, CD80 and CD86) on APC bind to their counterparts (eg, CD28) on T cells (signal #2). Without signal #2 (which verifies that the antigen detected is foreign) the T cell becomes functionally inert (anergic). On receiving both signals, the helper T cell becomes specific to one particular antigen, expresses the T-cell growth factor IL-2 and its receptor, proliferates, differentiates, and is released into the circulation. On reexposure to the allergen, the elicitation phase commences. Antigen-specific T cells enter the exposure site (eg, the skin) and using IL-2 and other cytokines, they can activate cytotoxic T cells (CD8⁺) and induce expression of adhesion molecules at the site of allergen contact. Whereas this response is protective against virus-infected cells and tumor cells, it causes inflammation and cell injury in cells containing xenobiotic

neoantigens. This model describes the response to contact allergens, such as nickel and urushiols, and is the basis of detecting contact allergens in mice with the local lymph node assay.

Besides the above-described classical mechanism of neoantigen-initiated APC-mediated T-cell activation, xenobiotics may cause T-cell activation by more direct ways. For example, Ni ions may not only form coordinate covalent bonds with proteins, making them neoantigens, but also apparently cross-link MHC of APC with the TCR of T cells, activating the latter. Moreover, some drugs (eg, sulfamethoxazole), which can be biotransformed into adduct forming metabolites (eg, nitroso-sulfamethoxazole) that triggers T-cell activation by the classical mechanism, purportedly may also stimulate the TCR of T cells directly, without involvement of APC.

Regarding contact allergens, a new concept has emerged: to elicit allergic contact dermatitis chemicals should not only initiate formation of antigen-specific T cells (as described above) but also evoke a less specific inflammatory reaction (referred to as innate immune signal). For example, nickel alone cannot give a positive response in the local lymph node assay in mice; however, it can when coadministered with lipopolysaccharide (LPS), a bacterial cell wall component. LPS acts through Toll-like receptor 4 (TLR4) on resident skin cells (macrophages, dendritic cells, fibroblasts) to trigger inflammatory gene expression via signaling pathways that involves NF- κ B. However, nickel alone can evoke contact dermatitis in sensitive humans, apparently because it activates the human TLR4 that, unlike the mouse receptor, contains 2 nonconserved histidine residues (Schmidt and Goebeler, 2011). The need for an innate immune signal may account for the observation that contact allergy may be facilitated by an injury evoking inflammatory response, such as toxic cell injury by an irritant chemical or microbial infection.

Drug-induced lupus and possibly many cases of drug-induced agranulocytosis are thought to be mediated by immune reactions triggered by drug-protein adducts. The causative chemicals are typically nucleophiles, such as aromatic amines (eg, aminopyrine, clozapine, procainamide, and sulfonamides), hydrazines (eg, hydralazine and isoniazid), and thiols (eg, propylthiouracil, methimazole, and captopril). These substances can be oxidized by myeloperoxidase of granulocytes and monocytes (the precursors of APC) or by the ROS/RNS such cells produce (HO^\bullet , ONOO^- , hypochlorous acid [HOCl], see Fig. 3-26) to reactive metabolites that bind to the surface proteins of these cells, making them antigens (Utrecht, 1992). The reactive metabolites may also activate monocytes and thus promote the immune reaction. Activation of CD4^+ T cells by inhibition of promoter methylation of specific genes by procainamide and hydralazine as a possible lupus-inducing mechanism is discussed in the section “Dysregulation of Transcription.”

Toxicity Not Initiated by Reaction with Target Molecules

Some xenobiotics not only interact with a specific endogenous target molecule to induce toxicity but also, instead, alter the biological microenvironment (see step 2b in Fig. 3-1). Included here are (1) chemicals that alter H^+ ion concentrations in the aqueous biophase, such as (a) acids and substances biotransformed to acids, such as methanol and ethylene glycol, (b) protonophoric uncouplers such as 2,4-dinitrophenol and pentachlorophenol, which dissociate their phenolic protons in the mitochondrial matrix, thus dissipating the proton gradient that drives ATP synthesis, and (c) cationic amphiphilic drugs (eg, chloroquine and amiodarone)

that diffuse into lysosomes and accumulate there after being protonated at their amino groups; (2) solvents and detergents that physicochemically alter the lipid phase of cell membranes and destroy transmembrane solute gradients that are essential to cell functions; and (3) other xenobiotics that cause harm merely by occupying a site or space. For example, some chemicals (eg, the ethylene glycol-derived Ca-oxalate, methotrexate, and acyclovir) form water-insoluble precipitates in renal tubules. The poorly water-soluble complex produced in renal tubules from melamine and its derivative cyanuric acid caused the renal injury observed in cats and dogs fed adulterated pet food (Dobson *et al.*, 2008) and is probably also responsible for a similar disorder that occurred in children fed melamine-contaminated infant formula. By occupying bilirubin binding sites on albumin, compounds such as the sulfonamides induce bilirubin toxicity (kernicterus) in neonates. Carbon dioxide displaces oxygen in the pulmonary alveolar space and causes asphyxiation.

STEP 3—CELLULAR DYSFUNCTION AND RESULTANT TOXICITIES

The reaction of toxicants with a target molecule may result in impaired cellular function as the third step in the development of toxicity (Fig. 3-1). Each cell in a multicellular organism carries out defined programs. Certain programs determine the destiny of cells—that is, whether they undergo division, differentiation (ie, express proteins for specialized functions), or apoptosis. Other programs control the ongoing (momentary) activity of differentiated cells, determining whether they secrete more or less of a substance, whether they contract or relax, and whether they transport and metabolize nutrients at higher or lower rates. For regulation of these cellular programs, cells possess signaling networks (such as those shown in Figs. 3-12 and 3-15) that can be activated and inactivated by external signaling molecules. To execute the programs, cells are equipped with synthetic, metabolic, kinetic, transport, and energy-producing systems as well as structural elements, organized into macromolecular complexes, cell membranes, and organelles, by which they maintain their own integrity (internal functions) and support the maintenance of other cells (external functions).

As outlined in Fig. 3-10, the nature of the primary cellular dysfunction caused by toxicants, but not necessarily the ultimate outcome, depends on the role of the target molecule affected. If the target molecule is involved in cellular regulation (signaling), dysregulation of gene expression and/or dysregulation of momentary cellular function occur primarily. However, if the target molecule is involved predominantly in the cell's internal maintenance, the resultant dysfunction can ultimately compromise the survival of the cell. The reaction of a toxicant with targets serving external functions can influence the operation of other cells and integrated organ systems. The following discussion deals with these consequences.

Toxicant-Induced Cellular Dysregulation

Cells are regulated by signaling molecules that activate specific cellular receptors linked to signal transducing networks that transmit the signals to the regulatory regions of genes and/or to functional proteins. Receptor activation may ultimately lead to (1) altered gene expression that increases or decreases the quantity of specific proteins and/or (2) a chemical modification of specific proteins, typically by phosphorylation, which activates or inhibits proteins. Programs controlling the destiny of cells primarily affect gene

Figure 3-10. The third step in the development of toxicity: alteration of the regulatory or maintenance function of the cell.

expression, whereas those regulating the ongoing activities primarily influence the activity of functional proteins; however, one signal often evokes both responses because of branching and interconnection of signaling networks.

Dysregulation of Gene Expression Gene expression is the process by which information from a gene is used in the synthesis of a functional gene product. The genetic information may be transcribed from DNA into messenger RNA (mRNA), which in turn is translated into a protein product. The nonprotein-coding genes may be transcribed into other RNAs, among them the recently discovered small silencing RNA or microRNA (miRNA), which can repress translation of mRNA into proteins, thereby regulating protein synthesis posttranscriptionally (Fig. 3-11). Chemicals may dysregulate the expression of genes encoding mRNA, miRNA, or both, in either way causing altered synthesis of specific proteins. Dysregulation of gene expression may occur at elements that are directly responsible for transcription, at components of the intracellular signal transduction pathway, and at the synthesis, storage, or release of the extracellular signaling molecules. Dysregulation of gene expression initiated by chemicals at these 3 levels is discussed below.

Dysregulation of Transcription Transcription of genetic information from DNA to mRNA and miRNA is controlled largely by interplay between TFs and the regulatory or promoter region of genes coding for mRNA and miRNA (Fig. 3-11). By binding to distinctive nucleotide sequences in this region, ligand- and signal-activated TFs facilitate or impede the formation of the preinitiation complex, thereby promoting or repressing transcription of the adjacent gene. Xenobiotics may interact with the TFs (or other components of the preinitiation complex) and/or may alter the promoter region of the gene.

Dysregulation of Transcription by Chemicals Acting Through Ligand-Activated Transcription Factors Several endogenous compounds, such as hormones (eg, steroids, thyroid hormones) and vitamins (retinoids and vitamin D), influence gene expression by binding to and activating TFs or intracellular receptors (Table 3-4). Xenobiotics may mimic the natural ligands. For example, fibric acid-type lipid-lowering drugs, phthalate esters, and compound Wy-14,643 substitute for polyunsaturated fatty acids as ligands for the peroxisome proliferator-activated receptor (PPAR α) (Poellinger *et al.*, 1992), and xenoestrogens (eg, DES, DDT, methoxychlor) substitute estradiol, an endogenous ligand for estrogen receptors (ER).

Acting through ligand-activated TFs, natural or xenobiotic ligands when administered at extreme doses or at critical periods during ontogenesis may cause toxicity by inappropriately influencing the fate of cells and inducing cell death or mitosis (Table 3-4). Glucocorticoids such as dexamethasone induce apoptosis of lymphoid cells. Whereas desirable in the treatment of lymphoid malignancies, this is an unwanted response in many other conditions. TCDD, a ligand of the AhR, produces thymic atrophy by causing apoptosis of thymocytes. Estrogens exert mitogenic effects in cells that express the ER, such as those found in female reproductive organs, mammary gland, and liver. ER-mediated proliferation appears to be responsible, at least in part, for formation of tumors in these organs during prolonged estrogen exposure (Green, 1992), as well as for induction of the rare vaginal adenocarcinoma in late puberty after transplacental exposure to the synthetic estrogen DES. Stimulation of these receptors during a critical prenatal period of differentiation reprograms the estrogen target tissue (ie, Mullerian duct), resulting in benign and malignant abnormalities in the reproductive tract later in life (Newbold, 2004). Mice exposed neonatally to DES served

Figure 3-11. Basic steps of gene expression—transcription factors regulate transcription, whereas microRNAs regulate (repress) translation. In the process of gene expression, information from a gene is used in the synthesis of a functional gene product. This simplified figure depicts how the synthesis of two important functional gene products, that is, proteins and microRNAs (miRNA, also called small silencing RNA), are interrelated. As described in the text, these normally controlled processes may be dysregulated by endobiotics and xenobiotics as well as during pathologic processes, such as carcinogenesis.

Genetic information in a protein-coding gene (red in the DNA strand) is transcribed into a precursor messenger RNA (mRNA), which is processed into the mature mRNA by capping at the 5' end, splicing (ie, removing noncoding introns) and polyadenylation at the 3' end (not shown). After export from the nucleus, the mRNA associates with the ribosome and serves as a template to determine the amino acid (aa) sequence of the protein being synthesized (translation).

DNA sequences between protein-coding genes (ie, intergenic regions) may code for miRNAs. These are small noncoding RNA molecules (21–25 nucleotides in length) that may control the translation of more than 60% of mRNAs into proteins. The gene for miRNA (black in the DNA strand) codes for an initial transcript, termed pri-miRNA, which may be several kilobases long (not shown; Wahid *et al.*, 2010). The pri-miRNA is then cut shorter in the nucleus by an RNase (Drosha), assisted by its partner protein DiGeorge syndrome critical region in gene 8 (DGCR8), to become pre-miRNA (60–70 nucleotides in length). After export into the cytoplasm, the pre-miRNA is further truncated by another RNase (Dicer) and its partner TRBP to form the mature miRNA. Finally, miRNA associates with an Argonaute protein, thus forming microRNA-induced silencing complex (miRISC). The miRNA guides miRISC to specifically recognize mRNAs, called target mRNAs. The miRNA binds with base pairing to the untranslated region (UTR) of the target mRNA and miRISC downregulates its translation into protein by translational repression and/or mRNA cleavage. Because miRNAs bind to their target mRNAs by partial complementarity over a short sequence, one miRNA may have several hundreds of mRNA targets; therefore, a single miRNA can silence the expression of many proteins. Often a single pri-miRNA is processed into a cluster of miRNAs; therefore, their expression pattern is usually similar. A well-known example is the miR17-92 cluster comprising 7 miRNAs that are often overexpressed in cancer.

Ligand- and signal-activated transcription factors (represented by the round and the rectangular symbols, respectively) can bind to the promoter regions (green in the DNA strand) of the protein-coding genes and the miRNA-coding genes and upregulate or downregulate their transcription, thereby directly influencing the expression of mRNA and/or miRNA and ultimately affecting the synthesis of specific proteins. Transcription factors and miRNAs thus regulate diverse cellular pathways. It is important to note that miRNAs, as a rule, repress the translation of proteins. Therefore, upregulation of miRNA transcription results in downregulation of protein translation from the target mRNAs, whereas downregulation of miRNA causes derepression of protein translation from the target mRNAs, thereby increasing the synthesis of specific proteins.

to model DES-induced late carcinogenesis in the reproductive tract. Compared with the wild-type animals, mice overexpressing estrogen receptor- α (ER α) were exceedingly sensitive to DES-induced uterine adenocarcinoma, whereas ER α -knockout mice were resistant, indicating the role of ER α in tumorigenesis. It has been speculated that environmental xenoestrogens such as DDT, polychlorinated biphenyls, bisphenol A, and atrazine contribute to an increased incidence of breast cancer. Zearalenone, a mycoestrogen feed contaminant, causes vulval prolapse in swine, an example of an ER-mediated proliferative lesion. The mitogenic and hepatic tumor-promoting effects of peroxisome proliferators in rodents are also receptor-mediated, because they are not observed in PPAR α -null mice (Peters *et al.*, 1998). Humans do not respond with hepatocellular and peroxisomal proliferation to

fibrates and express PPAR α at low levels and often in nonfunctional forms. Humanized mice (ie, PPAR α -null mice transfected with human PPAR α) also fail to respond with hepatocellular and peroxisomal proliferation to fibrates, indicating that the human receptor cannot signal for proliferation (Gonzalez and Yu, 2006). In addition, pathways downstream of the receptor are also inappropriate to produce such a response in humans, because transfection of rat PPAR α into human hepatocytes failed to make the peroxisomes inducible by PPAR α ligands in the human cells. Chemicals that act on ligand-activated TFs, such as glucocorticoids, TCDD, and retinoids, induce fetal malformations that may be regarded as inappropriate gene expression. Candidate target genes are the homeobox genes that determine the body plan during early ontogenesis.

Table 3-4

Toxicants Acting on Ligand-Activated Transcription Factors

LIGAND-ACTIVATED TRANSCRIPTION FACTOR	ENDOGENOUS LIGAND	EXOGENOUS LIGAND	EFFECT
Estrogen receptor (ER)	Estradiol	Ethinylestradiol Diethylstilbestrol DDT, methoxychlor Zearalenone	Mammary and hepatic carcinogenesis Porcine vulval prolapse
Glucocorticoid receptor (GR)	Cortisol	Dexamethasone	Apoptosis of lymphocytes Teratogenesis (cleft palate)
Retinoic acid receptor (RAR, RXR)	All- <i>trans</i> -retinoic acid	13- <i>cis</i> -Retinoic acid	Teratogenesis (craniofacial, cardiac, thymic malformations)
Aryl hydrocarbon receptor (AhR)	Unknown	TCDD PCBs PAHs	Thymic atrophy Wasting syndrome Teratogenesis (cleft palate) Hepatocarcinogenesis in rats Enzyme induction (eg, CYP1A1)
Peroxisome proliferator-activated receptor (PPAR α)	Fatty acids	Fibrate esters (eg, clofibrate) Phthalate esters (eg, DEHP)	Hepatocarcinogenesis in mice Peroxisome proliferation Enzyme induction (eg, CYP4A1, acyl-CoA oxidase)
Constitutive androstane receptor (CAR)	3 α ,5 α -Androstenol 3 α ,5 α -Androstanol (inhibitors)	TCPOBOP, phenobarbital* DDT, PCP, chlorpromazine	Enzyme induction (eg, CYP2B, CYP3A) Hepatocarcinogenesis in mice
Pregnane X receptor (PXR)	Pregnenolone Progesterone	PCN, dexamethasone Spironolactone, cyproterone Rifampicin, zearalenone Lithocholic acid	Enzyme induction (eg, CYP3A) Transporter induction (eg, Oatp1a4, Mdr1, Mrp1, Mrp2, Mrp3)

TCPOBOP, 1,2-bis[2-(3,5-dichloropyridyloxy)]benzene.
*Phenobarbital indirectly activates CAR, not as a ligand.

In addition to altering the fate of specific cells, compounds that act on ligand-activated TFs can also evoke changes in the metabolism of endobiotics and xenobiotics by inducing overexpression of relevant enzymes. For example, the PPAR α -ligand fibrates induce lipoprotein lipase and enzymes involved in fatty acid oxidation. Unlike the hepatic proliferative effects of PPAR α agonists, these effects occur not only in rodents but also in humans, and form the basis of the use of fibrates as lipid-lowering drugs. TCDD, phenobarbital, and pregnenolone 16 α -carbonitrile (PCN) activate AhR, the constitutive androstane receptor (CAR), and the pregnane X receptor (PXR), respectively (Table 3-4), thereby exerting their well-known cytochrome P450-inducing effects. However, rodent, rabbit, and human PXR and CARs exhibit low degree of sequence conservation in their ligand-binding domains. This accounts for marked species differences in the induction potential of their ligands, such as PCN, rifampicin, and TCPOBOP (Gonzalez and Yu, 2006). Genes of several xenobiotic-metabolizing enzymes may be activated by these chemicals. For example, TCDD increases the expression of cytochrome P450 1A1, UDP-glucuronosyltransferase-1, and several subunits of mouse and rat glutathione *S*-transferase in an AhR-dependent manner. In AhR-null mice, TCDD induces neither these enzymes nor the adverse effects listed in Table 3-4 (Gonzalez and Fernandez-Salguero, 1998). CYP1A1 becomes also strongly expressed in the epithelial cells of the dioxin-induced cystic lesions in the human skin and thus CYP1A1 induction (which is detectable

immunohistochemically in these structures) may serve as a biomarker of human dioxin exposure (Saurat *et al.*, 2012). Chloracne, as this multiple dermal lesion has been called inappropriately, is now identified as hamartoma. Dioxin-induced hamartomas appear in the epidermis and are characterized by (1) nonmalignant proliferation of columnar epithelial cells enclosing cysts with inflammatory signs and (2) involution of sebaceous glands. Whole genome microarray analysis of TCDD-induced hamartomas revealed severe dysregulation of gene expression, with marked overexpression of some genes, such as those coding for CYP1A1, inflammatory proteins, and gremlin 2 (a cytokine that inhibits bone morphogenic protein, a transforming growth factor- β [TGF- β]-like growth factor), and repression of many others, such as those encoding several sebaceous lipid synthesis enzymes and solute carriers (Saurat *et al.*, 2012). Mechanistic interpretation of many of these TCDD-induced alterations in gene expression and their role in development of dioxin-induced dermal hamartomas is still uncertain.

The above-mentioned alterations in cell fate and function caused by endobiotics and xenobiotics that act on ligand-activated TFs may in part be mediated by transcriptional upregulation or downregulation of protein-coding genes, that is, genes that are transcribed into mRNA, which in turn is translated into protein (Fig. 3-11). For example, the drug-metabolizing enzymes are induced by TCDD (see above) because the promoter regions of their genes contain a dioxin (or xenobiotic) response element (DRE or

XRE). The TCDD-activated AhR complexed with its nuclear translocator protein Arnt (also called HIF-1 β) binds to this sequence and promotes the transcription of these genes and secondarily the synthesis of enzyme proteins. The cyclooxygenase-2 (COX-2) gene, whose product is involved in the synthesis of inflammatory prostaglandins, also contains DRE/XRE permitting its transactivation by TCDD-activated AhR. Similarly, the ligand-activated PPAR α , after dimerizing with RXR, upregulates the transcription of genes encoding enzymes involved in fatty acid transport and β -oxidation by interacting with the peroxisome proliferator response element (PPRE) located in the promoter of these genes.

As discovered recently, the effects of endobiotics and xenobiotics that act on ligand-activated TFs may also be mediated by transcriptional upregulation or downregulation of genes coding for miRNAs. Because miRNAs repress the translation of target mRNAs into proteins, upregulation of miRNA transcription results in increased repression of protein translation, whereas downregulation of miRNA causes derepression of protein translation from the target mRNAs, and in turn increases the synthesis of specific proteins (Fig. 3-11). The mechanism of hepatocellular proliferation in mice exposed to the peroxisome proliferator Wy-14,643 involves transcriptional downregulation by the Wy-14,643-activated mouse PPAR α of the gene coding for let-7c, a miRNA (Gonzalez and Shah, 2008). Let-7c is known to target c-Myc mRNA and represses its translation into c-Myc protein. Therefore, declining levels of let-7c in response to Wy-14,643 result in derepression of c-Myc mRNA and a consequential surge in c-Myc protein synthesis. As c-Myc is a TF signaling for mitosis (see Figs. 3-12 and 3-32), its increased abundance in the liver induces hepatocellular proliferation. Interestingly, the proliferative action of c-Myc also involves miRNA gene regulation: c-Myc upregulates miR-17-92, a cluster of miRNAs, which in turn repress the translation of p21, a cyclin-dependent kinase inhibitor with antimitotic action (see Fig. 3-32), and Bim, a proapoptotic protein (see Fig. 3-15), thereby permitting mitosis and opposing apoptosis. In contrast to normal mice, PPAR α -humanized mice (expressing the human PPAR α) exhibit neither downregulation of let-7c gene expression nor hepatocellular proliferation on Wy-14,643 treatment, supporting a causative relationship between these events. The mode of action of some other ligand-activated TFs also involves downregulation of miRNA gene transcription with subsequent derepression of the target mRNAs, causing their increased translation into specific proteins. For example, dexamethasone downregulates the expression of the miRNA cluster miR-17-92, which results in elevated levels of Bim, a proapoptotic member of the Bcl family of proteins (see Fig. 3-15). In addition, glucocorticoids can also upregulate the transcription of the Bim gene. Overexpression of the Bim protein, at both transcriptional and translational levels, may be the principal mechanism of glucocorticoid-induced apoptosis in lymphoid cells (Molitoris *et al.*, 2011). Glucocorticoids also cause skeletal muscle wasting, partly because they stimulate the production of myostatin by the muscle. Acting on the muscle in a paracrine manner, this TGF- β -like signaling protein negatively regulates muscle mass (see Fig. 3-30). Glucocorticoids decrease the expression of miR-27a and b (which normally repress the translation of myostatin mRNA, as this mRNA contains a recognition sequence for miR-27a and b in its 3'-untranslated region), thereby increasing the synthesis of myostatin protein. Whereas TCDD, acting through the AhR and the XRE in the COX-2 gene promoter, can transcriptionally upregulate COX-2 expression as mentioned above, studies on mice indicate that TCDD can induce COX-2 protein also by downregulating of miR-101a gene, because one of the targets for miR-101a is the mRNA that translates into the COX-2 enzyme (Yoshioka *et al.*, 2011). It appears

that COX-2 induction plays a role in TCDD-induced liver injury in mice. Furthermore, the expression of drug-metabolizing enzymes is regulated not only by TFs (see above and in Table 3-4) but also by miRNAs. For example, the translation of CYP3A4 (which forms the genotoxic metabolites of aflatoxin B₁ and benzo[*a*]pyrene) and CYP2E1 (which contributes to toxicification of acetaminophen, carbon tetrachloride, and dimethylnitrosamine) is repressed by miR-27b and miR-378, respectively (Yokoi and Nakajima, 2011). The complexity of protein expression regulation is underlined by the recent recognition that while TFs can control the expression of miRNAs at their transcription, miRNAs can control the expression of TFs at their translation (Yokoi and Nakajima, 2011).

Finally, ligand-activated TFs do not act only by regulating gene expression through binding to their cognate response element but also by interacting with other proteins, including other nuclear receptors or their associates. Such interactions underlie, for example, the antiestrogenic effect of TCDD and dioxin-like chemicals, which involves at least two mechanisms. First, the TCDD-ligated AhR can associate with the ER, facilitating its nuclear export and proteasomal degradation. In addition, dimerization of the TCDD-ligated AhR with its partner Arnt reduces the availability of this protein for ER that employs Arnt as a transcriptional coactivator (Denison *et al.*, 2011).

Dysregulation of Transcription by Chemicals Altering the Regulatory Region of Genes Xenobiotics may dysregulate transcription by also altering the regulatory gene regions through direct chemical interaction or by changing their methylation pattern. It has been hypothesized that thalidomide (or its hydrolysis product) exerts teratogenic effect in the embryo by intercalating to GGGCGG sequences (also called GC boxes) that are binding sites for Sp1 and Egr-1 TFs (Stephens *et al.*, 2000). Thalidomide would thus impair insulin-like growth factor-1 (IGF-1) and fibroblast growth factor-2 (FGF2) signaling pathways necessary for angiogenesis and limb formation, because both pathways encompass multiple proteins whose genes contain GC boxes in the regulatory region but lack TATA and CCAAT boxes (eg, specific integrins, FGF2, IGF-1, and IGF-1 receptor substrate-1). Another chemical feature of thalidomide that may account for impaired Sp1-mediated transcriptional activation is that the hydrolysis product of this drug is a glutamine analogue and thus mimics the glutamine-rich activation domain of Sp1 protein.

As described in more detail in the section "Carcinogenesis," methylation of cytosines in CpG islands located in the promoter of genes is a major epigenetic mechanism, which together with coupled histone modifications (eg, acetylation, methylation) influences the transcriptional activity of the adjacent gene. Increased promoter methylation (hypermethylation) silences genes, whereas decreased methylation (hypomethylation) permits their activation. Importantly, when DNA replication occurs, the methylation pattern is copied from the parent strand to the daughter strand by DNA methyltransferase-1 (DNMT1), making the pattern heritable. Nevertheless, promoter methylation is subject to environmental influences, which can thus cause heritable changes in gene regulation. Altered promoter methylation has been implicated in chemically induced systemic lupus erythematosus (SLE), in developmental deficiencies manifested postnatally or even in subsequent generations, and in cancer. The antiarrhythmic drug procainamide and the antihypertensive hydralazine often induce SLE, an autoimmune inflammatory disease. Both drugs inhibit DNA methylation and induce global DNA hypomethylation in CD4⁺ T lymphocytes with concomitant overexpression of proteins important in inflammation, such as CD11a (an integrin subunit), CD70 (a B-cell costimulatory molecule), and perforin (a cell-killing molecule) (Ballestar *et al.*, 2006). Idiopathic

lupus also involves global DNA hypomethylation in T cells with overexpression of these proinflammatory proteins. Therefore, promoter hypomethylation and overexpression of critical genes that convert T cells into aggressive inflammatory cells appears fundamental in the pathogenesis of both idiopathic and drug-induced SLE.

DNA methylation is an important process also in genomic imprinting that takes place during formation of germ cells. The vast majority of genes in both germ cells (ie, the sperm and the egg) similarly undergo or avoid epigenetic alterations (eg, methylation and related histone modifications); therefore, the offspring carries equally expressed 2 copies (ie, maternal and paternal alleles) of most genes. However, a relatively few (100–200) genes (called the imprinted genes) are epigenetically altered (generally methylated and thus typically silenced) only in the male or female germ cells; therefore, either the paternal or the maternal gene copy is expressed in the offspring, whereas the other allele is not expressed. For example, the insulin-like growth factor-2 gene, which encodes an autocrine growth factor important in fetal growth, is expressed only from the paternal allele. Because the genomically imprinted genes have only a single active copy, they are especially susceptible for epigenetic dysregulation. Dysregulation of imprinting can range from loss of imprinting, which results in biallelic expression and double amounts of the gene product, to silencing of both alleles. Although prenatal exposure to chemicals, such as TCDD and ethanol, influences genomic imprinting (Wu *et al.*, 2004; Stouder *et al.*, 2011), mechanistic interpretation of the role of such epigenetic alterations in chemically induced embryonic, early postnatal, or transgenerational defects in somatic or germ cell development is still uncertain due to the complexity of gene regulation.

The genome is especially susceptible to epigenetic alterations during early development, as in the preimplantation mammalian embryo, the genome (except for the imprinted genes) undergoes extensive demethylation, and appropriate patterns of cytosine methylation are reestablished after implantation. Developing mammalian germ cells are also subject to such changes: primordial germ cells undergo genomic demethylation while they migrate into the early gonad, and then they undergo remethylation during sex determination in the gonad, for example, testis development. During this period (embryonic 11–15 days in the rat), the androgen receptor and ER- β are expressed in the developing testis, and ligands of these nuclear receptors can influence the methylation process. Indeed, transient exposure of gestating female rats during the period of gonadal sex determination to vinclozolin (an agricultural fungicide with antiandrogenic activity) or methoxychlor (a DDT-type insecticide with estrogenic activity) decreased the spermatogenic capacity (with reduced sperm number and viability) in the adult male offspring and increased the incidence of male infertility (Anway *et al.*, 2005). Importantly, these effects were transferred through the male germ line to nearly all males of the subsequent 3 generations. These adverse transgenerational effects on reproduction correlate with altered DNA methylation patterns in the germ line. Thus, endocrine disruptors have the potential to epigenetically reprogram the germ line and promote transgenerational disease state, although the relevance of these findings under human exposure conditions is still uncertain.

Transcription is also severely dysregulated in cancer cells by altered promoter methylation (ie, global DNA hypomethylation and tumor suppressor gene hypermethylation). DNA methylation, including its biochemistry, its influence on histone modifications (acetylation and methylation), and its role in chemical carcinogenesis, is discussed in this chapter in the section “Epigenetic Mechanisms in Carcinogenesis: Inappropriate Activation or Responsiveness of the Regulatory Region of Critical Genes.”

Dysregulation of Signal Transduction Extracellular signaling molecules (such as growth factors, cytokines, hormones, neurotransmitters, and some secreted proteins) engage cell surface receptors and intracellular signal transducing networks and ultimately activate TFs. Fig. 3-12 depicts a simplified scheme for some of these networks and identifies some signal-activated TFs that are turned on by these systems and that in turn control the transcriptional activity of genes that determine the fate of cells by influencing mitosis and/or apoptosis. Among these TFs are c-Fos and c-Jun proteins, which bind in dimeric combinations (called AP-1) to the tetradecanoylphorbol acetate (TPA) response element (TRE), for example, in the promoter of the cyclin D gene whose product promotes the cell division cycle (see Figs. 3-25 and 3-32). Other signal-activated TFs that upregulate the transcription of cyclin D gene by binding to their cognate nucleotide sequences include c-Myc, E2F, NF- κ B, CREB, and STAT. Mitogenic signaling molecules thus induce cell proliferation. In contrast, TGF- β activates SMADs and induces the expression of cyclin-dependent kinase inhibitor proteins (eg, p15, p21, and p57), which mediate its antimitotic effect (Johnson and Walker, 1999) (see Fig. 3-32), as well as the proapoptotic protein Bim (see Fig. 3-19), which conveys its apoptotic action.

In addition to the proliferatory signaling pathways illustrated in Fig. 3-12, Figs. 3-13 and 3-14 depict 2 other pathways, the activation of which can also promote cell division. These are set in motion by secreted glycoproteins, the Wnt and Hedgehog (Hh) ligands, which act on specific cell surface receptors, ultimately activating the transcriptional coactivator β -catenin and the TF Gli, respectively, which in turn can also activate the transcription of cyclin D gene, among many others. The Wnt- β -catenin and Hh-Gli systems are especially important in certain proliferative processes, such as embryogenesis, development of adult stem cells as well as progenitor cells, tissue regeneration after injury, and oncogenesis.

The signal from the cell surface receptors to the TFs is relayed mainly by successive protein–protein interactions and protein phosphorylations at specific serine, threonine, or tyrosine hydroxyl groups. Cell surface growth factor receptors (item 4 in Fig. 3-12) are in fact phosphorylating enzymes (ie, receptor protein tyrosine kinases). Their ligands induce them to phosphorylate themselves, which, in turn, enable these receptors to bind adapter proteins. Through these, the growth factor receptors can initiate proliferative signaling via two important pathways: (1) by activating Ras, they set in motion the mitogen-activated protein kinase (MAPK) cascade (Qi and Elion, 2005), and (2) by activating PI3K, they start the PI3K–Akt pathway. A crucial step in the latter is the PI3K-catalyzed phosphorylation of a plasma membrane lipid to generate phosphatidylinositol-3,4,5-triphosphate (PIP₃) that recruits protein kinase Akt to the membrane for activation. Because Akt (also called protein kinase B) has numerous substrates, the PI3K–Akt pathway branches (Morgensztern and McLeod, 2005). Fig. 3-12 shows the branch that leads to activation of the TF NF- κ B, a prolife pathway. In addition, Akt may also indirectly activate the mammalian target of rapamycin (mTOR), a ubiquitous protein kinase, whose phosphorylated products promote the trophic state of cells by boosting protein synthesis and restraining autophagy (see Fig. 3-29). Furthermore, Akt catalyzes the inactivating phosphorylation of two important signaling proteins. One is glycogen synthase kinase 3 (GSK), a ubiquitous multifunctional constitutively active protein kinase, whose inactivation by Akt (or by some other Ser/Thr kinases) causes numerous effects ranging from promotion of glycogen synthesis from UDP-glucose to suppression of apoptosis (see later), and whose incapacitation by Wnt and Hh signaling permits β -catenin and Gli, respectively, to escape degradation and

act as transcription activators (see Figs. 3-13 and 3-14). The other is the FoxO family of TFs, whose inactivation by Akt-catalyzed phosphorylation prevents protein degradation in the skeletal muscle and promotes proliferation, thereby countering muscle atrophy (see Fig. 3-30).

The intracellular signal transducer proteins are typically but not always activated by phosphorylation, which is catalyzed by protein kinases, and are usually inactivated by dephosphorylation, which is carried out by protein phosphatases. Interestingly, growth factor receptors can amplify their signals by inducing formation of HOOH. As discussed earlier, by attacking protein thiolate groups and converting them into sulfenic acid groups, HOOH reversibly inactivates PTP and PTEN, a lipid phosphatase that eliminates PIP₃ (see Fig. 3-12; Rhee *et al.*, 2005). The source of HOOH is O₂[•] produced by the enzyme complex Nox, which is activated by growth factor receptors via the PI3K → PIP₃ → Rac (a G-protein that associates with Nox) pathway. Even if once thought to be restricted to phagocytes, Nox occurs in the plasma membrane of many other cells, such as endothelial cells and vascular smooth muscle cells (Bokoch and Knaus, 2003). Although Nox in these cells is much less efficient to produce O₂[•] than Nox in phagocytes, the nonphagocytotic Nox releases O₂[•] into the cytoplasm, whereas the phagocytotic Nox delivers it to the external face of the plasma membrane (El-Benna *et al.*, 2005).

Chemicals may cause aberrant signal transduction in a number of ways, most often by altering protein phosphorylation, occasionally by interfering with the GTPase activity of G proteins (eg, Ras), by disrupting normal protein–protein interactions or by establishing abnormal ones, or by altering the synthesis or degradation of signaling proteins. Such interventions may ultimately influence cell cycle progression.

Chemically Altered Signal Transduction with Proliferative Effect Xenobiotics that facilitate phosphorylation of signal transducers often promote mitosis and tumor formation. Such are the phorbol esters and fumonisin B that activate PKC. These chemicals functionally mimic diacylglycerol (DAG), one of the physiologic activators of PKC (Fig. 3-12). The other physiologic PKC activator Ca²⁺ is mimicked by Pb²⁺, whose effect on PKC α is concentration-dependent: stimulatory at picomolar concentration, when Pb²⁺ occupies only high-affinity binding sites on PKC, and inhibitory at micromolar concentration, where the low-affinity sites are also occupied (Sun *et al.*, 1999). Lead salts do induce marked hepatocellular proliferation in rats. The activated PKC promotes mitogenic signaling at least in two ways: (1) by phosphorylating Raf, the first protein kinase in the MAPK pathway (Fig. 3-12), and (2) by phosphorylating a protein phosphatase that dephosphorylates the TF c-Jun at specific sites (Thr 231, Ser 234, and Ser 249), thereby permitting its binding to DNA. Protein kinases may also be activated by interacting proteins that had been altered by a xenobiotic. For example, the TCDD-liganded AhR binds to MAPK. This so-called nongenomic effect of TCDD may contribute to overexpression of cyclins and cyclin-dependent kinases in guinea pig liver (Ma and Babish, 1999).

Hyperphosphorylation of proteins may result not only from increased phosphorylation by kinases but also from decreased dephosphorylation by phosphatases. Inhibition of phosphatases, including the lipid phosphatase PTEN (see Fig. 3-12), appears to be the underlying mechanism of the mitogenic effect of various chemicals, oxidative stress, and ultraviolet (UV) irradiation (Herrlich *et al.*, 1999). PTP and dual-specificity phosphatases (ie, enzymes that remove phosphate from phosphorylated tyrosine as well as serine and threonine residues) as well as PTEN contain a catalytically active cysteine, and are susceptible to inactivation by

HOOH via sulfenic acid formation and by covalent reaction with other SH-reactive chemicals (Forman *et al.*, 2004; Rhee *et al.*, 2005). Indeed, xenobiotics such as the SH-reactive iodoacetamide, the organometal compound tributyltin, arsenite, as well as HOOH cause phosphorylation of the epidermal growth factor (EGF) receptor (item 4 in Fig. 3-12) by interfering with the PTP that would dephosphorylate and thus “silence” this receptor (Herrlich *et al.*, 1999; Chen *et al.*, 1998). Arsenite-induced oxidative stress (Lynn *et al.*, 2000; Smith *et al.*, 2001) may in fact result from activation of growth factor receptors. These signal via the PI3K → PIP₃ → Rac pathway to the neighboring Nox, which also resides in the plasma membrane. Overproduction of O₂[•] by the activated Nox in endothelial cells and vascular smooth muscle cells might contribute to the vasculotoxic effects of arsenic. Arsenite may also inactivate the dual-specificity phosphatase that dephosphorylates and “silences” certain MAPKs (c-jun N-terminal kinase [JNK], p38), whereas methylmethane sulfonate (MMS) appears to inhibit a protein phosphatase that inactivates Src, a protein tyrosine kinase (Herrlich *et al.*, 1999). The thiol-oxidizing agent diamide (which increases phosphorylation of MAPKs) and phenolic antioxidants (which form phenoxyl radicals and increase c-Fos and c-Jun expression) (Dalton *et al.*, 1999) may also act by incapacitating PTP. Protein phosphatase 2A (PP2A) is the major soluble Ser/Thr phosphatase in cells and is likely responsible, at least in part, for reversing the growth factor–induced stimulation of MAPK, thereby keeping the extent and duration of MAPK activation under control (Goldberg, 1999). PP2A also removes an activating phosphate from a mitosis-triggering protein kinase (p34^{cdc2}). Several natural toxins are extremely potent inhibitors of PP2A, including the blue-green algae poison microcystin-LR and the dinoflagellate-derived okadaic acid (Toivola and Eriksson, 1999), which are tumor promoters in experimental animals subjected to prolonged low-dose exposure. It is to be noted, however, that acute high-dose exposure to microcystin induces severe liver injury, whereas such exposure to okadaic acid is the underlying cause of the diarrhetic shellfish poisoning. In these conditions, hyperphosphorylation of proteins other than those involved in proliferative signaling (eg, hepatocellular microfilaments in microcystin poisoning) may be primarily responsible for the pathogenesis.

Apart from phosphatases, there are also inhibitory binding proteins that can keep signaling under control. Such is I κ B, which binds to NF- κ B, preventing its transfer into the nucleus and its function as a TF. On phosphorylation by its designated I κ B kinase (IKK), I κ B is degraded by the proteasome and NF- κ B is set free. IKK can be phosphorylated (activated) by other protein kinases, such as Raf (a member of the MAPK cascade) and Akt (a member of the PI3K–Akt pathway) (Fig. 3-12). NF- κ B is an important contributor to proliferative and prolife signaling, because via the above pathways, growth factor receptor stimulation can cause I κ B phosphorylation and thus the release of NF- κ B, and because the released NF- κ B transactivates genes whose products accelerate the cell division cycle (eg, cyclin D1 and c-Myc) and inhibit apoptosis (eg, antiapoptotic Bcl proteins and the caspase inhibitor of apoptosis proteins [IAP]) (Karin, 2006). NF- κ B activation, via the Akt-mediated IKK phosphorylation, is involved in the proliferative (and possibly carcinogenic) effect of arsenite, nicotine, and the NNK. In addition, because NF- κ B also targets the genes of several cytokines (eg, TNF, IL-1 β), chemokines (eg, monocyte chemoattractant protein-1 [MCP-1], cytokine-induced neutrophil chemoattractant [CINC]-1), cell adhesion molecules (eg, ICAM-1, E- and P-selectins), enzymes producing inflammatory lipid mediators (eg, PLA2, COX-2), and acute-phase proteins (eg, C-reactive protein, α 1-acid glycoprotein), and because such cytokines acting on their receptors (items 2 and 3 in Fig. 3-12) activate

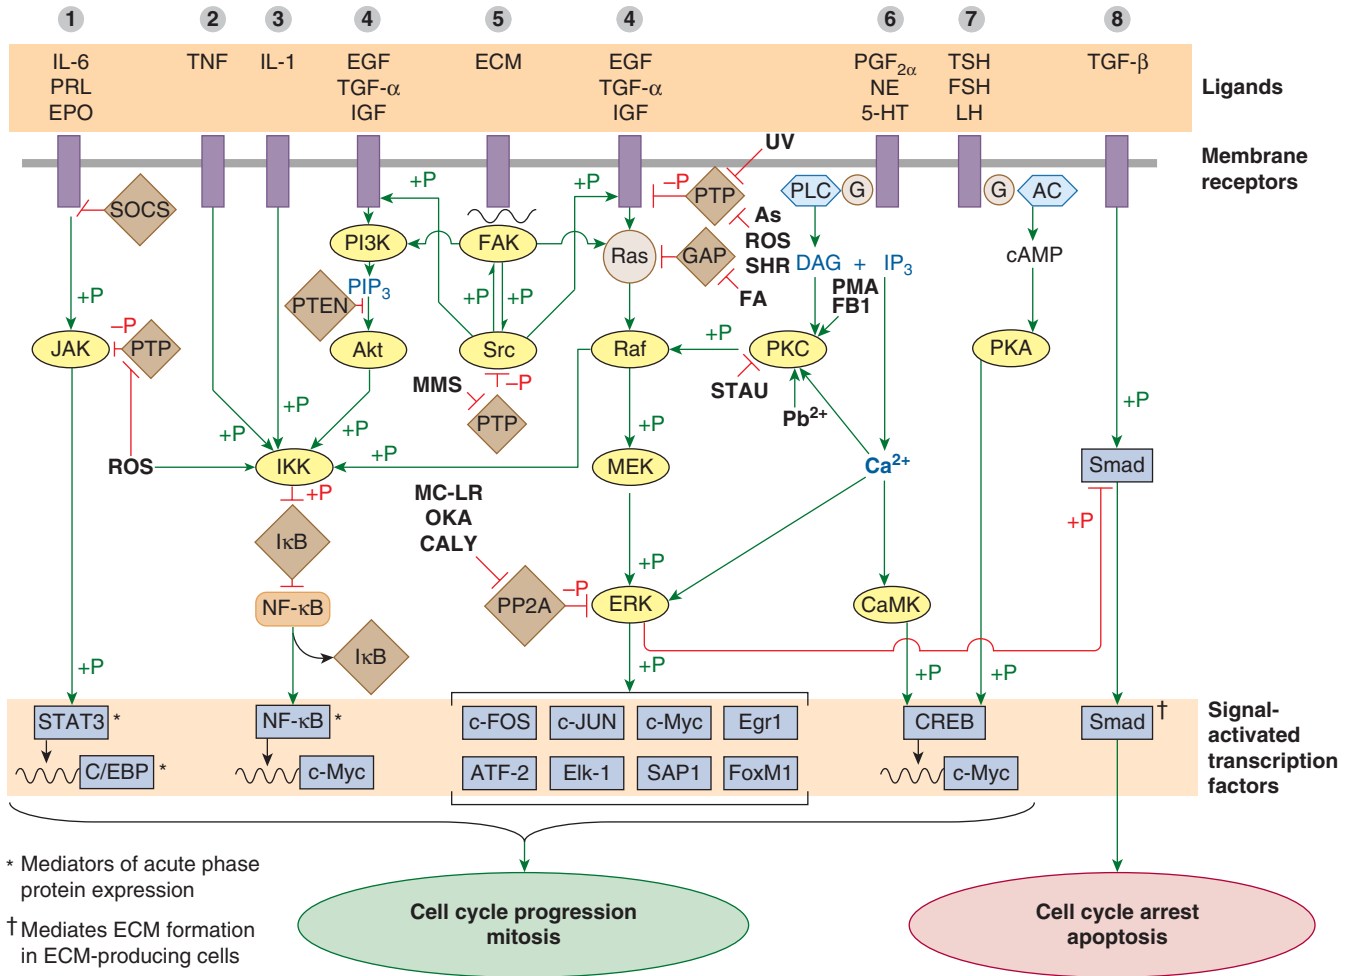

Figure 3-12. Some signal transduction pathways from cell membrane receptors to signal-activated nuclear transcription factors that influence transcription of genes involved in cell-cycle regulation. The symbols of cell membrane receptors are numbered 1 to 8 and some of their activating ligands are indicated. Circles represent G proteins, oval symbols protein kinases, rectangles transcription factors, wavy lines genes, and diamond symbols inhibitory proteins, such as protein phosphatases (PTP, PP2A) and the lipid phosphatase PTEN, the GTPase-activating protein GAP, and inhibitory binding proteins, such as I κ B and suppressor of cytokine signaling (SOCS). Arrowheads indicate stimulation or formation of second messengers (eg, DAG, IP₃, PIP₃, cAMP, Ca²⁺), whereas blunt arrows indicate inhibition. Phosphorylation and dephosphorylation are indicated by +P and -P, respectively. Abbreviations for interfering chemicals are printed in black (As, arsenite; CALY, calyculin A; FA, fatty acids; FB1, fumonisin B; MC-LR, microcystin-LR; OKA, okadaic acid; MMS, methylmethane sulfonate; PMA, phorbol miristate acetate; ROS, reactive oxygen species; SHR, SH-reactive chemicals, such as iodoacetamide; STAU, staurosporin).

Two important proliferative signaling can be evoked by growth factors, such as EGF, acting on their tyrosine kinase receptors (#4), which are duplicated in the figure for clarity. These receptors use adaptor proteins (Shc, Grb2, and SOS; not shown) to activate Ras by converting it from inactive GDP-bound form to active GTP-bound state, which in turn activates the MAP-kinase phosphorylation cascade built up from specific forms of MAPKKK, MAPKK, and MAPK proteins (here Raf, MEK, and ERK, respectively). The phosphorylated MAPK (eg, ERK) moves into the nucleus and phosphorylates transcription factors (eg, c-Fos), thereby enabling them to bind to cognate sequences in the promoter regions of genes (eg, cyclin genes) to facilitate transcription. The same growth factor receptors (#4) can signal through the phosphatidylinositol-3-kinase (PI3K)–Akt–I κ B–kinase (IKK)–I κ B–NF- κ B pathway (see the text for more details). There are numerous interconnections between the signal transduction pathways. For example, the G-protein-coupled receptor (#6) can relay signal into the MAPK pathway via phospholipase C (PLC)–catalyzed formation of second messengers that activate protein kinase C (PKC), whereas signals from TNF and IL-1 receptors (#2 and 3) are channeled into the PI3K–Akt–NF- κ B pathway by phosphorylating IKK. (Note that TNF may also signal for apoptosis when its receptor recruits an adaptor molecule FADD; see Fig. 3-19.) The integrin receptor (#5), whose ligands are constituents of the extracellular matrix (ECM), can also engage the growth factor receptors and Ras as well as PI3K via focal adhesion kinase (FAK) and the tyrosine kinase Src. The cell cycle acceleration induced by these and other signal transduction pathways is further enhanced by the ERK-catalyzed inhibitory phosphorylation of Smad that blocks the cell-cycle arrest signal from the TGF- β receptor (#8). Activation of protein kinases (PKC, CaMK, MAPK) by Ca²⁺ can also trigger mitogenic signaling. Several xenobiotics that are indicated in the figure may dysregulate the signaling network. Some may induce cell proliferation by either activating mitogenic protein kinases (eg, PKC) or inhibiting inactivating proteins, such as protein phosphatases (PTP, PP2A), GAP, or I κ B. Others, for example, inhibitors of PKC, oppose mitosis and facilitate apoptosis.

This scheme is oversimplified and tentative in several details. Virtually all components of the signaling network (eg, G proteins, PKCs, MAPKs) are present in multiple, functionally different forms whose distribution may be cell-specific. The pathways depicted are not equally relevant for all cells. In addition, these pathways regulating gene expression not only determine the fate of cells but also control certain aspects of the ongoing cellular activity. For example, NF- κ B induces synthesis of acute-phase proteins.

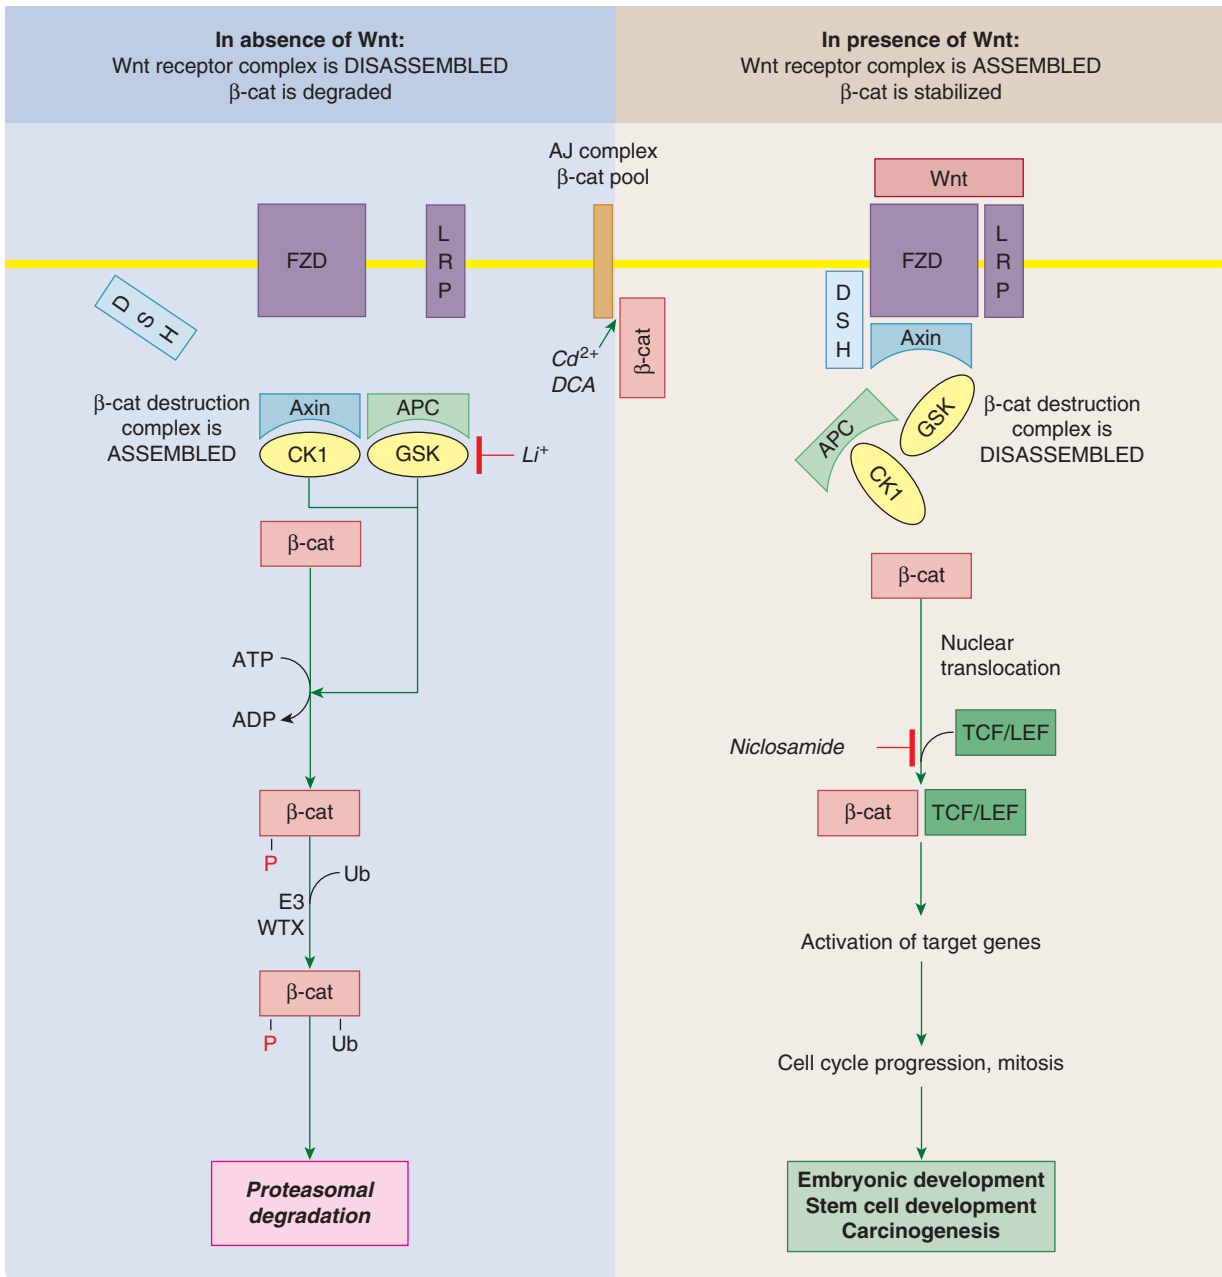

Figure 3-13. The Wnt signaling—a proliferative pathway especially important in embryogenesis, stem cell and progenitor cell development, and carcinogenesis. Wnt ligands are a secreted proteins covalently modified by palmitoylation and glycosylation. They act in autocrine, paracrine, or endocrine manner through their cell surface receptor frizzled (FZD) and coreceptor lipoprotein receptor–related protein (LRP).

In the absence of Wnt (as in the left side of the figure) intracellular proteins, including Axin, adenomatous polyposis coli (APC), casein kinase 1 (CK1), and glycogen synthase kinase 3 (GSK), form the so-called β-catenin (β-cat) destruction complex. The kinase members of this complex phosphorylate β-cat, thereby targeting it for ubiquitination by an E3 ubiquitin ligase (which is facilitated by WTX) and subsequent proteasomal degradation.

On binding of Wnt to FZD and LRP (as in the right side of the figure) the Wnt receptor complex assembles, and with recruitment of Axin into this complex, the β-cat destruction complex becomes disassembled. Consequently, β-cat escapes phosphorylation, ubiquitination, and degradation. Therefore, β-cat accumulates in the cell, translocates into the nucleus, and is recruited to its target genes by TCF/LEF family of transcription factors. Wnt signaling thus upregulates the transcription of numerous genes, including cyclin-D1, c-Myc, ABCB1 (P-glycoprotein), and S100A4 (a Ca²⁺-binding protein involved in cell cycle progression, cell motility, and metastasis development). Interestingly, β-cat is not only a transcriptional coactivator but also a structural protein that associates with E-cadherin at adherens junctions (AJ), thus participating in cell–cell adhesion. The disruption of E-cadherin–β-cat complexes causes an increase in β-cat-mediated transcription of Wnt-responsive genes. In contrast, stabilization of the E-cadherin–β-cat complex brings about reduced β-cat-mediated Wnt signaling.

Chemicals that influence Wnt signaling may interfere with embryonic development, cell proliferation, and carcinogenesis. Inhibition of GSK activity (eg, by Li⁺ ion) can lead to stabilization of β-cat and activation of β-cat-dependent gene transcription. Cd²⁺ disrupts the E-cadherin/β-cat complex of epithelial AJ, and the resultant β-cat-mediated proliferation of renal tubular cells could contribute to cadmium-induced nephrocarcinogenesis (Thévenod and Chakraborty, 2010). By a similar mechanism, deoxycholic acid (DCA) increases the proliferation and invasiveness of colon cancer cells. Inactivating mutations of APC and WTX, negative regulators of Wnt signaling, typically occur in colon cancer and Wilms tumor, respectively. The antihelminthic drug niclosamide inhibits formation of the β-cat-TCF/LEF complex at the promoter of S100A4 gene and thus counters colon cancer metastasis. DSH, disheveled; LEF, lymphoid enhancer-binding factor; TCF, T-cell factor; WTX, Wilms tumor suppressor.

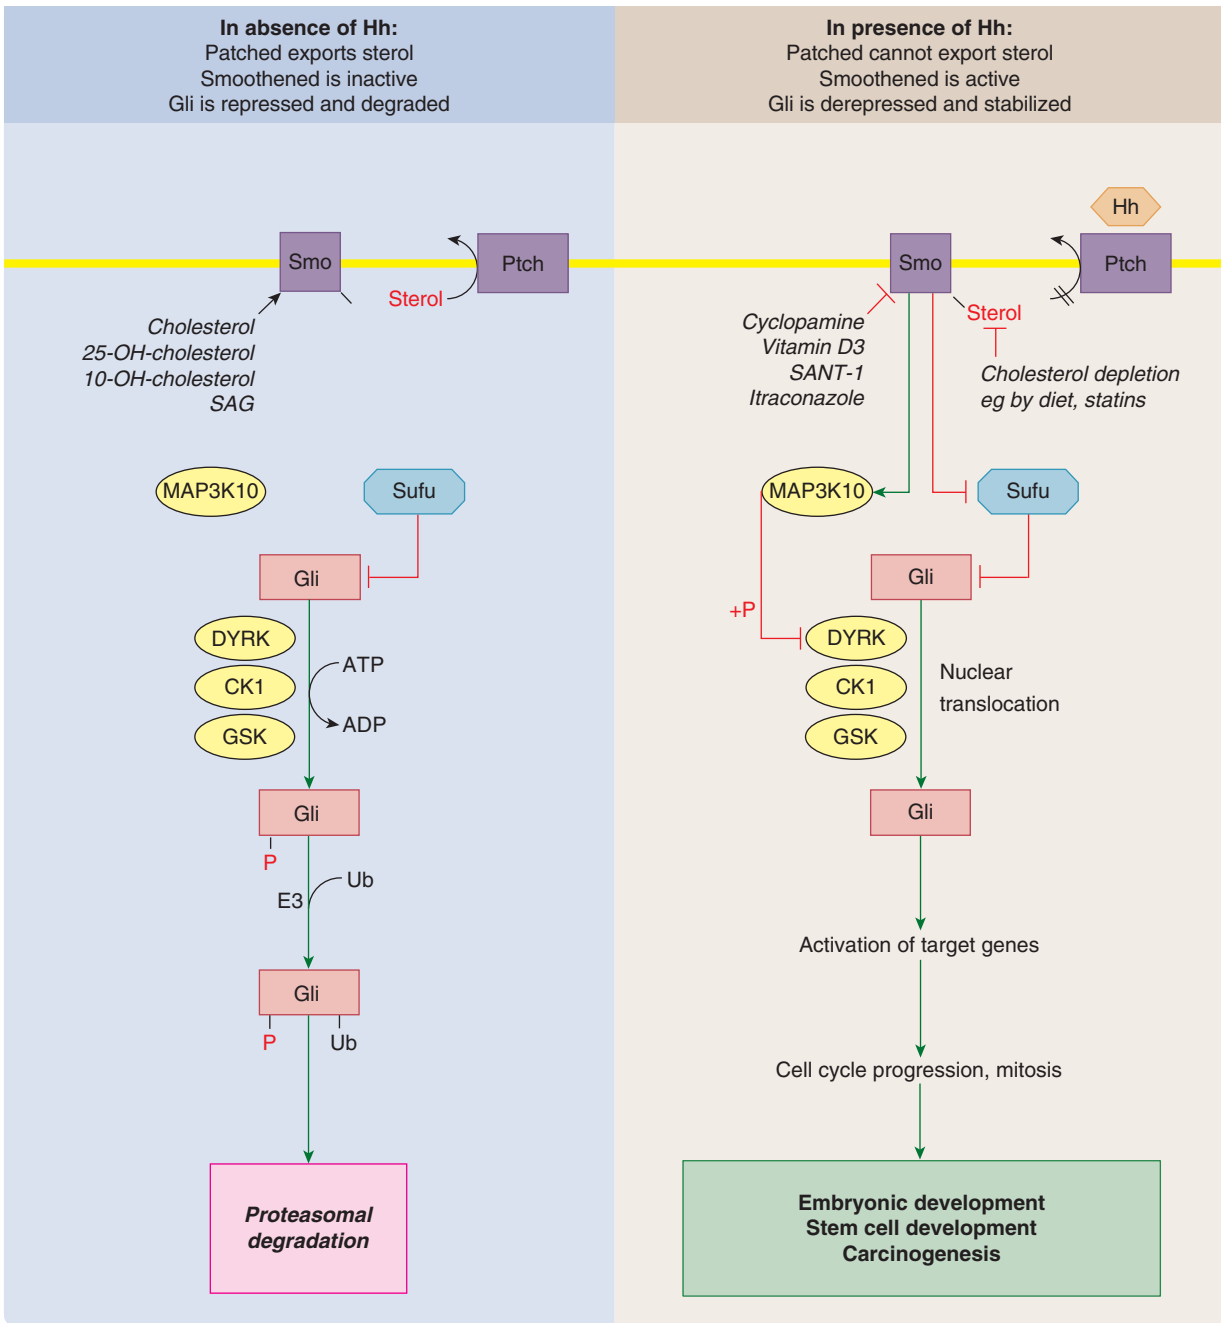

Figure 3-14. The hedgehog (Hh) signaling—a proliferative pathway especially important in embryogenesis, stem cell and progenitor cell development, and carcinogenesis. Hh ligands are secreted proteins covalently modified by palmitate and cholesterol. They act in autocrine, paracrine, or endocrine manner through their membrane receptor Patched (Ptch), which is the key inhibitor of Hh signaling in the unligated form (Katoh and Katoh, 2008).

In the absence of Hh (as in the left side of the figure) Ptch impedes the Hh pathway by inhibiting the activity of Smoothed (Smo), a positive regulator of signaling. According to the model presented in the figure, Ptch is a sterol pump that exports sterols (cholesterol or an oxysterol), thereby removing these activator molecules from Smo and making Smo idle. The repression of Smo by Ptch incapacitates the downstream Hh effectors, the glioma-associated family of transcription factors (Gli). This occurs partly because Gli is suppressed by Sufu (suppressor of fused) and partly because protein kinases, such as the dual-specificity tyrosine-(Y)-phosphorylation regulated kinase (DYRK), casein kinase 1 (CK1), and glycogen synthase kinase 3 (GSK), phosphorylate Gli, thereby marking Gli for ubiquitination by a ubiquitin ligase (E3) and subsequent degradation by the proteasome.

Binding of Hh to Ptch (as in the right side of the figure) abrogates its sterol-exporting activity; therefore, the sterol can activate Smo. In a manner incompletely understood, the active Smo suppresses Sufu, thereby permitting Gli activation, and activates mitogen-activated protein kinase kinase kinase 10 (MAP3K10), which in turn phosphorylates and inhibits DYRK, thereby preventing phosphorylation, ubiquitination, and proteasomal degradation of Gli. Thereafter the active Gli accumulates in the cell, translocates into the nucleus, and binds to its target genes. Hh signaling thus upregulates the transcription of numerous genes, including those that encode Ptch and Gli (a positive feedback loop), cyclin-D1 and -D2 (for cell cycle acceleration), several transcription factors such as those of the Forkhead box protein family (for cell fate determination), receptor ligands such as Jagged 2 (a ligand protein that activates Notch and related receptors), and ligand-binding proteins such as the Secreted frizzled-related protein 1 (SFRP1) that binds Wnt protein, thus preventing Wnt signaling (Fig. 3-13).

Chemicals that activate or inhibit Smo (shown in the left and right sides of the figure, respectively) may interfere with embryonic development. For example, the plant alkaloid cyclopamine inhibits Smo and causes cyclopia, a birth defect, in lambs. Smo inhibitors are potentially anticarcinogenic, whereas Smo activators may promote carcinogenesis by increased Hh signaling. Inactivating mutation of Ptch, the main inhibitor of Hh signaling, typically occurs in basal cell carcinoma of the skin that may be induced by UV and ionizing radiation, as well as arsenic exposure (Tang *et al.*, 2007). SAG, Smoothed Agonist; SANT-1, Smoothed Antagonist 1.

NF- κ B, this TF plays a leading role also in inflammatory and acute-phase reactions, as well as in cancer caused by chronic inflammation (Karin, 2006; Waddick and Uckun, 1999). Conversely, inactivation of a subtype of NF- κ B protein (RelA/p65) by binding to the TCDD-ligated AhR may contribute to the immunosuppressive effect of TCDD (Denison *et al.*, 2011). The proliferative Wnt signaling is also restrained by a set of binding proteins and protein kinases, the so-called β -catenin destruction complex that includes axin, adenomatous polyposis coli (APC), casein kinase 1 (CK1), and glycogen synthase kinase 3 (GSK), which destroy the transcriptional coactivator β -catenin by phosphorylation and ubiquitination (see Fig. 3-13). Impaired function of this complex (eg, by inactivating mutation of APC) can lead to unleashing the transcriptional coactivator β -catenin and in turn to colon cancer.

Another site from which aberrant mitogenic signals may originate is the GTP/GDP-binding protein Ras, which is active in GTP-bound form but inactive in GDP-bound form. The activity of Ras is normally terminated via stimulation of its own GTPase activity by a GTPase-activating protein (GAP) (Fig. 3-12) that returns Ras into its inactive GDP-bound state. Fatty acids, which may accumulate, for example, in response to phospholipase A activation and exposure to peroxisome proliferators (Rose *et al.*, 1999), inhibit GAP and can delay the turning off of Ras. As discussed in more detail later in the chapter, genotoxic carcinogens may mutate Ras, and if the mutation leads to a loss of its GTPase activity, this would result in permanent signaling for the MAPK pathway—a condition that contributes to malignant transformation of the affected cell population.

Finally, increased mobilization of a mitogenic TF from a “silent” intracellular pool may also be a mechanism for chemically altered signal transduction with proliferative effect. This may underlie, at least in part, the nephrocarcinogenicity of cadmium and the colon tumor-promoting action of secondary bile acids, such as deoxycholic acid. By disrupting the E-cadherin/ β -catenin complex in the adherens junctions (AJ) of renal and colonic epithelial cells, respectively, these chemicals mobilize β -catenin from AJ (where this protein serves a structural function) into the cytoplasm and the nucleus. There β -catenin functions as a TF of Wnt signaling (Fig. 3-13) and activates the transcription of several genes, including cyclin D1 that promotes the G1/S transition of cells in the cell division cycle.

Chemically Altered Signal Transduction with Antiproliferative Effect Turning off the increased proliferative signaling after cell injury may compromise replacement of injured cells. This prediction has been made from a study on cultured Hepa 1–6 cells that exhibited the following, seemingly consequential alterations on exposure to acetaminophen (follow the path in Fig. 3-12): inhibition of Raf \rightarrow diminished degradation of I κ B \rightarrow diminished binding of NF- κ B to DNA \rightarrow diminished expression of c-Myc mRNA (Boulares *et al.*, 1999). Downregulation of a normal mitogenic signal is a step away from survival and toward apoptosis. Indeed, inhibitors of PKC (staurosporin), PI3K (wortmannin), and I κ B degradation (gliotoxin) (Waddick and Uckun, 1999) are apoptosis inducers. TGF- β and glucocorticoids increase I κ B synthesis and, in turn, decrease NF- κ B activation and c-Myc expression (Waddick and Uckun, 1999). These mechanisms may contribute to the apoptotic effect of TGF- β and glucocorticoids, the latter in lymphoid cells.

Offsetting the Hh–Gli pathway (Fig. 3-14), a key mitogenic signaling pathway controlling embryonic development, is the mechanism of the teratogenic action of cyclopamine (ie, cyclopia). This severe cephalic malformation was observed in the offspring of sheep grazing in a field where *Veratrum californicum* grew. This plant contains the steroidal alkaloid cyclopamine, which is an inhibitor of Smoothened, a positive regulator of Hh signaling (Chen *et al.*, 2002).

Dysregulation of Extracellular Signal Production Hormones of the anterior pituitary exert mitogenic effects on endocrine glands in the periphery by acting on cell surface receptors. Pituitary hormone production is under negative feedback control by hormones of the peripheral glands. Perturbation of this circuit adversely affects pituitary hormone secretion and, in turn, the peripheral gland. For example, xenobiotics that inhibit thyroid hormone production (eg, the herbicide amitrole and the fungicide metabolite ethylenethiourea) or enhance thyroid hormone elimination (eg, phenobarbital) reduce thyroid hormone levels and increase the secretion of thyroid-stimulating hormone (TSH) because of the reduced feedback inhibition. The increased TSH secretion stimulates cell division in the thyroid gland, which is responsible for the goiters or thyroid tumors caused by such toxicants (see Chap. 21). Decreased secretion of pituitary hormone produces the opposite adverse effect, with apoptosis followed by involution of the peripheral target gland. For example, estrogens produce testicular atrophy in males by means of feedback inhibition of gonadotropin secretion. The low sperm count in workers intoxicated with the xenoestrogen chlordecone probably results from such a mechanism.

Dysregulation of Ongoing Cellular Activity Ongoing control of specialized cells is exerted by signaling molecules acting on membrane receptors that transduce the signal by regulating Ca²⁺ entry into the cytoplasm or stimulating the enzymatic formation of intracellular second messengers. The Ca²⁺ or other second messengers ultimately alter the phosphorylation of functional proteins, changing their activity and, in turn, cellular functions almost instantly. Toxicants can adversely affect ongoing cellular activity by disrupting any step in signal coupling.

Dysregulation of Electrically Excitable Cells Many xenobiotics influence cellular activity in excitable cells, such as neurons, skeletal, cardiac, and smooth muscle cells. Cellular functions such as the release of neurotransmitters and muscle contraction are controlled by transmitters and modulators synthesized and released by adjacent neurons. The major mechanisms that control such cells are shown schematically in Fig. 3-15, and chemicals that interfere with these mechanisms are listed in Table 3-5.

Altered regulation of neural and/or muscle activity is the basic mechanism of action of many drugs and is responsible for toxicities associated with drug overdosage, pesticides, and microbial, plant, and animal toxins (Herken and Hucho, 1992). As neurons are signal-transducing cells, the influence of chemicals on neurons is seen not only on the neuron affected by the toxicant but also on downstream cells influenced by the primary target. Thus, tetrodotoxin, which blocks voltage-gated Na⁺ channels (item 7 in Fig. 3-15) in motor neurons, causes skeletal muscle paralysis. In contrast, cyclodiene insecticides, which block GABA receptors (item 3 in Fig. 3-15) in the central nervous system, induce neuronal excitation and convulsions (Narahashi, 1991).

Perturbation of ongoing cellular activity by chemicals may be due to an alteration in (1) the concentration of neurotransmitters, (2) receptor function, (3) intracellular signal transduction, or (4) the signal-terminating processes.

Alteration in Neurotransmitter Levels Chemicals may alter synaptic levels of neurotransmitters by interfering with their synthesis, storage, release, or removal from the vicinity of the receptor. The convulsive effect of hydrazine and hydrazides (eg, isoniazid) is due to their ability to decrease the synthesis of the inhibitory neurotransmitter GABA (Gale, 1992). Reserpine causes its several adverse effects by inhibiting the neuronal storage of norepinephrine, 5-hydroxytryptamine, and dopamine, thereby depleting these

Figure 3-15. Signaling mechanisms for neurotransmitters. This simplified scheme depicts major cellular signaling mechanisms that are operational in many neurons and muscle and exocrine cells. Chemicals acting on the numbered elements are listed in Table 3-5. Fast signaling is initiated by the opening of ligand-gated $\text{Na}^+/\text{Ca}^{2+}$ channels (1, 2). The resultant cation influx decreases the inside negative potential (ie, evokes depolarization) and thus triggers the opening of the voltage-gated Na^+ and Ca^{2+} channels (7, 8). As a second messenger, the influxed Ca^{2+} activates intracellular Ca^{2+} -binding proteins such as calmodulin (CM) and troponin C (TC), which, in turn, enhance the phosphorylation of specific proteins, causing activation of specific cellular functions. The signal is terminated by channels and transporters (eg, 9, 10) that remove cations from the cells and thus reestablish the inside negative resting potential (ie, cause repolarization) and restore the resting Ca^{2+} level. Fast signaling can be suppressed by the ligand-activated Cl^- or K^+ channels (3–6), which increases the inside negativity (ie, induces hyperpolarization) and thus counteracts opening of the voltage-gated Na^+ and Ca^{2+} channels (7, 8). Signal transduction from other receptors (11–13) that are coupled to G_q proteins involves generation of the second messenger inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) by phospholipase C (PLC), whereas signaling from receptor 14 that is coupled to G_s protein involves production of cyclic AMP (cAMP) by adenylyl cyclase (AC). These second messengers in turn influence cellular activities by mobilizing Ca^{2+} from the sarcoplasmic or endoplasmic reticulum (SR and EPR), as IP_3 does, or by activating protein kinases, as cAMP and DAG do, which activate PKA and PKC, respectively. For clarity, this figure does not depict that inhibitory receptors 5 and 6 are G_i protein-coupled and that besides opening K^+ channels, they also inhibit AC. Ach, acetylcholine; Glu, glutamate; GABA, γ -aminobutyric acid; Gly, glycine; Op, opioid peptides; NE, norepinephrine; E, epinephrine; 5HT, 5-hydroxytryptamine; G, G protein; PIP_2 , phosphatidylinositol 4,5-bisphosphate. Encircled positive and negative signs indicate activation and inhibition, respectively.

transmitters. Skeletal muscle paralysis caused by botulinum toxin is due to inhibition of acetylcholine release from motor neurons and the lacking stimulation of the acetylcholine receptors at the neuromuscular junction (receptor 1 in Fig. 3-15). In contrast, inhibition of acetylcholinesterase by organophosphate or carbamate insecticides or chemical warfare agents (eg, soman) prevents the hydrolysis of acetylcholine, resulting in massive stimulation of cholinergic receptors (receptors 1, 5, and 11 in Fig. 3-15) and a cholinergic crisis (Table 3-5). Inhibition of the neuronal reuptake of norepinephrine by cocaine or tricyclic antidepressants is responsible for overexcitation of α_1 -adrenergic receptors on vascular smooth muscles, resulting in nasal mucosal ulceration and myocardial infarction in heavy cocaine abusers, whereas overstimulation of β_1 -adrenergic receptors contributes to life-threatening arrhythmias. Similar cardiac complications may result from amphetamine abuse, because amphetamine enhances the release of norepinephrine from adrenergic neurons and competitively inhibits neuronal reuptake of

this transmitter. A hypertensive crisis can occur with the combined use of tricyclic antidepressants and monoamine oxidase inhibitors, drugs that block different mechanisms of norepinephrine elimination (Hardman *et al.*, 1995). Concomitant use of drugs that increase the level of serotonin (5-HT) by enhancing its neuronal release and decreasing its neuronal reuptake (eg, fluoxetine) or its biotransformation (eg, monoamine oxidase inhibitors) induce the serotonin syndrome with cognitive and behavioral changes, autonomic dysfunction, and neuromuscular abnormalities. It is thought that cytotoxic antineoplastic drugs (eg, cisplatin) and radiation cause nausea and emesis, a disturbing reaction to chemotherapy and radiotherapy, by inducing release of 5-HT from enterochromaffin cells of the intestinal mucosa, which stimulates the 5-HT₃ receptors (5-HT-gated cation channel, functionally similar to item 1 in Fig. 3-15) on the adjacent vagal afferent neurons, thereby evoking the vomiting reflex (Endo *et al.*, 2000). Intestinal release of 5-HT and stimulation of vagal afferent neurons are also involved in the

Table 3-5

Agents Acting on Signaling Systems for Neurotransmitters and Causing Dysregulation of the Momentary Activity of Electrically Excitable Cells such as Neurons and Muscle Cells*

RECEPTOR/CHANNEL/PUMP		AGONIST/ACTIVATOR		ANTAGONIST/INHIBITOR	
NAME	LOCATION	AGENT	EFFECT	AGENT	EFFECT
1. Acetyl-choline nicotinic receptor	Skeletal muscle	Nicotine Anatoxin-a Cytisine <i>Ind:</i> ChE inhibitors	Muscle fibrillation, and then paralysis	Tubocurarine, lophotoxin α -Bungarotoxin α -Cobrotoxin α -Conotoxin Erabutoxin b <i>Ind:</i> botulinum toxin	Muscle paralysis
	Neurons	See above	Neuronal activation	Pb ²⁺ , general anesthetics	Neuronal inhibition
2. Glutamate receptor	CNS neurons	<i>N</i> -Methyl-D-aspartate Kainate, domoate Quinolate Quisqualate <i>Ind:</i> hypoxia, HCN → glutamate release	Neuronal activation → convulsion, neuronal injury (“excitotoxicity”)	Phencyclidine Ketamine General anesthetics	Neuronal inhibition → anesthesia Protection against “excitotoxicity”
3. GABA _A receptor	CNS neurons	Muscimol, Avermectins, Sedatives (barbiturates, benzodiazepines), General anesthetics (halothane), Alcohols (ethanol)	Neuronal inhibition → sedation, general anesthesia, coma, depression of vital centers	Bicuculline Picrotoxin Pentylene-tetrazole Cyclodiene insecticides Lindane, TCAD <i>Ind:</i> isoniazid	Neuronal activation → tremor, convulsion
4. Glycine receptor	CNS neurons, motor neurons	Avermectins (?), General anesthetics	Inhibition of motor neurons → paralysis	Strychnine <i>Ind:</i> tetanus toxin	Disinhibition of motor neurons → tetanic convulsion
5. Acetylcholine M ₂ muscarinic receptor	Cardiac muscle	<i>Ind:</i> ChE inhibitors	Decreased heart rate and contractility	Belladonna alkaloids (eg, atropine), atropine-like drugs (eg, TCAD)	Increased heart rate
6. Opioid receptor	CNS neurons, visceral neurons	Morphine and congeners (eg, heroin, meperidine) <i>Ind:</i> clonidine	Neuronal inhibition → analgesia, central respiratory depression, constipation, urine retention	Naloxone	Antidotal effects in opiate intoxication
7. Voltage-gated Na ⁺ channel	Neurons, muscle cells, etc	Aconitine, veratridine Grayanotoxin Batrachotoxin Scorpion toxins Ciguatoxin DDT, pyrethroids	Neuronal activation → convulsion	Tetrodotoxin, saxitoxin μ -Conotoxin Local anesthetics Phenytoin Quinidine	Neuronal inhibition → paralysis, anesthesia Anticonvulsive action
8. Voltage-gated Ca ²⁺ channel	Neurons, muscle cell, etc	Maitotoxin (?) Atrotoxin (?) Latrotoxin (?)	Neuronal/muscular activation, cell injury	ω -Conotoxin Pb ²⁺	Neuronal inhibition → paralysis
9. Voltage/Ca ²⁺ -activated K ⁺ channel	Neurons, smooth and skeletal muscle, cardiac muscle	Pb ²⁺	Neuronal/muscular inhibition	Ba ²⁺ , apamin (bee venom), dendrotoxin, 20-HETE, hERG inhibitors (eg, cisapride, terfenadine)	Neuronal/muscular activation → convulsion/spasm vasoconstriction, PMV tachycardia (torsade de pointes)

Table 3-5

(Continued)

RECEPTOR/CHANNEL/PUMP		AGONIST/ACTIVATOR		ANTAGONIST/INHIBITOR	
NAME	LOCATION	AGENT	EFFECT	AGENT	EFFECT
10. Na ⁺ ,K ⁺ -ATPase	Universal			Digitalis glycosides Oleandrin Chlordecone	Increased cardiac contractility, excitability Increased neuronal excitability → tremor
11. Acetylcholine M ₃ muscarinic receptor	Smooth muscle, glands	<i>Ind</i> : ChE inhibitors	Smooth muscle spasm, salivation, lacrimation	Belladonna alkaloids (eg, atropine), atropine-like drugs (eg, TCAD)	Smooth muscle relaxation → intestinal paralysis, decreased salivation, decreased perspiration
Acetylcholine M ₁ muscarinic receptor	CNS neurons	Oxotremorine <i>Ind</i> : ChE inhibitors	Neuronal activation → convulsion	See above	
12. Adrenergic α ₁ receptor	Vascular smooth muscle	(Nor)epinephrine <i>Ind</i> : cocaine, tyramine, amphetamine, TCAD	Vasoconstriction → ischemia, hypertension	Prazosin	Antidotal effects in intoxication with α ₁ -receptor agonists
13. 5-HT ₂ receptor	Smooth muscle	Ergot alkaloids (ergotamine, ergonovine)	Vasoconstriction → ischemia, hypertension	Ketanserine	Antidotal effects in ergot intoxication
14. Adrenergic β ₁ receptor	Cardiac muscle	(Nor)epinephrine <i>Ind</i> : cocaine, tyramine, amphetamine, TCAD	Increased cardiac contractility and excitability	Atenolol, metoprolol	Antidotal effects in intoxication with β ₁ -receptor agonists

CNS, central nervous system; ChE, cholinesterase; *Ind*, indirectly acting (ie, by altering neurotransmitter level); 20-HETE, 20-hydroxy-5,8,11,14-eicosatetraenoic acid; PMV, polymorphic ventricular; TCAD, tricyclic antidepressant.

*Numbering of the signaling elements in this table corresponds to the numbering of their symbols in Fig. 3-12. This tabulation is simplified and incomplete. Virtually all receptors and channels listed occur in multiple forms with different sensitivity to the agents. The reader should consult the pertinent literature for more detailed information.

emetic effect of ipecac syrup and its alkaloids (cephaelin and emetine). The α₂-adrenergic receptor agonist clonidine induces release in the brain of β-endorphin, an endogenous peptide that stimulates opioid receptors (item 6 in Fig. 3-15). This explains why clonidine intoxication mimics several symptoms of morphine poisoning, including depressed respiration and pinpoint pupils.

Toxicant–Neurotransmitter Receptor Interactions Some chemicals interact directly with neurotransmitter receptors, including (1) agonists that associate with the ligand-binding site on the receptor and mimic the natural ligand, (2) antagonists that occupy the ligand-binding site but cannot activate the receptor, (3) activators, and (4) inhibitors that bind to a site on the receptor that is not directly involved in ligand binding. In the absence of other actions, agonists and activators mimic, whereas antagonists and inhibitors block, the physiologic responses characteristic of endogenous ligands. For example, muscimol, a mushroom poison, is an agonist at the inhibitory GABA_A receptor (item 3 in Fig. 3-15), whereas barbiturates, benzodiazepines, general anesthetics, and alcohols are activators (Narahashi, 1991). Thus, all these chemicals cause inhibition of central nervous system activity, resulting in sedation, general anesthesia, coma, and ultimately blockade of the medullary

respiratory center, depending on the dose administered. There are also similarities in the responses evoked by agonist/activators on excitatory receptors and those elicited by antagonists/inhibitors on inhibitory sites. Thus, glutamate receptor agonists and muscarinic receptor agonists cause neuronal hyperactivity in the brain and ultimately convulsions, as do inhibitors of GABA_A receptor. It is also apparent that chemicals acting as agonists/activators on inhibitory receptors and those acting as antagonists/inhibitors on excitatory receptors may exert similar effects. Moreover, general anesthetic solvents induce general anesthesia not only by activating the inhibitory ligand-gated chloride-ion channels (ie, GABA_A and glycine receptors; see items 3 and 4, respectively, in Fig. 3-15) but also by inhibiting the excitatory ligand-gated cation channels (ie, neuronal nicotinic acetylcholine receptor and glutamate receptors; see items 1 and 2, respectively, in Fig. 3-15) (Franks and Lieb, 1998; Perouansky *et al.*, 1998). Because there are multiple types of receptors for each neurotransmitter, these receptors may be affected differentially by toxicants. For example, the neuronal nicotinic acetylcholine receptor is extremely sensitive to inhibition by lead ions, whereas the muscular nicotinic receptor subtype is not (Oortgiesen *et al.*, 1993). Other chemicals that produce neurotransmitter receptor–mediated toxicity are listed in Table 3-5.

Some sensory neurons have membrane receptors that are stimulated by noxious chemicals and operate as ligand-gated cation channels. Such are the transient receptor potential (TRP) channels, whose opening cause influx of Na^+ and Ca^{2+} that depolarize and activate the neuron. The TRPV1 receptor is excited by capsaicin, the pungent ingredient of red peppers, and mediates the burning sensation of the tongue and reflex stimulation of the lacrimal gland associated with exposure to pepper spray (also called OC tear gas). The TRPA1 receptor, however, is activated by thiol-reactive and oxidant chemicals, such as the lacrimator compounds in tear gas (eg, chloroacetophenone, chlorobenzalmalonitrile, and dibenzoxazepine), acrolein, methyl isocyanate, corrosive gases (eg, phosgene, chloropicrin, and chlorine) and other irritants. These chemicals evoke sensations (irritation and pain), secretory and respiratory reflexes (lacrimation, bronchial secretion, sneezing, coughing, and bronchospasm), and neurogenic inflammation through the TRPA1 receptor (Bessac and Jordt, 2010).

Toxicant–Signal Transducer Interactions Many chemicals alter neuronal and/or muscle activity by acting on signal transduction processes. Voltage-gated Na^+ channels (item 7 in Fig. 3-15), which transduce and amplify excitatory signals generated by ligand-gated cation channels (receptors 1 and 2 in Fig. 3-15), are activated by a number of toxins derived from plants and animals (Table 3-5) as well as by synthetic chemicals such as DDT, resulting in overexcitation (Narahashi, 1992). In contrast, chemicals that block voltage-gated Na^+ channels (such as tetrodotoxin and saxitoxin) cause paralysis. The Na^+ channels are also important in signal transduction in sensory neurons; therefore, Na^+ -channel activators evoke sensations and reflexes, whereas Na^+ -channel inhibitors induce anesthesia. This explains the reflex bradycardia and burning sensation in the mouth that follow the ingestion of monkshood, which contains the Na^+ -channel activator aconitine, as well as the use of Na^+ -channel inhibitors such as procaine and lidocaine for local anesthesia.

Toxicant–Signal Terminator Interactions The cellular signal generated by cation influx is terminated by removal of the cations through channels or by transporters (Fig. 3-15). Inhibition of cation efflux may prolong excitation, as occurs with the blockade of Ca^{2+} -activated K^+ channels (item 9 in Fig. 3-15) by Ba^{2+} , which is accompanied by potentially lethal neuroexcitatory and spasmogenic effects. The arachidonic acid metabolite 20-hydroxy-5,8,11,14-eicosatetraenoic acid (20-HETE) also blocks Ca^{2+} -activated K^+ channels, causing vasoconstriction. Induction by cyclosporine of 20-HETE production in renal proximal tubular cells and the resultant decrease in renal cortical blood flow may underlie the nephrotoxic effect of cyclosporine (Seki *et al.*, 2005). Blockade of specific voltage-gated K^+ channels (called hERG channels; item 9 in Fig. 3-15) in the heart delays cardiac repolarization (as indicated by prolonged QT time in ECG) and may evoke polymorphic ventricular tachycardia (termed torsade de pointes), which may cause sudden death if degenerates into ventricular fibrillation (Sanguinetti and Mitcheson, 2005). Several drugs with such an effect (eg, astemizole, cisapride, grepafloxacin, terfenadine) have been withdrawn from clinical use. Glycosides from digitalis and other plants inhibit Na^+, K^+ -ATPase (item 10 in Fig. 3-15) and thus increase the intracellular Na^+ concentration, which, in turn, decreases Ca^{2+} export by $\text{Ca}^{2+}/\text{Na}^+$ exchange (Fig. 3-15). The resultant rise in the intracellular concentration of Ca^{2+} enhances the contractility and excitability of cardiac muscle. Inhibition of brain Na^+, K^+ -ATPase by chlordecone may be responsible for the tremor observed in chlordecone-exposed workers (Desai, 1982). Lithium salts, although used therapeutically, have the potential to produce hyperreflexia, tremor, convulsions, diarrhea, and cardiac arrhythmias (Hardman *et al.*, 1995).

Lithium also markedly potentiates cholinergic-mediated seizures. Besides inhibition of Li^+ -sensitive enzymes (eg, inositol mono-phosphatase, bisphosphate 3'-nucleotidase, and GSK), another possible reason for these toxic effects is inefficient repolarization of neurons and muscle cells in the presence of Li^+ . Whereas Li^+ readily enters these cells through Na^+ channels, contributing to the signal-induced depolarization, it is not a substrate for the Na^+, K^+ pump. Therefore, the cells fail to repolarize properly if a fraction of intracellular Na^+ is replaced by Li^+ .

Failure of the Na^+, K^+ pump is also believed to contribute to the neuronal damage resulting from hypoxia, hypoglycemia, and cyanide intoxication. Inasmuch as 70% of the ATP produced in neurons is used to drive the Na^+, K^+ pump, cessation of ATP synthesis causes a cell to become or remain depolarized. The depolarization-induced release of neurotransmitters such as glutamate from such neurons is thought to be responsible for the hypoxic seizures and further amplification of neuronal injury by the neurotoxic actions of glutamate (Patel *et al.*, 1993).

Dysregulation of the Activity of Other Cells While many signaling mechanisms also operate in nonexcitable cells, disturbance of these processes is usually less consequential. For example, rat liver cells possess α_1 -adrenergic receptors (item 12 in Fig. 3-15) whose activation evokes metabolic changes, such as increased glycogenolysis and glutathione export, through elevation of intracellular Ca^{2+} , which may have toxicological significance.

Many exocrine secretory cells are controlled by muscarinic acetylcholine receptors (item 11 in Fig. 3-15). Salivation, lacrimation, and bronchial hypersecretion after organophosphate insecticide poisoning are due to stimulation of these receptors. In contrast, blockade of these receptors contributes to the hyperthermia characteristic of atropine poisoning. Kupffer cells, resident macrophages in the liver, secrete inflammatory mediators (see Fig. 3-26) that can harm neighboring cells. Because Kupffer cells possess glycine receptors, that is, glycine-gated Cl^- channels (item 4 in Fig. 3-15), the secretory function of these macrophages (eg, secretion of inflammatory mediators) can be blocked by administration of glycine, which induces hyperpolarization via influx of Cl^- . Such intervention alleviates ethanol-induced liver injury (Yin *et al.*, 1998).

The discovery that some sulfonamides produce hypoglycemia in experimental animals led to the development of oral hypoglycemic agents for diabetic patients. These drugs inhibit K^+ channels in pancreatic β cells, inducing sequential depolarization, Ca^{2+} influx through voltage-gated Ca^{2+} channels, and exocytosis of insulin (Hardman *et al.*, 1995). The antihypertensive diazoxide acts in the opposite fashion on K^+ channels and impairs insulin secretion. Whereas this effect is generally undesirable, it is exploited in the treatment of inoperable insulin-secreting pancreatic tumors.

Toxic Alteration of Cellular Maintenance

Numerous toxicants interfere with cellular maintenance functions. In a multicellular organism, cells must maintain their own structural and functional integrity as well as provide supportive functions for other cells. Execution of these functions may be disrupted by chemicals, resulting in a toxic response.

Impairment of Internal Cellular Maintenance: Mechanisms of Toxic Cell Death For survival, all cells must synthesize endogenous molecules; assemble macromolecular complexes, membranes, and cell organelles; maintain the intracellular environment; and produce energy for operation. Chemicals that disrupt these functions, especially the energy-producing function of mitochondria and protein synthesis controlling function of the genome, jeopardize survival and may cause toxic cell death.

There are three critical biochemical disorders that chemicals inflicting cell death may initiate, namely, ATP depletion, sustained rise in intracellular Ca^{2+} , and overproduction of ROS and RNS. In the following discussion, these events and the chemicals that may cause them are individually characterized. Then it is pointed out how their concerted action may induce a bioenergetic catastrophe, culminating in necrosis. Finally, there follows a discussion of the circumstances under which the cell can avoid this disordered decay and how it can execute death by activating catabolic processes that bring about an ordered disassembly and removal of the cell, called apoptosis.

Primary Metabolic Disorders Jeopardizing Cell Survival: ATP Depletion, Ca^{2+} Accumulation, ROS/RNS Generation

Depletion of ATP ATP plays a central role in cellular maintenance both as a chemical for biosynthesis and as the major source of energy. It is utilized in numerous biosynthetic reactions, activating endogenous compounds by phosphorylation and adenylation, and is incorporated into cofactors as well as nucleic acids. It is required for muscle contraction and polymerization of the cytoskeleton, fueling cellular motility, cell division, vesicular transport, and the maintenance of cell morphology. ATP drives ion transporters, such as the Na^+, K^+ -ATPase in the plasma membrane, the Ca^{2+} -ATPase in the plasma and the ER membranes, and H^+ -ATPase in the membrane of lysosomes and neurotransmitter-containing vesicles. These pumps maintain conditions essential for various cell functions. For example, the Na^+ concentration gradient across the plasma membrane generated by the Na^+, K^+ pump drives Na^+ -glucose and Na^+ -amino acid cotransporters as well as the $\text{Na}^+/\text{Ca}^{2+}$ antiporter, facilitating the entry of these nutrients and the removal of Ca^{2+} .

Chemical energy is released by hydrolysis of ATP to ADP or AMP. The ADP is rephosphorylated in the mitochondria by ATP synthase (Fig. 3-16). Coupled to oxidation of hydrogen to water, this process is termed *oxidative phosphorylation*. In addition to ATP synthase, oxidative phosphorylation requires the (1) delivery of hydrogen in the form of NADH to the initial electron transport complex; (2) delivery of oxygen to the terminal electron transport complex; (3) delivery of ADP and inorganic phosphate to ATP

synthase; (4) flux of electrons along the electron transport chain to O_2 , accompanied by ejection of protons from the matrix space across the inner membrane; and (5) return of protons across the inner membrane into the matrix space down an electrochemical gradient to drive ATP synthase (Fig. 3-16).

Several chemicals impede these processes, interfering with mitochondrial ATP synthesis (Commandeur and Vermeulen, 1990; Wallace and Starkov, 2000; Wallace, 2008). These chemicals are divided into 5 groups (Table 3-6). Substances in class A interfere with the delivery of hydrogen to the electron transport chain. For example, fluoroacetate inhibits the citric acid cycle and the production of reduced cofactors. Class B chemicals such as rotenone and cyanide inhibit the transfer of electrons along the electron transport chain to oxygen. Class C agents interfere with oxygen delivery to the terminal electron transporter, cytochrome oxidase. All chemicals that cause hypoxia ultimately act at this site. Chemicals in class D inhibit the activity of ATP synthase, the key enzyme for oxidative phosphorylation. At this site, the synthesis of ATP may be inhibited in one of four ways: (1) direct inhibition of ATP synthase, (2) interference with ADP delivery, (3) interference with inorganic phosphate delivery, and (4) deprivation of ATP synthase from its driving force, the controlled influx of protons into the matrix space. Protonophoric chemicals (uncouplers) such as 2,4-dinitrophenol and pentachlorophenol import protons into the mitochondrial matrix, dissipating the proton gradient that drives the controlled influx of protons into the matrix, which, in turn, drives ATP synthase. Finally, chemicals causing mitochondrial DNA injury, and thereby impairing synthesis of specific proteins encoded by the mitochondrial genome (eg, subunits of complex I and ATP synthase), are listed in group E. These include the dideoxynucleoside antiviral drugs used against AIDS, such as zidovudine. Table 3-6 lists other chemicals that impair ATP synthesis.

ATP synthase is also present at sites in addition to the mitochondria, such as the outer segment disk of the retinal rods as well as the plasma membrane of certain cells and the concentric membranes that form the myelin sheath around the axon of neurons. Unlike its mitochondrial counterpart, the ATP synthase in plasma and myelin

Figure 3-16. ATP synthesis (oxidative phosphorylation) in mitochondria. Arrows with letters A to D point to the ultimate sites of action of 4 categories of agents that interfere with oxidative phosphorylation (Table 3-6). For simplicity, this scheme does not indicate the outer mitochondrial membrane and that protons are extruded from the matrix space along the electron transport chain at 3 sites. β OX, beta-oxidation of fatty acids; e^- , electron; P_i , inorganic phosphate; ANT, adenine nucleotide translocator; ATP SYN, ATP synthase (F_0F_1 -ATPase).

Table 3-6

Agents Impairing Mitochondrial ATP Synthesis*

A. Inhibitors of hydrogen delivery to the electron transport chain acting on/as

- Glycolysis (critical in neurons): hypoglycemia; iodoacetate, koningic acid, and NO⁺ at GAPDH
- Gluconeogenesis (critical in renal tubular cells): coenzyme A depletors (see below)
- Fatty acid oxidation (critical in cardiac muscle): hypoglycin, 4-pentenoic acid, 4-ene-valproic acid
- Pyruvate dehydrogenase: arsenite, DCVC, *p*-benzoquinone
- Citrate cycle
 - Aconitase: fluoroacetate, ONOO⁻
 - Isocitrate dehydrogenase: DCVC
 - Succinate dehydrogenase: malonate, DCVC, PCBD-Cys, 2-bromohydroquinone, 3-nitropropionic acid, *cis*-crotonalide fungicides
- Depletors of TPP (inhibit TPP-dependent PDH and α -KGDH): ethanol (when chronically consumed)
- Depletors of coenzyme A (CoA)
 - Thiol-reactive electrophiles: 4-(dimethylamino)phenol, *p*-benzoquinone
 - Drugs enzymatically conjugated with CoA: salicylic acid (the metabolite of aspirin), valproic acid
- Depletors of NADH
 - See group A.V.1. in Table 3-7
 - Activators of poly(ADP-ribose) polymerase: agents causing DNA damage (eg, MNNG, hydrogen peroxide, ONOO⁻)

B. Inhibitors of electron transport acting on/as

- Inhibitors of electron transport complexes
 - NADH-coenzyme Q reductase (complex I): rotenone, amytal, MPP⁺, paraquat
 - Coenzyme Q-cytochrome *c* reductase (complex III): antimycin-A, myxothiazole
 - Cytochrome oxidase (complex IV): cyanide, hydrogen sulfide, azide, formate, *NO, phosphine (PH₃)
 - Multisite inhibitors: dinitroaniline and diphenylether herbicides, ONOO⁻
- Electron acceptors: CCl₄, doxorubicin, menadione, MPP⁺

C. Inhibitors of oxygen delivery to the electron transport chain

- Chemicals causing respiratory paralysis: CNS depressants (eg, opioids), convulsants
- Chemicals impairing pulmonary gas exchange: CO₂, "deep pulmonary irritants" (eg, NO₂, phosgene, perfluoroisobutene)
- Chemicals inhibiting oxygenation of Hb: carbon monoxide, methemoglobin-forming chemicals
- Chemicals causing ischemia: ergot alkaloids, cocaine

D. Inhibitors of ADP phosphorylation acting on/as

- ATP synthase: oligomycin, cyhexatin, DDT, chlordecone
- Adenine nucleotide translocator: atractyloside, DDT, free fatty acids, lysophospholipids
- Phosphate transporter: *N*-ethylmaleimide, mersalyl, *p*-benzoquinone
- Chemicals dissipating the mitochondrial membrane potential (uncouplers)
 - Cationophores: pentachlorophenol, dinitrophenol-, benzonitrile-, thiadiazole herbicides, salicylate, CCCP, cationic amphiphilic drugs (bupivacaine, perhexiline), valinomycin, gramicidin, calcimycin (A23187)
 - Chemicals permeabilizing the mitochondrial inner membrane: PCBD-Cys, chlordecone
- Multisite inhibitor drugs: phenformin, propofol, salicylic acid (when overdosed)

E. Chemicals causing mitochondrial DNA damage and/or impaired transcription of key mitochondrial proteins

- Antiviral drugs: zidovudine, zalcitabine, didanosine, fialuridine
- Antibiotics: chloramphenicol (when overdosed), linezolid
- Ethanol (when chronically consumed)

CCCP, carbonyl cyanide *m*-chlorophenylhydrazone; DCVC, dichlorovinyl-cysteine; GAPDH, glyceraldehyde 3-phosphate dehydrogenase; α -KGDH, α -ketoglutarate dehydrogenase; MNNG, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine; MPP⁺, 1-methyl-4-phenylpyridinium; PCBD-Cys, pentachlorobutadienylcysteine; PDH, pyruvate dehydrogenase; TPP, thiamine pyrophosphate.

*The ultimate sites of action of these agents are indicated in Fig. 3-13.

membranes forms ATP on the external membrane face and is called ecto-ATP synthase. It is hypothesized that ATP produced by the myelinic ATP synthase (supported by the colocalized respiratory chain complexes and O₂ well dissolved in the myelin lipids) is delivered into the axon through gap junctions that traverse the myelin membranes and the axolemma (Morelli *et al.*, 2011). Myelinic ATP supply to axons, in which mitochondria are sparse, may explain why demyelinated axons die and why the white matter (composed of myelinated axons) is sensitive to hypoxia. Oxidative phosphorylation of ADP in isolated myelin vesicles (which are devoid of mitochondria) is sensitive to chemicals listed in Table 3-6 as mitochondrial

electron transport chain inhibitors (eg, antimycin and cyanide), ATP synthase inhibitors (eg, oligomycin), and uncouplers (eg, CCCP and valinomycin). If the trophic role of myelin in axonal maintenance under *in vivo* conditions becomes validated, it will be necessary to evaluate whether the ATP-synthesizing machinery of myelin is a relevant target for known neurotoxicants, such as lead, methyl mercury, hexachlorophene, and the methanol-derived formic acid.

Impairment of oxidative phosphorylation is detrimental to cells because failure of ADP rephosphorylation results in the accumulation of ADP and its breakdown products as well as depletion of ATP. Accordingly, hepatocytes exposed to KCN and iodoacetate

exhibit a rapid rise in cytosolic H^+ and Mg^{2+} as a result of the hydrolysis of adenosine diphosphates and triphosphates (existing as Mg salts) and the release of phosphoric acid and Mg^{2+} (Herman *et al.*, 1990). The increased conversion of pyruvate to lactate also may contribute to the acidosis. The lack of ATP compromises the operation of ATP-requiring ion pumps, leading to the loss of ionic and volume-regulatory controls (Buja *et al.*, 1993). Shortly after intracellular acidosis and hypermagnesemia, liver cells exposed to KCN and iodoacetate exhibit a rise in intracellular Na^+ , probably as a result of the failing Na^+ pump, after which plasma membrane blebs appear. The intracellular phosphoric acidosis is beneficial for the cells presumably because the released phosphoric acid forms insoluble calcium phosphate, preventing the rise of cytosolic Ca^{2+} , with its deleterious consequences (see below). In addition, a low pH also directly decreases the activity of phospholipases and inhibits mitochondrial permeability transition (MPT; see later). Terminally, the intracellular pH rises, increasing phospholipase activity, and this contributes to irreversible membrane damage (ie, rupture of the blebs) not only by degrading phospholipids but also by generating endogenous detergents such as lysophospholipids and free fatty acids. The lack of ATP aggravates this condition because the reacylation of lysophospholipids with fatty acids is impaired.

Sustained Rise of Intracellular Ca^{2+} Intracellular Ca^{2+} levels are highly regulated (Fig. 3-17). The 10,000-fold difference between extracellular and cytosolic Ca^{2+} concentration is maintained by the impermeability of the plasma membrane to Ca^{2+} and by transport mechanisms that remove Ca^{2+} from the cytoplasm (Richter and Kass, 1991). Ca^{2+} is actively pumped from the cytosol across the plasma membrane and is sequestered in the ER and mitochondria (Fig. 3-17). Because mitochondria are equipped with a low-affinity

Figure 3-17. Four mechanisms for the elimination of Ca^{2+} from the cytoplasm: Ca^{2+} -ATPase-mediated pumping into (1) the extracellular space as well as (2) the endoplasmic reticulum (EPR) and ion-gradient-driven transport into (3) the extracellular space (by the Ca^{2+}/Na^+ exchanger) as well as (4) the mitochondria (M; by the Ca^{2+} uniporter). Some chemicals that inhibit these mechanisms are listed in Table 3-7, group B.

Ca^{2+} transporter, they play a significant role in Ca^{2+} sequestration only when the cytoplasmic levels rise into the micromolar range. Under such conditions, a large amount of Ca^{2+} accumulates in the mitochondria, where it is deposited as calcium phosphate.

Toxicants induce elevation of cytoplasmic Ca^{2+} levels by promoting Ca^{2+} influx into or inhibiting Ca^{2+} efflux from the cytoplasm (Table 3-7). Opening of the ligand- or voltage-gated Ca^{2+} channels

Table 3-7

Agents Causing Sustained Elevation of Cytosolic Ca^{2+}

A. Chemicals inducing Ca^{2+} influx into the cytoplasm

- I. Via ligand-gated channels in neurons
 1. Glutamate receptor agonists (“excitotoxins”): glutamate, kainate, domoate
 2. TRPV1 receptor (capsaicin receptor) agonists: capsaicin, resiniferatoxin
 3. TRPA1 receptor agonists: SH-reactive electrophiles, such as lacrimators (eg, chlorobenzalmalonitrile), acrolein, methyl isocyanate, phosgene, chloropicrin
- II. Via voltage-gated channels: maitotoxin (?), HO^{\bullet}
- III. Via “newly formed pores”: maitotoxin, amphotericin B, chlordecone, methylmercury, alkyltins
- IV. Across disrupted cell membrane
 1. Detergents: exogenous detergents, lysophospholipids, free fatty acids
 2. Hydrolytic enzymes: phospholipases in snake venoms, endogenous phospholipase A_2
 3. Lipid peroxidants: carbon tetrachloride
 4. Cytoskeletal toxins (by inducing membrane blebbing): cytochalasins, phalloidin
- V. From mitochondria
 1. Oxidants of intramitochondrial NADH: alloxan, *t*-BHP, NAPBQI, divicine, fatty acid hydroperoxides, menadione, MPP^+
 2. Others: phenylarsine oxide, gliotoxin, $^{\bullet}NO$, $ONOO^-$
- VI. From the endoplasmic reticulum
 1. IP_3 receptor activators: γ -HCH (lindane), IP_3 formed during “excitotoxicity”
 2. Ryanodine receptor activators: δ -HCH

B. Chemicals inhibiting Ca^{2+} export from the cytoplasm (inhibitors of Ca^{2+} -ATPase in cell membrane and/or endoplasmic reticulum)

- I. Covalent binders: acetaminophen, bromobenzene, CCl_4 , chloroform, DCE
- II. Thiol oxidants: cystamine (mixed disulfide formation), diamide, *t*-BHP, $O_2^{\bullet-}$, and $HOOH$ generators (eg, menadione, diquat)
- III. Others: vanadate, Cd^{2+} , thapsigargin (specific SERCA inhibitor)
- IV. Chemicals impairing mitochondrial ATP synthesis (see Table 3-6)

KEY: DCE, 1,1-dichloroethylene; *t*-BHP, *t*-butyl hydroperoxide; HCH, hexachlorocyclohexane; MPP^+ , 1-methyl-4-phenylpyridinium; NAPBQI, *N*-acetyl-*p*-benzoquinoneimine; SERCA, sarco/endoplasmic reticulum calcium ATPase.

or damage to the plasma membrane causes Ca^{2+} to move down its concentration gradient from extracellular fluid to the cytoplasm. Toxicants also may increase cytosolic Ca^{2+} by inducing its leakage from the mitochondria or the EPR. They also may diminish Ca^{2+} efflux through inhibition of Ca^{2+} transporters or depletion of their driving forces. Several chemicals that can cause a sustained rise in cytoplasmic Ca^{2+} levels are listed in Table 3-7.

Sustained elevation of intracellular Ca^{2+} is harmful because it can result in (1) depletion of energy reserves, (2) dysfunction of microfilaments, (3) activation of hydrolytic enzymes, and (4) generation of ROS and RNS. There are at least 3 mechanisms by which sustained elevations in intracellular Ca^{2+} unfavorably influence the cellular energy balance. First, high cytoplasmic Ca^{2+} concentrations cause increased mitochondrial Ca^{2+} uptake by the Ca^{2+} “uniporter,” which, like ATP synthase, utilizes the inside negative mitochondrial membrane potential ($\Delta\Psi\text{m}$) as the driving force. Consequently, mitochondrial Ca^{2+} uptake dissipates $\Delta\Psi\text{m}$ and inhibits the synthesis of ATP. Moreover, chemicals that oxidize mitochondrial NADH activate a transporter that extrudes Ca^{2+} from the matrix space (Richter and Kass, 1991). The ensuing continuous Ca^{2+} uptake and export (“ Ca^{2+} cycling”) by the mitochondria further compromise oxidative phosphorylation. Second, Ca^{2+} may also impair ATP synthesis by causing oxidative injury to the inner membrane by mechanisms described later. Third, a sustained rise in cytoplasmic Ca^{2+} not only impairs ATP synthesis but also increases ATP consumption by the Ca^{2+} -ATPases working to eliminate the excess Ca^{2+} .

A second mechanism by which an uncontrolled rise in cytoplasmic Ca^{2+} causes cell injury is microfilament dissociation (Nicotera *et al.*, 1992; Leist and Nicotera, 1997). The cell-wide network of actin filaments maintains cellular morphology by attachment of the filaments to actin-binding proteins in the plasma membrane. An increase of cytoplasmic Ca^{2+} causes dissociation of actin filaments from α -actinin and fodrin, proteins involved in anchoring the filaments to the plasma membrane. This represents a mechanism leading to plasma membrane blebbing, a condition that predisposes the membrane to rupture.

A third event whereby high Ca^{2+} concentrations are deleterious to cells is activation of hydrolytic enzymes that degrade proteins, phospholipids, and nucleic acids (Nicotera *et al.*, 1992; Leist and Nicotera, 1997). Many integral membrane proteins are targets for Ca^{2+} -activated neutral proteases, or calpains (Liu *et al.*, 2004). Calpain-mediated hydrolysis of actin-binding proteins may also cause membrane blebbing. Indiscriminate activation of phospholipases by Ca^{2+} causes membrane breakdown directly and by the generation of detergents. Activation of a Ca^{2+} - Mg^{2+} -dependent endonuclease causes fragmentation of chromatin. Elevated levels of Ca^{2+} can lock topoisomerase II in a form that cleaves but does not religate DNA. In summary, intracellular hypercalcemia activates several processes that interfere with the ability of cells to maintain their structural and functional integrity. The relative importance of these processes in vivo requires further definition.

Overproduction of ROS and RNS There are a number of xenobiotics that can directly generate ROS and RNS, such as the redox cyclers (Fig. 3-3) and the transition metals (Fig. 3-4). In addition, overproduction of ROS and RNS can be secondary to the intracellular hypercalcemia, as Ca^{2+} activates enzymes that generate ROS and/or RNS in the following ways:

1. Activation of the dehydrogenases in the citric acid cycle by Ca^{2+} accelerates the hydrogen output from the citrate cycle and, in turn, the flux of electrons along the electron transport chain (see Fig. 3-16). This, together with the suppressed

ATP-synthase activity (owing to the Ca^{2+} -induced uncoupling), increases the formation of O_2^{\bullet} by the mitochondrial electron transport chain.

2. Ca^{2+} -activated proteases proteolytically convert xanthine dehydrogenase into xanthine oxidase, whose by-products are O_2^{\bullet} and HOOH (Harrison, 2002).
3. Neurons and endothelial cells constitutively express NOS that is activated by Ca^{2+} . Given the extremely high reactivity of $\bullet\text{NO}$ with O_2^{\bullet} , coproduction of these radicals will inevitably lead to formation of ONOO⁻, a highly reactive oxidant (Murphy, 1999) (Fig. 3-4). Moreover, ONOO⁻ can increase its own formation by incapacitating the highly sensitive Mn-SOD, which would eliminate O_2^{\bullet} , a precursor of ONOO⁻.

Interplay between the Primary Metabolic Disorders Spells Cellular Disaster

The primary derailments in cellular biochemistry discussed above do not remain isolated but interact and amplify each other in a number of ways (Fig. 3-18):

1. Depletion of cellular ATP reserves deprives the endoplasmic and plasma membrane Ca^{2+} pumps of fuel, causing elevation of Ca^{2+} in the cytoplasm. With the influx of Ca^{2+} into the mitochondria, $\Delta\Psi\text{m}$ declines, hindering ATP synthase.
2. As stated above, intracellular hypercalcemia facilitates formation of ROS and RNS, which oxidatively inactivate the thiol-dependent Ca^{2+} pump, which, in turn, aggravates the hypercalcemia.
3. The ROS and RNS can also drain the ATP reserves. $\bullet\text{NO}$ is a reversible inhibitor of cytochrome oxidase; NO^+ (nitrosonium cation, a product of $\bullet\text{NO}$) S-nitrosylates and thus inactivates glyceraldehyde 3-phosphate dehydrogenase, impairing glycolysis, whereas ONOO⁻ irreversibly inactivates respiratory chain complexes I, II, III, and aconitase (by reacting with their Fe-S center) (Murphy, 1999). Therefore, $\bullet\text{NO}$ and ONOO⁻ inhibit cellular ATP synthesis.
4. Furthermore, ONOO⁻ can induce DNA SSB, which activates poly(ADP-ribose) polymerase (PARP) (Szabó, 1996). As part of the repair strategy, activated PARP transfers multiple ADP-ribose moieties from NAD^+ to nuclear proteins and PARP itself (D'Amours *et al.*, 1999). Consumption of NAD^+ severely compromises ATP synthesis (see Fig. 3-16), whereas

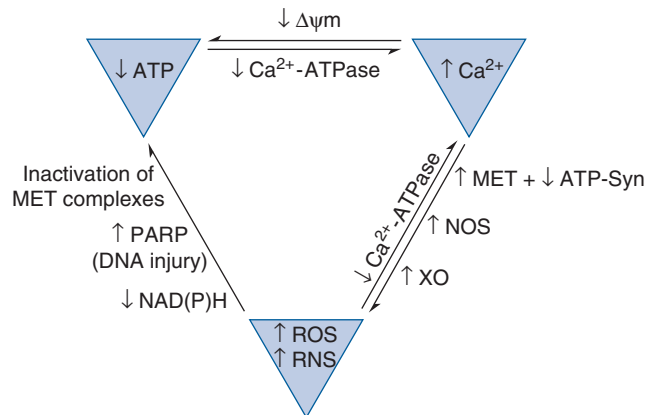

Figure 3-18. Interrelationship between the primary metabolic disorders (ATP depletion, intracellular hypercalcemia, and overproduction of ROS/RNS) that ultimately cause necrosis or apoptosis. See text for details. ATP-Syn, ATP synthase; MET, mitochondrial electron transport; NOS, nitric oxide synthase; PARP, poly(ADP-ribose) polymerase; ROS, reactive oxygen species; RNS, reactive nitrogen species; XO, xanthine oxidase; $\Delta\Psi\text{m}$, mitochondrial membrane potential.

resynthesis of NAD^+ consumes ATP. Hence, a major consequence of DNA damage by ONOO^- is a cellular energy deficit (Murphy, 1999).

The chain of events and their contribution to the worsening metabolic conditions are somewhat cell- and toxicant-specific. For example, cyanide toxicity in neurons is associated with depolarization and glutamate release (Patel *et al.*, 1993), followed by Ca^{2+} influx through voltage-gated as well as glutamate-gated channels (see items 8 and 2, respectively, in Fig. 3-15). As they express Ca^{2+} -activated NOS, neurons are also prone to generate “nitrosative stress,” which affects not only themselves but also perhaps more significantly the neighboring astrocytes (Szabó, 1996). In contrast, in cyanide- and iodoacetate-poisoned liver cells, the increase in cytoplasmic Ca^{2+} is not an early event (Herman *et al.*, 1990). A nitrosative stress critically contributes to propagation of acetaminophen-induced hepatocellular injury, in which the initiating event is covalent binding of *N*-acetyl-*p*-benzoquinoneimine (NAPBQI) to mitochondrial proteins (Jaeschke and Bajt, 2006). This purportedly causes a surge in mitochondrial (O_2^{\cdot}) generation, followed by *in situ* formation of ONOO^- . Owing to depletion of the protective glutathione by NAPBQI, ONOO^- readily nitrates mitochondrial proteins. Concomitantly, covalent binding incapacitates the plasma membrane Ca^{2+} pump and the resultant hypercalcemia further deteriorates mitochondrial function and ATP production. It appears that in this and many other cytotoxicities the interplay of ATP depletion, intracellular hypercalcemia, and overproduction of ROS and RNS, involving multiple vicious cycles (Fig. 3-18), can progressively aggravate the biochemical disorder until it becomes a disaster.

Mitochondrial Permeability Transition and the Worst Outcome: Necrosis

Mitochondrial Ca^{2+} uptake, decreased $\Delta\Psi\text{m}$, generation of ROS and RNS, depletion of ATP, and consequences of the primary metabolic disorders (eg, accumulation of inorganic phosphate, free fatty acids, and lysophosphatides) are all considered as causative factors of an abrupt increase in the mitochondrial inner-membrane permeability, termed MPT. This is thought to be caused by misfolded proteins from the inner and outer membranes, which aggregate and open a proteinaceous pore (“megachannel”) that spans both mitochondrial membranes (Kroemer *et al.*, 1998; Kim *et al.*, 2003; Rodriguez-Enriquez *et al.*, 2004). As this pore is permeable to solutes of size <1500 Da, its opening permits free influx of protons into the matrix space, causing rapid and complete dissipation of $\Delta\Psi\text{m}$ and cessation of ATP synthesis as well as osmotic influx of water, resulting in mitochondrial swelling. Ca^{2+} that accumulates in the matrix space effluxes through the pore, flooding the cytoplasm. Such mitochondria not only are incapable of synthesizing ATP but also even waste the remaining resources because depolarization of the inner membrane forces the ATP synthase to operate in the reverse mode, as an ATPase, hydrolyzing ATP. Then even glycolysis may become compromised by the insufficient ATP supply to the ATP-requiring glycolytic enzymes (hexokinase, phosphofructokinase). A complete bioenergetic catastrophe ensues in the cell if the metabolic disorders evoked by the toxic chemical (such as ones listed in Tables 3-6 and 3-7) are so extensive that most or all mitochondria in the cell undergo MPT, causing depletion of cellular ATP (see Fig. 3-20). Degradative processes already outlined (eg, oxidative and hydrolytic degradation of macromolecules and membranes as well as disintegration of intracellular solute and volume homeostasis) will go to completion, causing a complete failure in maintenance of cellular structure and functions and culminating in cell lysis or necrosis.

An Alternative Outcome of MPT: Apoptosis Chemicals that adversely affect cellular energy metabolism, Ca^{2+} homeostasis, and redox state and then ultimately cause necrosis may also induce apoptosis, another form of cell demise. Whereas the necrotic cell swells and lyses, the apoptotic cell shrinks; its nuclear and cytoplasmic materials condense, and then it breaks into membrane-bound fragments (apoptotic bodies) that are phagocytosed (Wyllie, 1997).

As discussed above, the multiple metabolic defects that a cell suffers in its way to necrosis are causal yet rather random in sequence. In contrast, the routes to apoptosis are ordered, involving cascade-like activation of catabolic processes that finally disassemble the cell. A scheme of the apoptotic pathways is presented in Fig. 3-19. Pathways initiated by EPR stress will be dealt with in the section “Mechanisms of Adaptation.”

It appears that most if not all chemical-induced cell deaths will involve the mitochondria, and the resulting mitochondrial dysfunction (such as Ca^{2+} accumulation, dissipation of $\Delta\Psi\text{m}$, and overproduction of ROS/RNS) may ultimately trigger either necrosis or apoptosis, and that MPT can be a crucial event in both. A related event is release into the cytoplasm of cytochrome *c* (cyt *c*), a small positively charged heme protein that normally resides in the mitochondrial intermembrane space attached electrostatically to cardiolipin, a specific inner membrane phospholipid with excess negative charge. Peroxidation of cardiolipin by HOOH , a process catalyzed by cyt *c*, results in detachment of cyt *c* from the lipid, which may be a critical first step of cyt *c* release into the cytoplasm (Orrenius *et al.*, 2011).

The significance of cyt *c* release is two-fold (Cai *et al.*, 1998): (1) as cyt *c* is the penultimate link in the mitochondrial electron transport chain, its loss will block ATP synthesis, increase formation of O_2^{\cdot} (instead of $\text{O}_2^{\cdot-}$ as shown in Fig. 3-16), and potentially thrust the cell toward necrosis. (2) Simultaneously, the unleashed cyt *c* (and some other proteins set free from the mitochondria) represents a signal or an initial link in the chain of events directing the cell to the apoptotic path (Cain, 2003) (Fig. 3-19). Cyt *c* together with dATP/ATP induces the cytoplasmic adapter protein apoptotic protease activating factor (Apaf-1) to oligomerize and bind the latent procaspase-9 (forming a complex called apoptosome), facilitating its conversion to active caspase-9.

Caspases are cysteine proteases (ie, they possess a catalytically active cysteine) that cleave proteins after specific aspartate residues. They reside mostly in the cytoplasm in inactive forms, as procaspases, which are activated by either dimerization (initiators) or proteolytic cleavage (effectors) (Boatright and Salvesen, 2003). Perhaps in order to guarantee that inadvertent activation of caspases should not occur, IAPs, such as XIAP and cIAP, reside in the cytoplasm and physically capture caspases that might have become activated (Cain, 2003). Therefore, cyt *c* alone probably could not induce sufficiently strong caspase activation if it were not for proteins that physically remove the IAPs from the caspases just being activated. These proteins, named Smac and Omi (or Diablo and HtrA2, respectively), are not only the helpers of cyt *c* but also residents of the mitochondrial intermembrane space, from where they are jointly mobilized to promote the caspase cascade. Some caspases on the “top” of the cascade (eg, 8 and 9) cleave and activate procaspases. Thereby these initiator caspases carry the activation wave to the so-called effector caspases (eg, 3, 6, and 7), which cleave specific cellular proteins, activating or inactivating them. It is the hydrolysis of these specific proteins that accounts directly or indirectly for the morphological and biochemical alterations in apoptotic cells. For example, proteolytic inactivation of PARP prevents futile DNA repair and wasting of ATP; caspase-mediated cleavage of Beclin 1 aborts autophagy, hydrolysis of the inhibitor of

Figure 3-19. Apoptotic pathways initiated by mitochondrial insult, nuclear DNA insult, and death receptor stimulation. The figure is a simplified scheme of 3 pathways to apoptosis. (1) Mitochondrial insult (see text) ultimately opens the permeability transition pore spanning both mitochondrial membranes and/or causes release of cytochrome *c* (Cyt *c*) and other proapoptotic and antiapoptotic proteins (not shown) from the mitochondria. Cyt *c* release is facilitated by Bax or truncated Bid (tBid) proteins and opposed by Bcl-2 protein. (2) DNA insult, especially double-strand breaks, activates p53 protein that increases the expression of Bax (which mediates Cyt *c* release) and the membrane receptor protein Fas. (3) Fas ligand, tumor necrosis factor (TNF), or TNF-related apoptosis-inducing ligand (TRAIL, not shown) binds to and activates their respective receptor, Fas, TNF receptor-1 (TNFR1), and TRAIL receptors (not shown). The ligand-bound death receptors and the released Cyt *c* interact with specific adapter proteins (ie, FADD, TRADD, and Apaf-1) through which specific initiator procaspases (PC, eg, PC-8 and PC-9) become active caspases (C). The latter in turn cleave and activate other proteins, for example, Bid and the main effector procaspase PC-3. The active effector caspase-3 activates other effector procaspases (PC-6, PC-7). Finally, C-3, C-6, and C-7 cleave specific cellular proteins, leading to morphological and biochemical features of apoptosis. These pathways are not equally relevant in all types of cells and other apoptotic pathways, such as those triggered by TGF- β as an extracellular signaling molecule (which upregulates the proapoptotic Bim protein) and ceramide as an intracellular signaling molecule, also exist. Note that through TNFR1 TNF may signal not only for apoptosis (via TNFR1-TRADD-FADD association, as shown above) but also for cell survival (via TNFR1-TRADD-TRAF2 association). The survival pathways thus triggered are the NF- κ B and the MAPK (specifically Jun kinase) pathways (see Fig. 3-12). FAK, focal adhesion kinase; ICAD, inhibitor of caspase-activated DNase; PARP, poly(ADP-ribose) polymerase; SREBP, sterol regulatory element-binding protein.

caspase-activated DNase (ICAD) permits caspase-activated DNase (CAD) to translocate to the nucleus and cleave internucleosomal DNA; cleavage of structural proteins (α -fodrin, actin, lamins) aids in disassembly of the cell; incapacitation of focal adhesion kinase (see Fig. 3-12) permits detachment of the cell from the extracellular matrix (ECM); and hydrolytic activation of sterol regulatory element-binding proteins may contribute to accumulation of sterols and externalization of phosphatidylserine in the plasma membrane that identify the apoptotic cell to phagocytes (and the latter also enables experimental detection of apoptotic cells with fluorescently labeled annexin-V that binds to phosphatidylserine residues on the cell surface). Besides caspases, DNA fragmentation can be induced by apoptosis-inducing factor (AIF) and endonuclease G that are also released from the mitochondrial intermembrane space and may contribute to DNA fragmentation during apoptosis and acetaminophen-induced caspase-independent hepatocellular necrosis (Jaeschke and Bajt, 2006). Prerequisite for the release of AIF is its hydrolysis by the Ca^{2+} -activated protease calpain localized to the intermembrane space. Oxidative modification of AIF by mitochondrial ROS increases its affinity to calpain (Orrenius *et al.*, 2011).

The decisive mitochondrial event of cell death, that is, release of cytochrome *c* and other proapoptotic proteins (eg, Smac, Omi, AIF), is controlled by the Bcl-2 family of proteins, which includes members that facilitate (eg, Bax, Bak, Bad, Bid, Bim, BNIP3, Puma, Noxa) and those that inhibit (eg, Bcl-2, Bcl-XL) these processes. The death-promoting members can oligomerize and form pores in the mitochondrial outer membrane (MOM). By doing so, they may facilitate release of cytochrome *c* and other intermembrane proapoptotic proteins via MPT induced by toxic insult of the mitochondria; however, mitochondrial outer membrane permeabilization (MOMP) alone by Bax and its congeners is sufficient to evoke egress of cytochrome *c* from the mitochondria. MOMP induced by Bax, Bak, and/or Bid is responsible for cytochrome *c* release in apoptosis initiated at extramitochondrial targets, including death receptors and the nuclear DNA (see below). The death suppressor Bcl-2 and Bcl-XL can dimerize with the death-inducing counterparts and neutralize them. Thus, the relative amount of these antagonistic proteins functions as a regulatory switch between cell survival and death (Reed *et al.*, 1998).

The proapoptotic Bax and Bid proteins, which can induce MOMP, represent links whereby death programs initiated extramitochondrially, for example, by DNA damage in the nucleus or by stimulation of the so-called death receptors (Fas receptor and TNF receptor-1 [TNFR1]) at the cell surface, can engage the mitochondria into the apoptotic process (Green, 1998) (Fig. 3-19). DNA damage evoked by ionizing and UV radiations, alkylating chemicals, and topoisomerase II inhibitors, such as doxorubicin (Adriamycin), induces stabilization and activation of p53 protein that can promote apoptosis at dual cellular locations and by dual mechanisms. In the nucleus, p53 acts as a TF, which increases expression of proapoptotic members of the Bcl-family of proteins, such as Bax, Puma, and Noxa (Liu and Chen, 2006) (see also Fig. 3-33). Cytoplasmic p53 participates in protein-protein interactions. In such a manner, p53 abrogates the function of antiapoptotic proteins (eg, Bcl-X_L) and activates the MOMP-forming function of proapoptotic Bax and Bak (Green and Kroemer, 2009). As discussed further on, DNA damage is potentially mutagenic and carcinogenic; therefore, apoptosis of cells with damaged DNA is an important self-defense of the body against oncogenesis. Furthermore, the antitumor drugs targeting the nuclear DNA exert their desirable toxic effects against tumor cells (and also their undesirable cytotoxic effects against rapidly dividing normal cells such as hematopoietic cells and small intestinal mucosal cells) by inducing apoptosis primarily via a p53-dependent mechanism.

Stimulation of the Fas receptor (also known as CD95 or Apo-1), TNFR1, or TNF-related apoptosis-inducing ligand (TRAIL) receptors (DR4 and DR5, not shown) by their ligands induces receptor oligomerization and recruitment of adapter proteins. The thus formed death-inducing protein complex (DISC) activates caspase-8, an initiator caspase that sets the caspase cascade in motion (Fig. 3-19). In addition, death receptor activation can also engage the mitochondria into the apoptosis program via caspase-8-mediated cleavage of Bid to its active form. The Fas system is involved in cell-mediated cytotoxicity, as cytotoxic T lymphocytes express the Fas ligand that activates the Fas receptor in the membrane of potential target cells, such as those of the liver, heart, and lung. Cholestatic liver injury involves apoptosis induced by the retained hydrophobic bile acids mediated partly through their mitochondrial effect (ie, MPT) and through the death receptors (Higuchi and Gores, 2003). By activating PKC, toxic bile acids promote trafficking of Fas receptor and TRAIL receptor-2 (also known as DR5) from the Golgi complex into the plasma membrane of liver cells, where the increased receptor density induces spontaneous (ie, ligand-independent) receptor oligomerization and caspase activation. Increased expression of soluble FasL and Fas receptor is thought to play a causative role in the apoptosis of pulmonary alveolar epithelial cells underlying acute lung injury (or acute respiratory distress syndrome) (Martin *et al.*, 2005), a potentially lethal outcome of various pathologies and heroin intoxication. The Fas system also mediates germ cell apoptosis in the testes of rodents exposed to mono-(2-ethylhexyl)phthalate or 2,5-hexanedione, the ultimate toxicant formed from hexane. These chemicals damage the microtubules in the Sertoli cells that normally nurse the germ cells. Unable to support the germ cells, Sertoli cells overexpress the Fas ligand to limit the number of germ cells (which upregulate their Fas receptor) by deleting them via apoptosis (Cohen *et al.*, 1997; Lee *et al.*, 1997).

Thus, apoptosis can be executed via multiple pathways, most involving caspase activation. The route preferred will depend, among others, on the initial insult (Fig. 3-19) as well as on the type and state of the cell. For example, T lymphocytes lacking the Bax gene can still undergo p53-dependent death in response to ionizing radiation, probably by increasing Fas expression (Fig. 3-19), whereas Bax-null fibroblasts cannot. AIF appears to play a critical role in neuronal cell death (Orrenius *et al.*, 2011), whereas TRAIL is an important death inducer in various tumor cells. In contrast, keratinocytes and endothelial cells are resistant to death ligand-mediated apoptosis, as they strongly express cFLIP, an inhibitor of caspase-8.

What Determines the Form of Cell Death? For reasons discussed later, it is not inconsequential for the surrounding tissue whether a cell dies by apoptosis or necrosis. Therefore, considerable research has focused on what determines the form of cell death. Interestingly, there are some common features in the process of apoptosis and necrosis. Both forms of cell death caused by cytotoxic agents may involve similar metabolic disturbances and MPT (Kim *et al.*, 2003; Kroemer *et al.*, 1998; Qian *et al.*, 1999), and blockers of the latter (eg, cyclosporin A, Bcl-2 overexpression) prevent both apoptosis and necrosis in different settings. Furthermore, many xenobiotics—such as the hepatotoxicant 1,1-dichloroethylene, thioacetamide, and cadmium as well as the nephrotoxicant ochratoxin—can cause both apoptosis and necrosis (Corcoran *et al.*, 1994). However, toxicants tend to induce apoptosis at low exposure levels or early after exposure at high levels, whereas they cause necrosis later at high exposure levels. This indicates that the severity of the insult determines the mode of cell death. Based on

experimental evidence, it appears that a larger toxic insult causes necrotic cell death rather than apoptosis because it incapacitates the cell to undergo apoptosis. This incapacitation may result from three causatively related cellular events, that is, increasing number of mitochondria undergoing MPT, depletion of ATP, and failed activation of caspases or their inactivation.

Lemasters and coworkers (Kim *et al.*, 2003; Rodriguez-Enriquez *et al.*, 2004) used confocal microscopy to visualize mitochondria in cells exposed to an apoptogenic stimulus and found that MPT does not occur uniformly in all mitochondria. They proposed a model in which the number of mitochondria undergoing MPT (which probably depends on the degree of chemical exposure) determines the fate of the cell. According to this model, when only a few mitochondria develop MPT, they are removed by selective autophagy (mitophagy; see the section “Cellular Repair”) and the cell survives. When more mitochondria suffer MPT, the autophagic mechanism becomes overwhelmed, and the released proapoptotic factors (eg, cyt *c*, Smac, and Omi) initiate caspase activation (Fig. 3-19). By hydrolyzing Beclin 1, a component of the autophagic mechanism, caspase-8 aborts mitophagy (Li *et al.*, 2011), and by hydrolyzing other cellular proteins (see above) and DNA, caspases and AIF, respectively, promote apoptosis. When eventually MPT involves virtually all mitochondria, cytolysis occurs. Fig. 3-20 illustrates an expanded version of this model.

For reasons discussed above, ATP is bound to become severely depleted in cells in which most mitochondria suffer MPT. The degree of ATP depletion may decide the fate of the cell. In experimental models as distinct as Ca^{2+} -exposed hepatocytes, Fas-stimulated T lymphocytes, and HOOH-exposed endothelial cells,

Figure 3-20. “Decision plan” on the fate of injured cell. See the text for details. MOMP, mitochondrial outer membrane permeabilization; MPT, mitochondrial permeability transition; Puma, p53-upregulated modulator of apoptosis; RO(N)S, reactive oxygen or nitrogen species.

necrosis occurs instead of apoptosis when cells are depleted of ATP, whereas apoptosis takes place rather than necrosis when ATP depletion is alleviated by providing substrates for ATP generation (Leist *et al.*, 1997; Kim *et al.*, 2003; Lelli *et al.*, 1998). Lack of ATP can prevent execution of the apoptotic program, because apoptosis involves ATP-requiring steps, such as activation of procaspase-9 in the apoptosome complex (Fig. 3-19).

Failure of caspase activation can also result from direct action of reactive toxicants on these enzymes. The active site of caspases is composed of a pentapeptide (QACXG) with a reactive cysteine in it. At high concentrations, soft electrophiles, disulfides (eg, glutathione disulfide), and oxidants (eg, ROS), can react with this cysteine, causing caspase inactivation and ablation of the apoptotic program, with necrosis rather than apoptosis as the final outcome. Such a scenario has been demonstrated for cell death evoked by tributyltin, pyrrolidine dithiocarbamate, and arsenic trioxide (Orrenius, 2004) and might also underlie the acetaminophen-induced hepatocellular necrosis, which involves cyt *c* release with no caspase activation or apoptosis (Jaeschke and Bajt, 2006).

Induction of Cell Death by Unknown Mechanisms In addition to chemicals that ultimately injure mitochondria by disrupting oxidative phosphorylation and/or intracellular Ca^{2+} homeostasis, there are toxicants that cause cell death by affecting other functions or structures primarily. Included here are (1) chemicals that directly damage the plasma membrane, such as lipid solvents, detergents, and venom-derived hydrolytic enzymes; (2) xenobiotics that damage the lysosomal membrane, evoking release of lysosomal hydrolases and Fe^{2+} , such as aminoglycoside antibiotics and hydrocarbons binding to α_{2u} -globulin that injure renal tubular cells; (3) toxins that destroy the cytoskeleton, such as the microfilament toxins (eg, phalloidin and cytochalasins) and the microtubule toxins (eg, colchicine and 2,5-hexanedione); (4) the protein phosphatase inhibitor and hepatotoxicant microcystin, which causes hyperphosphorylation of microfilaments and other cellular proteins (Toivola and Eriksson, 1999); (5) toxins that disrupt protein synthesis, such as α -amanitin and ricin; and (6) cholesterol-lowering drugs (statins) that inhibit HMG-coenzyme A reductase, the rate-limiting enzyme in the mevalonate pathway, and rarely cause myotoxicity.

The events leading to cell death after exposure to these chemicals are generally unknown. It is likely that cell death caused by these chemicals is ultimately mediated by impairment of oxidative phosphorylation, sustained elevation of intracellular Ca^{2+} , and/or overproduction of ROS/RNS, and that it takes the form of necrosis if these processes are abrupt, but apoptosis if they are protracted. For example, direct injury of the plasma membrane would lead rapidly to increased intracellular Ca^{2+} levels. Neurofilamental toxins that block axonal transport cause energy depletion in the distal axonal segment. HMG-coenzyme A reductase inhibitors not only diminish the synthesis of cholesterol but may also compromise formation of other products of the mevalonate pathway. Such are the mitochondrial electron-transporting molecule ubiquinone (also called coenzyme Q) and isopentenyl pyrophosphate, which is utilized for isopentenylation of selenocysteinyl-tRNA, an obligatory step for synthesis of selenoproteins, including the antioxidant glutathione peroxidase (see Fig. 3-5) and thioredoxin reductase (see Fig. 3-22). These alterations may contribute to statin-induced myopathy and rhabdomyolysis.

Impairment of External Cellular Maintenance Toxicants may also interfere with cells that are specialized to provide support to other cells, tissues, or the whole organism. Chemicals acting on the liver illustrate this type of toxicity. Hepatocytes produce and

release into the circulation a number of proteins and nutrients. They remove cholesterol and bilirubin from the circulation, converting them into bile acids and bilirubin glucuronides, respectively, for subsequent excretion into bile. Interruption of these processes may be harmful to the organism, the liver, or both. For example, inhibition of hepatic synthesis of coagulation factors by coumarins does not harm the liver, but may cause death by hemorrhage (Hardman *et al.*, 1995). This is the mechanism of the rodenticidal action of warfarin. In the fasting state, inhibitors of hepatic gluconeogenesis, such as hypoglycin (the ackee fruit-derived causative agent of Jamaican vomiting sickness; methylene cyclopropyl alanine), may be lethal by limiting the supply of glucose to the brain. Similarly, Reye syndrome, which is viewed as a hepatic mitochondrial injury caused by a combination of a viral disease (which may induce hepatic NOS) and intake of salicylate (which provokes MPT) (Fromenty and Pessayre, 1997; Kim *et al.*, 2003), causes not only hepatocellular injury but also severe metabolic disturbances (hypoglycemia, hyperammonemia) that affect other organs as well. Chemical interference with the β -oxidation of fatty acids or the synthesis, assembly, and secretion of lipoproteins overloads the hepatocytes with lipids, causing hepatic dysfunction (Fromenty and Pessayre, 1997). α -Naphthylisothiocyanate (ANIT) causes separation of the intercellular tight junctions that seal bile canaliculi (Krell *et al.*, 1987), impairing biliary secretion and leading to the retention of bile acids and bilirubin; this adversely affects the liver as well as the entire organism.

STEP 4—INAPPROPRIATE REPAIR AND ADAPTATION

The fourth step in the development of toxicity is inappropriate repair and adaptation (Fig. 3-1). As noted previously, many toxicants alter macromolecules, which eventually cause damage at higher levels of the biological hierarchy in the organism. Progression of toxic lesions can be intercepted by repair mechanisms operating at molecular, cellular, and tissue levels (Fig. 3-21). Another strategy whereby the organism can resist the noxious chemical is by increasing its own readiness to cope with it and with its harmful effects. This phenomenon is called adaptation. Because the capacity of the organism to repair itself and adapt to the toxic exposure and effects is so important in determining the outcome of chemical exposure, the mechanisms of repair and adaptation will be discussed below.

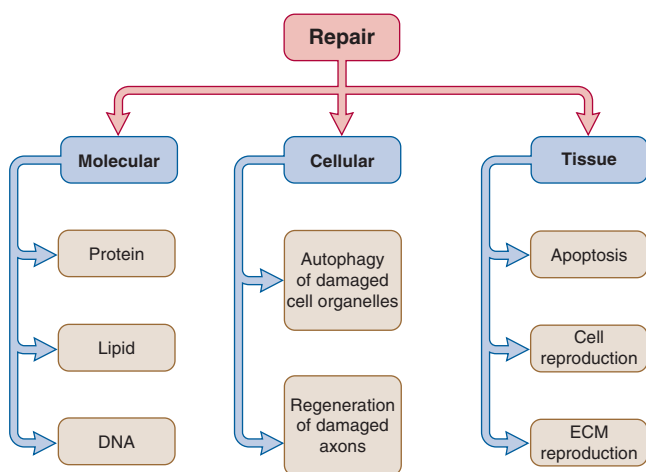

Figure 3-21. Repair mechanisms. Dysfunction of these mechanisms results in dysrepair, the fourth step in the development of numerous toxic injuries. ECM, extracellular matrix.

Mechanisms of Repair

Molecular Repair Damaged molecules may be repaired in different ways. Some chemical alterations, such as oxidation of protein thiols and methylation of DNA, are simply reversed. Hydrolytic removal of the molecule's damaged unit or units and insertion of a newly synthesized unit or units often occur with chemically altered DNA and peroxidized lipids. In some instances, the damaged molecule is totally degraded and resynthesized. This process is time-consuming but unavoidable in cases such as the regeneration of cholinesterase after organophosphate intoxication.

Repair of Proteins Thiol groups are essential for the function of numerous proteins, such as receptors, enzymes, cytoskeletal proteins, and TFs. Oxidation of protein thiols (Prot-SHs) to protein disulfides (Prot-SS, Prot₁-SS-Prot₂), protein–glutathione mixed disulfides (Prot-SSG), and protein sulfenic acids (Prot-SOH) can be reversed by reduction (Watson *et al.*, 2004; Gravina and Mieyal, 1993) (Fig. 3-22). The endogenous reductants are thioredoxins and glutaredoxins, small, ubiquitous proteins with two redox-active cysteines in their active centers (Holmgren *et al.*, 2005). These proteins as well as thioredoxin reductase have two isoenzymes; those labeled 1 are located in the cytosol, whereas those labeled 2 are mitochondrial. Because the catalytic thiol groups in these proteins become oxidized, they are reduced by NADPH, which is generated by NADP⁺-dependent isocitrate dehydrogenase localized in various cell compartments (cytosol, mitochondria, peroxisomes), as well as by the cytosolic glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase in the pentose phosphate pathway. ROS may oxidize methionines in proteins into sulfoxides (protein-Met-S=O), forming both the S and R epimers, which can be reduced by methionine sulfoxide reductase (Msr) A and B enzymes, respectively (Moskovitz, 2005). Msr enzymes can reverse this modification at the expense of oxidation of their catalytic cysteine to sulfenic acid (Msr-Cys-S-OH). This then reacts with a neighboring thiol (in MsrA), forming an intramolecular disulfide, or with glutathione (in some other Msr proteins), forming a protein–glutathione disulfide. Finally the disulfide enzyme is reduced by thioredoxin or glutaredoxin, respectively, with subsequent steps depicted in Fig. 3-22. Reduction of methionine sulfoxides in lens proteins (eg, α -crystallin) is especially critical for maintenance of the transparency of the eye lens. MsrA knockout mice develop cataract on repeated exposure to hyperbaric oxygen (Kantorow *et al.*, 2010). Repair of oxidized hemoglobin (methemoglobin) occurs by means of electron transfer from cytochrome *b*₅, which is then regenerated by a NADH-dependent cytochrome *b*₅ reductase (also called methemoglobin reductase).

Soluble intracellular proteins such as cytosolic enzymes are typically folded into a globular form with their hydrophobic amino acid residues hidden inside, whereas the hydrophilic residues are located externally together with a hydrophobic cleft that constitutes the ligand (substrate) binding site. Physical or chemical insults may evoke an unduly large opening of this cleft that may lead to unfolding of the protein (denaturation) and its aggregation. Molecular chaperones such as the heat-shock proteins (Hsp, eg, Hsp90, Hsp70, and Hsp40) can prevent protein unfolding by “clamping down” onto the exposed hydrophobic region of their client protein, using the energy of ATP hydrolysis to execute their conformational change that entails this maneuver. According to a recent model (Pratt *et al.*, 2010), Hsp90 plays the leading role in stabilizing the cleft and impeding further unfolding, which would eventually lead to degradation of the protein by the ubiquitin–proteasome system (UPS) as described below. Indeed, the benzoquinone ansamycin Hsp90

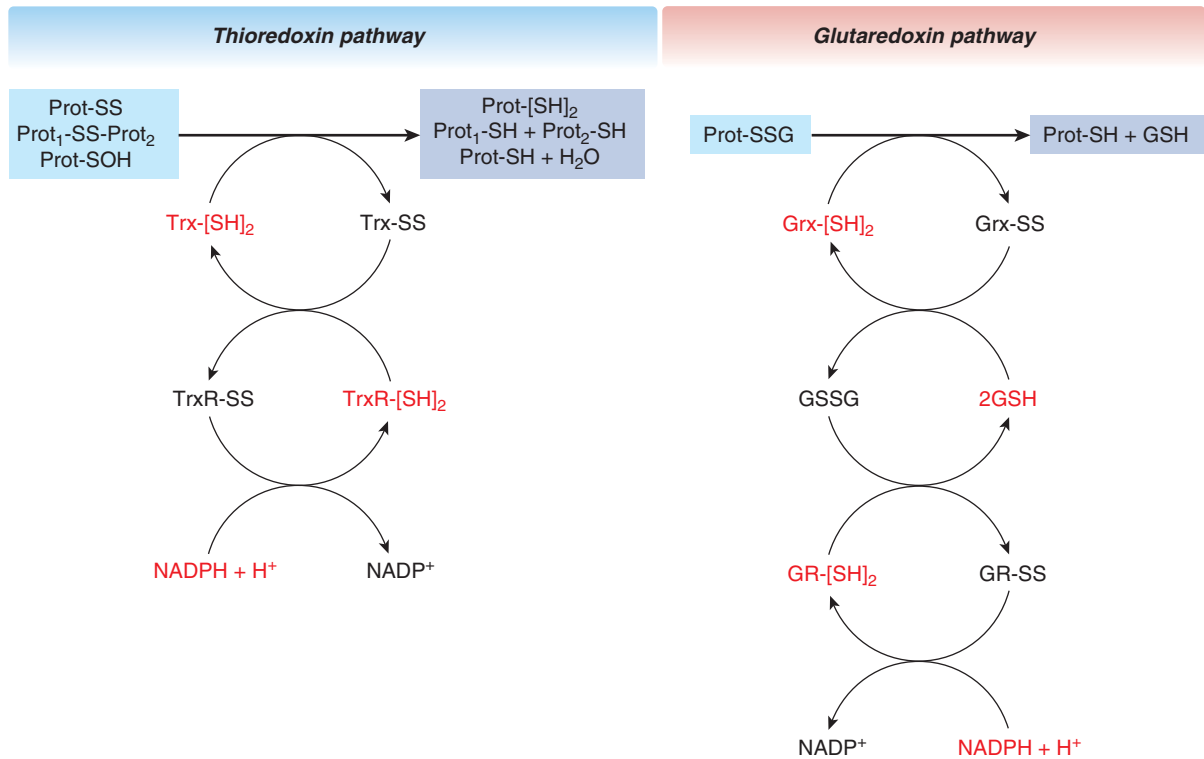

Figure 3-22. Repair of proteins oxidized at their thiol groups. Protein disulfides (Prot-SS, Prot₁-SS-Prot₂) and protein sulfenic acids (Prot-SOH) are reduced by thioredoxin (Trx-[SH]₂) or thioredoxin-like proteins. Protein–glutathione mixed disulfides (Prot-SSG) are reduced by glutaredoxin (Grx-[SH]₂), which is also called thioltransferase. The figure also indicates how Trx-[SH]₂ and Grx-[SH]₂ are regenerated from their disulfides (Trx-SS and Grx-SS, respectively). In the mitochondria, Trx-SS also can be reduced by the dithiol dihydrolipoic acid, a component of the pyruvate- and α -ketoglutarate dehydrogenase complexes. GSH, glutathione; GSSG, glutathione disulfide; GR-[SH]₂ and GR-SS, glutathione reductase (dithiol and disulfide forms, respectively); TrxR-[SH]₂ and Trx-SS, thioredoxin reductase (dithiol and disulfide forms, respectively).

inhibitors (eg, geldanamycin and herbimycin) promote degradation of Hsp90 client proteins by the UPS.

When unfolding progresses beyond a limit, Hsp90 dissociates. This may occur in response to chemical-induced protein damage, such as that inflicted by mechanism-based enzyme inactivators that are converted into reactive metabolites that bind covalently to the catalytic site of the enzyme. Dissociation of Hsp90 from the unfolding protein allows Hsp70 and its co-chaperone Hsp40 to recruit the Hsp70-dependent E3 ubiquitin ligases (eg, CHIP and Parkin) that in turn direct ubiquitin-charged E2 enzymes to the Hsp70-bound client protein to tag it with a polyubiquitin chain as the final step in a process presented in Fig. 3-23 (Bedford *et al.*, 2011). The protein tagged with a Lys48-linked polyubiquitin chain is then recognized and degraded in the proteasomes. The 26S proteasome is large barrel-shaped multiprotein complex that binds the ubiquitinated protein, deubiquitinates and unfolds it using ATP, and finally hydrolyzes the protein with its threonine-containing protease active sites into small peptides. The UPS controls the cellular level of numerous regulatory proteins (eg, p53, I κ B, Nrf2, β -catenin, cyclins) and also has a prominent role in eliminating oxidized or otherwise damaged and unfolded intracellular proteins (Poppek and Grune, 2006). NOS exposed to its mechanism-based inactivator guanabenz that causes loss of tetrahydrobiopterin from the substrate-binding cleft will suffer this fate (Pratt *et al.*, 2010). CYP2E1, in which the heme becomes cross-linked to the protein as a consequence of reductive dechlorination of CCl₄ to the trichloromethyl free radical by this enzyme, is also eliminated by proteasomal degradation.

Oligomerization and aggregation of damaged and unfolded proteins preclude the proteasome from degrading them; such substrates can even trap proteasomes, rendering them nonfunctional.

After ubiquitination, protein aggregates can be eliminated by autophagy, a process described in more detail in the section “Cellular Repair.” Ubiquitin on the modified proteins is recognized and bound by autophagic adaptor proteins, such as p62 or Nbr1, which interact with LC3 to deliver them to autophagosomes, newly formed vesicles that encapsulate their protein cargo. After fusing of autophagosomes with lysosomes, the damaged protein is hydrolyzed by proteases. Lysosomal proteases degrade, for example, the immunogenic trifluoroacetylated proteins that are formed in the liver during halothane anesthesia (Cohen *et al.*, 1997). Erythrocytes have ATP-independent, nonlysosomal proteolytic enzymes that rapidly and selectively degrade proteins denatured by HO[•] (Davies, 1987). Red blood cells containing protein aggregates (Heinz body) after exposure to methemoglobin-forming chemicals are removed via phagocytosis by macrophages in the spleen.

Repair of Lipids Phospholipids containing fatty acid hydroperoxides are preferentially hydrolyzed by phospholipase A2, with the peroxidized fatty acids replaced by normal fatty acids (van Kuijk *et al.*, 1987). Peroxidized lipids (eg, fatty acid hydroperoxides and phospholipid-associated hydroperoxides) may be reduced by the glutathione peroxidase–glutathione–glutathione reductase system (see Fig. 3-24) or by the peroxiredoxin–thioredoxin–thioredoxin reductase system (shown in part in Fig. 3-22). Again, NADPH is needed to “repair” the reductants that are oxidized in the process.

Repair of DNA Despite its high reactivity with electrophiles and free radicals, nuclear DNA is remarkably stable, in part because it is packaged in chromatin and because several repair mechanisms are available to correct alterations. The mitochondrial DNA, however,

Figure 3-23. The process of ubiquitination and its possible outcomes. Ubiquitin (Ub) is a small (8.6 kDa) ubiquitous protein that when covalently linked to a target protein (as a monomer or as a polymer of Ub units) alters its fate and/or function. Ubiquitination is a posttranslational protein modification that takes place in an enzymatic cascade composed of 3 types of proteins—the E1 Ub-activating enzyme, the E2 Ub-conjugating enzyme, and the E3 Ub ligase. Humans possess 8 E1, over 30 E2, and hundreds of E3 enzymes. E1 first activates Ub in an ATP-consuming reaction by adenylating the terminal carboxyl group of Ub, thus forming Ub-AMP, and then it transfers Ub from Ub-AMP to its catalytic SH group, forming a high-energy thioester bond between E1 and Ub. In the subsequent transthiolation reaction, Ub is transferred from E1 to the catalytic SH group of E2. Thereafter, E3 binds both the target protein and the Ub-charged E2 and catalyzes the transfer of Ub from E2 to the target protein, forming an isopeptide bond between the terminal carboxyl group of Ub and the ϵ -amino group of a lysine in the substrate. Most E3 ligases, including the so-called RING finger domain-containing E3 ligases (which constitute 1 of the largest enzyme groups in the cell), ubiquitinate proteins this way. However, the HECT domain-containing E3 ligases, which possess an active site cysteine, take Ub from E2 in a transthiolation reaction, and then they (rather than E2) transfer Ub to the target protein. As Ub contains 7 lysine residues, it can also be ubiquitinated. Multiple rounds of ubiquitination generate polyubiquitin chains. In general, monoubiquitination triggers endocytosis or autophagy of the protein. Substrates that are tagged with Lys48-linked Ub chains are recognized and degraded by the 26S proteasome into small peptides, with the Ubs released for reuse. Proteins polyubiquitinated with Lys63-linked Ub chains are generally not degraded but are essential components of signaling pathways, functioning as scaffolds to assemble signaling complexes. For example, the activation of transcription factor NF- κ B on signaling (see Fig. 3-12) involves assembly of a signaling complex by means of Lys63-linked Ub chains. Ubiquitination can be reversed by deubiquitinating enzymes, which are Ub-specific proteases (cysteine proteases or zinc metalloproteases). These may rescue a substrate from degradation by removing a degradative Ub signal or may change or remove a nondegradative Ub signal. Instead of Ub, proteins may also be modified by covalent attachment of Ub-like proteins, such as NEDD8, SUMO, and ISG15, using the enzymatic machinery described above.

lacks histones and efficient repair mechanisms and therefore is more prone to damage. Different types of damages are corrected by specialized mechanisms, each employing a different set of repair proteins (Christmann *et al.*, 2003).

Direct Repair Certain covalent DNA modifications are directly reversed by enzymes such as DNA photolyase, which cleaves adjacent pyrimidines dimerized by UV light. Inasmuch as this chromophore-equipped enzyme uses the energy of visible light to correct damage, its function is restricted to light-exposed cells.

Minor adducts, such as methyl groups, attached to DNA bases by alkylating agents (eg, MMS) may be removed by special

enzymes (Christmann *et al.*, 2003). Such groups attached to the O^6 position of guanine are cleaved off by O^6 -methylguanine-DNA-methyltransferase (MGMT). While repairing the DNA, this alkyltransferase sacrifices itself, transferring the adduct onto one of its cysteine residues. This results in its inactivation, ubiquitination, and proteasomal degradation. Thus, like glutathione, which is depleted during detoxication of electrophiles, MGMT is consumed during the repair of DNA. Methyl groups attached to N^1 of adenine and guanine, and N^3 of thymine and cytosine are removed by oxidative demethylation catalyzed by DNA dioxygenases (ABH2 and ABH3). These peculiar O_2 , Fe^{2+} , ascorbate, and 2-oxoglutarate-dependent

Figure 3-24. Repair of peroxidized lipids. Phospholipid peroxy radicals (PL-OO*) formed as a result of lipid peroxidation (Fig. 3-9) may abstract hydrogen from α -tocopherol (TOC-OH) and yield phospholipid hydroperoxide (PL-OOH). From the latter, the fatty acid carrying the hydroperoxide group is eliminated via hydrolysis catalyzed by phospholipase (PLase), yielding a fatty acid hydroperoxide (FA-OOH) and a lysophospholipid (LPL). The former is reduced to a hydroxy fatty acid (FA-OH) by glutathione peroxidase (GPX), utilizing glutathione (GSH), or peroxiredoxins (not shown), whereas the latter is reacylated to phospholipid (PL) by lysophosphatidyl fatty acyl-coenzyme A transferase (LFTF), utilizing long-chain fatty acid-coenzyme A (FA-CoA). The figure also indicates regeneration of TOC-OH by ascorbic acid (HO-ASC-OH), regeneration of ascorbic acid from dehydroascorbic acid (O=ASC=O) by glutaredoxin (Grx-[SH]₂), and reduction of the oxidized glutaredoxin (Grx-SS) by GSH. Oxidized glutathione (GSSG) is reduced by glutathione reductase (GR-[SH]₂), which is regenerated from its oxidized form (GR-SS) by NADPH, the ultimate reductant. NADPH is produced by NADP⁺-dependent isocitrate dehydrogenases and during metabolism of glucose via the pentose phosphate shunt. TOC-O*, tocopheroxyl radical; *O-ASC-OH, ascorbyl radical.

enzymes oxygenate the methyl group adduct, which in turn leaves as formaldehyde, whereas 2-oxoglutarate is oxidatively decarboxylated to succinate.

Excision Repair Base excision and nucleotide excision are two mechanisms for removing damaged bases from DNA (see Chaps. 8 and 9). Lesions that do not cause major distortion of the helix typically are removed by base excision, in which the altered base is recognized by a relatively substrate-specific DNA glycosylase that hydrolyzes the *N*-glycosidic bond, releasing the modified base and creating an apurinic or apyrimidinic (AP) site in the DNA. For example, 8-OH-Gua, a major mutagenic product of oxidative stress, is removed from the DNA by a specific 8-OH-Gua DNA glycosylase. The AP site is recognized by the AP endonuclease, which hydrolyzes the phosphodiester bond adjacent to the abasic site. After its removal, the abasic sugar is replaced with the correct nucleotide by a DNA polymerase and is sealed in place by a DNA ligase. Interestingly, AP endonuclease is a bifunctional protein and is also called redox factor-1 (Ref-1). In concert with thioredoxin and thioredoxin reductase, it maintains TFs with sensitive thiol groups in their DNA-binding domain (Fos, Jun, NF- κ B) in an active reduced state (Hansen *et al.*, 2006).

Bulky lesions such as adducts produced by aflatoxins or aminofluorene derivatives and dimers caused by UV radiation are removed by nucleotide excision repair system, which consists of approximately 30 proteins (Christmann *et al.*, 2003). Lesions in the nontranscribed strands or the nontranscribed regions of the genome are corrected by the global genomic repair system. This involves proteins that recognize the distorted double helix at the lesion, unwind the DNA, and excise a number of intact nucleotides on both sides of the lesion together with the one containing the adduct. The excised section of the strand is restored by insertion of nucleotides into the gap by DNA polymerase and ligase, using the complementary strand as a template. Lesions in the transcribed DNA strand blocking the RNA polymerase in the actively transcribed genes are removed by another variation of nucleotide excision repair, the transcription-coupled repair system. This involves assembly of repair proteins to remove the stalled RNA polymerase before excision of the damage and filling the gap. Resynthesis of the removed section of the strand is designated "unscheduled DNA synthesis" and can be detected by the appearance of altered deoxynucleosides in urine. Excision repair has a remarkably low error rate of less than one mistake in 10⁹ bases repaired.

PARP appears to be an important contributor to excision repair. On base damage or SSB, PARP binds to the injured DNA and becomes activated. The active PARP cleaves NAD⁺ to use the ADP-ribose moiety of this cofactor for attaching long chains of polymeric ADP-ribose to nuclear proteins, such as histones. Because one ADP-ribose unit contains two negative charges, the poly(ADP-ribosyl)ated proteins accrue negativity and the resultant electrorepulsive force between the negatively charged proteins and DNA causes decondensation of the chromatin structure. It is hypothesized that PARP-mediated opening of the tightly packed chromatin allows the repair enzymes to access the broken DNA and fix it. Thereafter, poly(ADP-ribose) glycohydrolase gains access to the nucleus from its perinuclear localization and reverses the PARP-mediated modification of nuclear proteins (D'Amours *et al.*, 1999). Other features of PARP that are relevant in toxicity—such as destruction of PARP by caspases during apoptosis as well as the significance of NAD⁺ (and consequently ATP) wasting by PARP in necrosis—have been discussed earlier in this chapter.

Nonhomologous End Joining This process repairs DSB that may be formed when two SSB occur in close proximity, or when DNA with SSB undergoes replication. This repair system directly ligates the broken ends without the need for a homologous template. DSBs are recognized by the Ku protein (a heterodimer of Ku70 and Ku80) that binds to the DNA end. Ku then binds and activates DNA-dependent protein kinase catalytic subunit (DNA-PKcs), leading to recruitment and activation of end-processing enzymes, DNA polymerases, and DNA ligase. Although the nonhomologous end joining is error-prone, it can operate in any phase of the cell cycle and is the mechanism for DSB repair in nondividing terminally differentiated cells (eg, neurons). By contrast, the other and more faithful mechanism for DSB repair, homologous recombination, can function only after replication (in S and G2 phases), when sister chromatid sequences are available for use as templates (see below), and thus is not an option in nondividing cells.

Recombinational (or Postreplication) Repair Homologous recombination can be used to fix postreplication gaps and DSBs (Li and Heyer, 2008). The former defect may result when excision of a bulky adduct or an intrastrand pyrimidine dimer fails to occur before DNA replication begins. At replication, such a lesion prevents DNA polymerase from polymerizing a daughter strand along a sizable stretch of the parent strand that carries the damage. Then the replication results in two homologous (“sister”) yet dissimilar DNA duplexes; one has a large postreplication gap in its daughter strand and an intact duplex synthesized at the opposite leg of the replication fork. This intact sister duplex is utilized to complete the postreplication gap in the damaged sister duplex. This is accomplished by recombination (“crossover”) of the appropriate strands of the two homologous duplexes. After separation, the sister duplex that originally contained the gap carries in its daughter strand a section originating from the parent strand of the intact sister, which in turn carries in its parent strand a section originating from the daughter strand of the damaged sister. This strand recombination explains the phenomenon of “sister chromatid exchange,” which is indicative of DNA damage corrected by recombinational repair. After completing the postreplication gap by recombination, the damage still present in the parent strand may be removed by nucleotide excision.

In addition to eliminating postreplication gaps, homologous recombination can also repair DSB in a complex process employing numerous proteins. These include, for example, the MRN complex (the trimer of Mre11, Rad50, and Nbs1 proteins, which binds to the DSB and is involved in end processing by generation of single-stranded DNA), Rad51, Rad54, and the breast cancer susceptibility

proteins BRCA1 and BRCA2 (which assist the single-stranded DNA in invading the undamaged template in an ATP-dependent process), as well as polymerases, nucleases, helicases, and other components, which mediate DNA ligation and substrate resolution. A combination of excision and recombinational repairs occurs in restoration of DNA with interstrand cross-links caused by bifunctional electrophiles, such as nitrogen mustard-type drugs and cisplatin.

Cellular Repair Autophagic removal of damaged cell organelles may be viewed as a universal mechanism of cellular repair, whereas clearance and regeneration of damaged axons is a mechanism specific for nerve cells.

Autophagy of Damaged Cell Organelles Cells suffering mild injury may repair themselves by removing and degrading damaged components, such as organelles and protein aggregates, in a process called autophagy, meaning eating of self (Rabinowitz and White, 2010). While autophagy serves the purpose of cell restitution in all cells, it is particularly important in terminally differentiated cells, such as neurons and myocytes, where cell renewal by cell replication is not possible. In addition, autophagy of normal cell constituents is an ultimate means of nutrient generation (see the section “Adaptation to Energy Depletion—The Energy Stress Response”).

In autophagy, a so-called isolation membrane (or phagophore) emerges possibly from the EPR, which engulfs the cytoplasmic material and then encapsulates it in a double-membrane vesicle (called autophagosome). This vesicle moves along microtubules, driven by dynein motors, to the lysosome and on fusing with the lysosome generates an autolysosome. The cargo as well as the inner membrane of the original autophagosome is then degraded by lysosomal hydrolytic enzymes, such as proteases, lipases, nucleases, and glycosidases (which work optimally at the acidic pH in the lysosomes) to amino acids, lipids, nucleosides, and carbohydrates. These breakdown products are then released by lysosomal permeases and transporters into the cytosol, where they may be further metabolized or used for synthesis of new macromolecules.

Autophagic removal of damaged cell organelles is a method of their quality control, disposal and recycling. This is well exemplified by deletion of depolarized mitochondria through selective autophagy or mitophagy in cells exposed to mitochondrial poisons, such as the protonophoric uncoupler CCCP, valinomycin, and paraquat (see Table 3-6). Several proteins mediate this process (Mehrpour *et al.*, 2010; Youle and Narendra, 2011), including (1) Pink1 (a protein kinase) localized in the MOM that accumulates there on dissipation of the mitochondrial membrane potential, (2) the cytosolic Parkin (an E3 ubiquitin ligase) that is recruited to the mitochondria by Pink1 and that then polyubiquitinates itself and other proteins, among them (3) the MOM protein mitofusins (Mfn1, Mfn2) and voltage-dependent anion channel (VDAC), (4) p62 (an autophagic adaptor protein) that binds to both ubiquitinated proteins and to (5) the cytosolic LC3 (microtubule-associated protein light chain 3), which, after cleavage to LC3-I, becomes conjugated with phosphatidylethanolamine by (6) a ubiquitin-like conjugation system that requires Atg7 (E1-like), Atg3 (E2-like), and the Atg12-Atg5:Atg16L complex (E3-like), (7) the phosphatidylinositol 3-kinase vesicular protein sorting 34 (Vps34), which is activated by interacting with (8) Beclin 1 (Bcl-2-interacting protein-1). The lipidated LC-3 (called LC3-II) can integrate into the membrane of autophagosome and can recruit the ubiquitin-tagged mitochondria into this structure. The latter protein (which later decomposes in the lysosome) is a marker for autophagosomes.

Removal of damaged mitochondria by autophagy is important not only for maintaining a functional mitochondrial pool but also for limiting oxidative cell damage and preventing apoptosis because injured mitochondria may be sources of ROS and apoptotic factors, such as cyt *c*, Smac, and AIF (see Fig. 3-20). Indeed, overexpression of Parkin suppresses cell death (Tanaka, 2010). In contrast, loss-of-function mutations in the genes encoding Pink1 and Parkin cause early onset monogenic forms of Parkinson disease probably through defective mitophagy of damaged mitochondria in the dopaminergic nigrostriatal neurons (Youle and Narendra, 2011). Autophagy also contributes to structural restitution of liver cells. For example, left-over peroxisomes after exposure to peroxisome proliferators (eg, fibrate esters) and lipid droplets in hepatic steatosis are also cleared by autophagy.

Regeneration of Damaged Axons Peripheral neurons with axonal damage can regenerate their axons with the assistance of macrophages and Schwann cells. Macrophages remove debris by phagocytosis and produce cytokines and growth factors, which activate Schwann cells to proliferate and transdifferentiate from myelinating operation mode into a growth-supporting mode. Distal to the injury, Schwann cells play an indispensable role in promoting axonal regeneration by increasing their synthesis of cell adhesion molecules (eg, N-CAM), by elaborating ECM proteins for base membrane construction, and by producing an array of neurotrophic factors (eg, brain-derived neurotrophic factor, glial cell line–derived neurotrophic factor, and nerve growth factor) and their receptors (Boyd and Gordon, 2003). While comigrating with the regrowing axon, Schwann cells physically guide as well as chemically lure the axon to reinnervate the target cell.

In the mammalian central nervous system, axonal regrowth is prevented partly by the nonpermissive external environment. At the site of injury, the oligodendrocytes produce growth inhibitory myelin-associated proteins (eg, Nogo, NI 35, myelin-associated glycoprotein, oligodendrocyte myelin glycoprotein, ephrin, and semaphorin), which act through specific receptors, whereas the astrocytes produce chondroitin sulfate proteoglycans and fibrotic scar (whose components include laminin, fibronectin, and collagen IV) (Johnson, 1993) that hinder axonal regrowth. Signaling by TGF- β through Smad2 TF (see pathway #8 in Fig. 3-12) plays a leading role in overexpression of these extrinsic growth inhibitory factors. In addition, CNS neurons lose their intrinsic growth capacity postnatally, which occurs simultaneously with increased expression of some neuronal growth inhibitory Krüppel-like TFs, such as KLF4. For these reasons, damage to central neurons is irreversible but is compensated for in part by the large number of reserve nerve cells that can take over the functions of lost neurons. For example, in Parkinson disease, symptoms are not observed until there is at least an 80% loss of nigrostriatal neurons.

Tissue Repair In tissues with cells capable of multiplying, damage is reversed by deletion of the injured cells and regeneration of the tissue by proliferation. The damaged cells are eliminated by apoptosis or necrosis.

Apoptosis: An Active Deletion of Damaged Cells Apoptosis initiated by cell injury can serve as tissue repair for two reasons: first, because it may intercept the process leading to necrosis, as discussed earlier (see Fig. 3-20). Necrosis is a more harmful sequel than apoptosis for the tissue in which the injured cell resides. A cell destined for apoptosis shrinks; its nuclear and cytoplasmic materials condense, and then it breaks into membrane-bound fragments (apoptotic bodies) that are phagocytosed (Bursch *et al.*, 1992). During necrosis, cells and intracellular organelles swell and disintegrate with membrane lysis. Whereas apoptosis is orderly, necrosis

is a disorderly process that ends with cell debris in the extracellular environment. The constituents of the necrotic cells attract aggressive inflammatory cells, and the ensuing inflammation amplifies cell injury (see further on). With apoptosis, dead cells are removed without inflammation. Second, apoptosis may intercept the process leading to neoplasia by eliminating the cells with potentially mutagenic DNA damage. This function of apoptosis is discussed in more detail in the final section of this chapter.

It must be emphasized, however, that apoptosis of damaged cells may serve tissue restoration only for tissues that are made up of constantly renewing cells (eg, the bone marrow, the respiratory and GI epithelium, and the epidermis of the skin), or of conditionally dividing cells (eg, hepatic and renal parenchymal cells), because in these tissues the apoptotic cells are readily replaced. The role of apoptosis as a tissue repair strategy is markedly lessened in organs containing nonreplicating and nonreplaceable cells, such as the neurons, cardiac muscle cells, and female germ cells, because deletion of such cells, if extensive, can cause a deficit in the organ's function. Apoptosis may also be harmful when it occurs at a critical location. For example, in the pulmonary alveolar epithelium, an extremely tight barrier, apoptosis could cause flooding of the alveolar space with interstitial fluid, a potentially lethal outcome.

Proliferation: Regeneration of Tissue Tissues are composed of various cells and the ECM. Tissue elements are anchored to each other by transmembrane proteins. Cadherins allow adjacent cells to adhere to one another, whereas connexins associate into tubular structures and connect neighboring cells internally (gap junctions). Integrins link cells to the ECM. Therefore, repair of injured tissues involves not only regeneration of lost cells and the ECM but also reintegration of the newly formed elements. In parenchymal organs such as liver, kidney, and lung, various types of cells are involved in the process of tissue restoration. Nonparenchymal cells of mesenchymal origin residing in the tissue, such as resident macrophages and endothelial cells, and those migrating to the site of injury, such as blood monocytes, produce factors that stimulate parenchymal cells to divide and stimulate some specialized cells (eg, the stellate cells in the liver) to synthesize ECM molecules.

Replacement of Lost Cells by Mitosis Soon after injury, cells adjacent to the damaged area enter the cell division cycle (Fig. 3-25). Enhanced DNA synthesis is detected experimentally as an increase in the labeling index (which is the proportion of cells that incorporate administered ^3H -thymidine or bromodeoxyuridine into their nuclear DNA during the S phase of the cycle), or by increased expression of proliferating cell nuclear antigen (PCNA, a trimeric protein that functions as a sliding clamp to hold DNA polymerase- δ to the template DNA strand during DNA replication). Also, mitotic cells can be observed microscopically. As early as 2 to 4 hours after administration of a low dose of carbon tetrachloride to rats, the mitotic index in the liver increases dramatically, indicating that cells already in the G_2 phase progress rapidly to the M phase. The mitotic activity of the hepatocytes culminates at 36 to 48 hours, after a full transit through the cycle, indicating that quiescent cells residing in G_0 enter and progress to mitosis (M). Peak mitosis of nonparenchymal cells occurs later, after activation and replication of parenchymal cells. In severe toxic liver injury, when hepatocyte replication is impaired (eg, in rats dosed with galactosamine or acetaminofluorene, and in humans intoxicated with acetaminophen), restoration of the liver may depend on stem cell–derived cells, called oval cells, which are located in the terminal bile ductules. These cells proliferate and differentiate into both hepatocytes and biliary epithelial cells (Fausto *et al.*, 2006; Vessey and Hall, 2001). As oval cells produce α -fetoprotein, the increase in serum

Figure 3-25. The cell division cycle and the participating cyclins and cyclin-dependent protein kinases. Areas representing phases of the cycle are meant to be proportional to the number of cells in each phase. Normally, most cells are in G_0 phase, a differentiated and quiescent state. After receiving signals to divide, they progress into the G_1 phase of the cell division cycle. G_0/G_1 transition involves activation of immediate early genes so that cells acquire replicative competence. Now increasingly responsive to growth factors, these cells progress to the phase of DNA synthesis (S). If this progression is blocked (eg, by the accumulated p53 protein), the cells may undergo apoptosis (A). After DNA replication, the cells prepare further for mitosis in the G_2 phase. Mitosis (M) is the shortest phase of the cell cycle (approximately 40 minutes out of the 40-hour-long cycle of hepatocytes) and most likely requires the largest energy expenditure per unit of time. The daughter cells produced may differentiate and enter into the pool of quiescent cells (G_0), substituting for those which had been lost. During the cycle, the levels of various cyclins temporarily surge by synthesis and degradation (see figure). These proteins bind to and activate specific cyclin-dependent protein kinases (Cdk, see figure), which, in turn, phosphorylate and thus activate enzymes and other proteins required for DNA replication and cell division (Johnson and Walker, 1999) (see Fig. 3-32). In addition to cyclins, phosphorylation also regulates the activity of Cdk: phosphorylation by Wee1 protein kinase (not shown) inactivates Cdk1 and Cdk2, whereas dephosphorylation by cdc25 phosphatases activates them. After tissue necrosis, the number of cells entering the cell division cycle markedly increases at areas adjacent to the injury. The proportion of cells that are in S phase in a given period is reflected by the labeling index, whereas the percentage of cells undergoing mitosis is the mitotic index (see text).

α -fetoprotein levels indicates an improved outcome of acetaminophen-induced injury. Hepatic sinusoidal endothelial cells originate from bone marrow progenitors and when they are chemically injured (eg, by monocrotaline) bone marrow-derived precursor cells move into the sinusoids and contribute to their replacement, as demonstrated in a rat model of hepatic sinusoidal obstruction syndrome (Harb *et al.*, 2009). Accordingly, bone marrow infusion ameliorates, and myelosuppression aggravates, such liver injury. In an ozone-exposed lung, the nonciliated Clara cells and type II pneumocytes undergo mitosis and terminal differentiation to replace, respectively, the damaged ciliated bronchial epithelial cells and

type I pneumocytes (Mustafa, 1990). In some tissues, such as intestinal mucosa and bone marrow, stem cells first divide to provide self-renewal and then differentiate to replace more mature cells lost through injury.

Sequential changes in gene expression occur in cells that are destined to divide. In rats subjected to partial hepatectomy to study regeneration of the liver, oligonucleotide microarray analysis revealed that more than 150 genes are involved in the early gene response with upregulation or downregulation (Su *et al.*, 2002). The overexpressed genes include those that code for TFs important in proliferative signaling, such as *c-fos*, *c-jun*, *Egr1*, and *c-myc* (see Fig. 3-12), the genes of the antiapoptotic protein Bcl- X_L (see Fig. 3-19), and that of *mdm2* that constrains p53, a proapoptotic and cell cycle inhibitory TF (see Fig. 3-32). Interestingly, some genes whose products decelerate the cell cycle also become temporarily overexpressed (eg, the cyclin-dependent kinase inhibitor p21 and *gadd45*; see Fig. 3-32), suggesting that this duality keeps tissue regeneration precisely regulated. Nevertheless, the genetic expression is apparently reprogrammed so that DNA synthesis and mitosis gain priority over specialized cellular activities. For example, as a result of dedifferentiation, regenerating hepatocytes underexpress cytochrome P450, *N*-acetyltransferase-2, as well as PPAR α , and hepatic stellate cells cease to accumulate fat and vitamin A.

It has been speculated that the regenerative process is initiated by the release of chemical mediators from damaged cells. The nonparenchymal cells, such as resident macrophages and endothelial cells, are receptive to these chemical signals and produce a host of secondary signaling molecules, cytokines, and growth factors that promote and propagate the regenerative process (Fig. 3-26). In rodents subjected to partial hepatectomy, the initial or priming phase of liver regeneration is controlled by the cytokines TNF and IL-6, whose hepatic mRNA and serum levels increase. TNF originates from the Kupffer cells. This cytokine acts on these macrophages in an autocrine manner, activating its receptor (item 2 in Fig. 3-12) and the coupled signal transducing network. This in turn causes activation of NF- κ B, which increases IL-6 expression. The secreted IL-6 then acts on the hepatocytes and through its receptor (item 1 in Fig. 3-12) activates Janus kinase (JAK) and induces TFs (eg, Stat3, C/EBP β), which activate several target genes. This cytokine network promotes transition of the quiescent liver cells (G_0) into cell cycle (G_1) and makes them receptive to growth factors (“priming”). Growth factors, especially the hepatocyte growth factor (HGF), transforming growth factor- α (TGF- α), and heparin-binding epidermal growth factor-like growth factor (HB-EGF), initiate the progression of the “primed” cells in the cycle toward mitosis (Costa *et al.*, 2003; Fausto *et al.*, 2006). Despite its name, neither the formation nor the action of HGF is restricted to the liver. It is produced by resident macrophages and endothelial cells of various organs—including liver, lung, and kidney—and in a paracrine manner activates receptors on neighboring parenchymal cells (Fig. 3-26). In rats intoxicated with carbon tetrachloride, the synthesis of HGF in hepatic and renal nonparenchymal cells increases markedly (Noji *et al.*, 1990) and HGF levels in blood rise rapidly (Lindroos *et al.*, 1991). The communication between parenchymal and nonparenchymal cells during tissue repair is mutual. For example, TGF- α , a potent mitogen produced by regenerating hepatocytes, acts both as an autocrine and a paracrine mediator on liver cells as well as on adjacent nonparenchymal cells (Fig. 3-26). By activating their receptors (item 4 in Fig. 3-12), these growth factors initiate signaling through the MAPK pathway and the PI3K-Akt pathway (Fig. 3-12), thereby mediating activation of TFs (*c-Jun*, *c-Fos*, *c-Myc*, FoxM1B, NF- κ B, Stat3). These, among others, induce cyclins and the protein phosphatase cdc25, two groups of short-lived regulatory proteins. Then cyclins activate

Figure 3-26. Mediators of tissue repair and side reactions to tissue injury in liver: (1) growth factors promoting replacement of cells and the extracellular matrix; (2) mediators of inflammation, acute-phase protein (APP) synthesis, and fever; and (3) cytotoxic mediators of inflammatory cells. HGF, hepatocyte growth factor; PDGF, platelet-derived growth factor; TGF- α , transforming growth factor-alpha; TGF- β , transforming growth factor-beta; NO*, nitric oxide; PGI₂, prostacyclin; LTC₄, leukotriene C₄; IL, interleukin; LTB₄, leukotriene B₄; PAF, platelet-activating factor; CINC (the rat homologue of IL-8), cytokine-induced neutrophil chemoattractant; MCP-1, monocyte chemoattractant protein; TNF, tumor necrosis factor. Cells presented are E, endothelial cells; G, granulocyte; H, hepatocyte; M, macrophage (Kupffer cell); S, stellate cell (also called perisinusoidal, Ito, or fat-storing cell). *Rather than the endothelial cells, other stromal cells are the main sources of chemokines (eg, stellate cells for MCP-1). Solid arrows represent effects of growth factors on cell division, whereas the dashed arrow shows the effect on extracellular matrix formation. When directed to a cell, pointed and blunted arrows indicate stimulation and inhibition, respectively. See text for further details.

Cdks by associating with them (Fig. 3-25), whereas cdc25 activates Cdk1 and Cdk2 by dephosphorylating their 2 amino acid residues (Thr14 and Tyr15). The activated Cdks accelerate the cell cycle mainly by phosphorylation of pRb. This in turn releases the TF E2F, which induces enzymes and regulatory proteins needed for cell cycle progression (Fig. 3-32). The growth factor signaling also activates mTOR that upregulates mRNA translation, thereby meeting the demand for increased protein synthesis (see Fig. 3-29). Similar signaling appears to mediate regeneration of the S-(1,2-dichlorovinyl)-L-cysteine-injured kidney that exhibits increased expression of the cytokine IL-6, the growth factors TGF- α and HB-EGF, the growth factor receptors EGFR (also receptor for TGF- α) and IGF-1R, and the MAP kinase isoform Erk1 (Vaidya *et al.*, 2003).

Although the cytokine- and growth factor-controlled mitotic cell replacement is likely an essential part in the repair

of most tissues built up of cells with proliferative capacity, there are also tissue-specific features of tissue repair. For example in the liver, bile acids also stimulate hepatocyte proliferation through their nuclear receptor, FXR (Huang *et al.*, 2006). In mice subjected to partial hepatectomy, liver regrowth is hastened by bile acid feeding, but is markedly delayed when FXR is deleted or recirculation of bile acids from the intestine to the liver is prevented. Epithelia composed of a single cell layer form important barriers; therefore, replacement of mortally injured epithelial cells, which become detached from the basement membrane, is an urgent need. This can be achieved more rapidly by cell migration than by mitotic cell replacement. For example, in the damaged mucosa of the GI tract, cells of the residual epithelium rapidly migrate to the site of injury as well as elongate and become thin to reestablish the continuity of the surface even before this could be achieved by cell replication. Cell movement involves orderly dissociation of cadherin-mediated cell-cell contacts (involving β -catenin phosphorylation) and integrin-mediated cell-ECM contacts at focal adhesions (involving FAK phosphorylation), assembly of actin stress fibers, and formation of lamellopodia (cell projection filled with F-actin meshwork). Mucosal repair is dictated not only by growth factors and cytokines operative in tissue repair elsewhere but also by trefoil factors (TFFs). TFFs are small (7–12 kDa) protease-resistant proteins that are abundantly secreted from specific mucosal cells (eg, intestinal goblet cells) and are associated with the mucous layer of the GI tract (Taupin and Podolsky, 2003). TFF expression is rapidly upregulated at the margins of mucosal injury by cytokine and growth factor signaling. Whereas growth factors (eg, HGF and EGF) exert both motogenic (motility-increasing) and mitogenic effects on enterocytes, TFFs are potent motogens, but are not mitogens. Although TFFs do not act alone, they are the only peptides shown to be essential for restitution of the injured intestinal mucosa. Normal mice exposed to dextran sodium sulfate in the drinking water develop diffuse colonic mucosal injury, some exhibiting bloody diarrhea. In contrast, the majority of TFF3-null mice develop frank bloody diarrhea and die in response to dextran sodium sulfate. The immediate target molecule (eg, receptor) for TFFs remains unknown. Migration of the surviving cells also precedes mitotic cell replacement in the tubular epithelium of the injured kidney. It appears that ECM components, such as collagen IV, beneath the tubular epithelial cells aid in the restitution of the injured epithelium and reestablishment of its polarity (Nony and Schnellmann, 2003).

Replacement of the Extracellular Matrix The ECM is composed of proteins, glycosaminoglycans, and the glycoprotein and proteoglycan glycoconjugates (Gressner, 1992). In liver, these molecules are synthesized by stellate or fat-storing cells located in the space of Disse, between the hepatic sinusoid and the hepatocytes (Fig. 3-26). The stellate cells become activated during liver regeneration, undergoing mitosis and major phenotypic changes. The latter changes include not only increased synthesis and secretion of ECM constituents but also expression of α -smooth muscle actin as well as the myogenic TF MyoD and loss of fat, vitamin A, and PPAR γ content. Thus, resting stellate cells become transdifferentiated into myofibroblast-like contractile and secretory cells. Activation of stellate cells is mediated chiefly by 2 growth factors—platelet-derived growth factor (PDGF) and TGF- β (Fig. 3-26). Both may be released from platelets (which accumulate and degranulate at sites of injury) and later from the activated stellate cells themselves. The main sources of TGF- β , however, are the neighboring tissue macrophages residing in the hepatic sinusoids (Gressner, 1992). A dramatic increase in TGF- β mRNA levels in Kupffer cells is observed with in situ hybridization after carbon tetrachloride-induced hepatic

necrosis. Proliferation of stellate cells is induced by the potent mitogen PDGF. Through its receptor (like item 4 in Fig. 3-12), PDGF activates the PI3K–Akt pathway, which not only signals for proliferation but also inactivates the FoxO1 TF, which would halt the cell cycle in G1 phase by increasing the expression of p27, a cyclin-dependent kinase inhibitor. TGF- β acts on the stellate cells to induce their transdifferentiation and to stimulate the synthesis of ECM components, including collagens, fibronectin, tenascin, and proteoglycans. TGF- β acts through its Ser/Thr kinase receptor (item 8 in Fig. 3-12), which phosphorylates the TFs Smad2 and 3 (Flanders, 2004). TGF- β also plays a central role in ECM formation in other tissues. In kidney and lung, for example, TGF- β targets the mesangial cells and the septal fibroblasts, respectively. Remodeling of the ECM is aided by matrix metalloproteinases, which hydrolyze specific components of the matrix, as well as by tissue inhibitors of matrix metalloproteinases. The former group of these proteins originates from various types of nonparenchymal cells, including inflammatory cells; however, their inhibitors are mainly produced by stellate cells (Arthur *et al.*, 1999).

The way in which tissue regeneration is terminated after repair is unclear, but the gradual dominance of TGF- β , which is a potent antimitogen and apoptogen, over mitogens is a contributing factor in the termination of cell proliferation. ECM production may be halted by an intracellular negative feedback mechanism in the ECM-producing cells, that is, by induction of Smad7 (an inhibitory Smad), which competitively inhibits phosphorylation of the receptor-activated Smads (Smad2 and 3). In addition, extracellular products of the proliferative response, such as the proteoglycan decorin and the positive acute-phase protein α_2 -macroglobulin, can bind and inactivate TGF- β ; thereby they may contribute to its silencing (Gressner, 1992).

Side Reactions to Tissue Injury In addition to mediators that aid in the replacement of lost cells and the ECM, resident macrophages and endothelial cells activated by cell injury also produce other mediators that induce ancillary reactions with uncertain benefit or harm to tissues (Fig. 3-26). Such reactions include inflammation, altered production of acute-phase proteins, and generalized reactions such as fever.

Inflammation—Leukocyte Invasion Alteration of the microcirculation and accumulation of inflammatory cells are the hallmarks of inflammation. These processes are largely initiated by resident macrophages secreting cytokines, such as TNF and interleukin-1 (IL-1), in response to tissue damage (Baumann and Gauldie, 1994) (Fig. 3-26). These cytokines, in turn, stimulate neighboring stromal cells, such as the endothelial cells and fibroblasts, to release mediators that induce dilation of the local microvasculature and cause permeabilization of capillaries. Activated endothelial cells also facilitate the egress of circulating leukocytes into the injured tissue by releasing chemoattractants and expressing cell adhesion molecules, which are cell surface glycoproteins (Jaeschke, 1997). One group of cell adhesion molecules, called selectins, located on the membrane of endothelial cells, interact with their ligands on the surface of leukocytes, thereby slowing down the flow of these cells and causing them to “roll” on the capillary surface. Subsequently a stronger interaction (adhesion) is established between the endothelial cells and leukocytes with participation of intercellular adhesion molecules (eg, ICAM-1) expressed on the endothelial cell membrane and integrins expressed on the membrane of leukocytes. This interaction is also essential for the subsequent transendothelial migration of leukocytes. This is facilitated by gradients of chemoattractants that induce expression of leukocyte integrins. Chemoattractants originate from various

stromal cells and include chemotactic cytokines (or chemokines), such as the MCP-1 and IL-8 (whose rat homologue is the CINC-1), as well as lipid-derived compounds, such as platelet-activating factor (PAF) and leukotriene B₄ (LTB₄). Ultimately all types of cells in the vicinity of injury express ICAM-1, thus promoting leukocyte invasion; the invading leukocytes also synthesize mediators, thus propagating the inflammatory response. Production of most inflammatory mediators is induced by signaling, turned on by TNF and IL-1, which results in activation of TFs, notably NF- κ B and C/EBP (Poli, 1998) (see Fig. 3-12). Genes of many of the proteins mentioned above (eg, selectins, ICAM-1, MCP-1, IL-8) and below (eg, inducible NOS, acute-phase proteins) as well as the genes of TNF and IL-1 themselves contain binding sites for the NF- κ B (Lee and Burckart, 1998).

Inflammation—ROS and RNS Production Macrophages, as well as leukocytes, recruited to the site of injury undergo a respiratory burst, discharging free radicals and enzymes (Weiss and LoBuglio, 1982) (Fig. 3-26). Free radicals are produced in the inflamed tissue in three ways, each of which involves a specific enzyme: Nox, NOS, or myeloperoxidase.

Nox is an electron-transporting protein complex composed of two transmembrane proteins (one of them the FAD- and heme-containing catalytic subunit) and 4 cytoplasmic proteins (including the G-protein Rac) (El-Benna *et al.*, 2005). In resting cells Nox is dormant; however, in activated cells the cytoplasmic subunits become extensively phosphorylated and move to the membrane to assemble the Nox complex. Constituents of microorganisms, such as the bacterial LPS (the active endotoxin component of gram-negative bacteria), acting through the cell surface Toll-like receptors (TLR), and PKC activators, such as phorbol myristate acetate (PMA), may evoke Nox activation. Unlike in nonphagocytic cells, in macrophages and granulocytes activation causes a sudden and rapid electron transfer from NADPH through the FAD and heme in Nox to the molecular oxygen, releasing the thus formed superoxide anion radical (O₂^{•-}) in a burst (“respiratory burst”) at the external membrane surface into the phagocytic vacuole:

The O₂^{•-} can give rise to the hydroxyl radical (HO[•]) in two sequential steps: the first is spontaneous or is catalyzed by SOD, and the second, the Fenton reaction, is catalyzed by transition metal ions (see also Fig. 3-4):

Macrophages, but not granulocytes, generate another cytotoxic free radical, nitric oxide (*NO). This radical is produced from arginine by NOS (Wang *et al.*, 1993), which is inducible in macrophages by bacterial endotoxin and the cytokines IL-1 and TNF:

Subsequently, O₂^{•-} and *NO, both of which are products of activated macrophages, can react with each other, yielding peroxynitrite anion; on reaction with carbon dioxide, this decays into two radicals, nitrogen dioxide and carbonate anion radical (Fig. 3-4):

Granulocytes, but not macrophages, discharge the lysosomal enzyme myeloperoxidase into engulfed extracellular spaces, the phagocytic vacuoles (Wang *et al.*, 1993). Myeloperoxidase

catalyzes the formation of HOCl, a powerful oxidizing agent, from HOOH and chloride ion:

Like HOOH, HOCl can form HO• as a result of electron transfer from Fe²⁺ or from O₂^{•-} to HOCl:

All these reactive chemicals, as well as the discharged lysosomal proteases, are destructive products of inflammatory cells. Although these chemicals exert antimicrobial activity at the site of microbial invasion, at the site of toxic injury they can damage the adjacent healthy tissues and thus contribute to propagation of tissue injury (see the section “Tissue Necrosis”). Moreover, in some chemically induced injuries, inflammation plays the leading role. For example, ANIT, a cholestatic chemical, causes neutrophil-dependent hepatocellular damage. ANIT apparently acts on bile duct epithelial cells, causing them to release chemoattractants for neutrophil cells, which on invading the liver, injure hepatocytes (Hill *et al.*, 1999). Kupffer cell activation, TNF release, and subsequent inflammation are also prominent and causative events in galactosamine-induced liver injury in rats (Stachlewitz *et al.*, 1999).

Whereas it is well recognized that chemical-inflicted tissue injury can induce inflammation as a side reaction of tissue repair, it is becoming clear that inflammation (even if harmless alone) can precipitate an overt tissue injury on chemical exposure that is noninjurious alone. For example, a small harmless quantity of the macrophage activator LPS converts the nontoxic doses of monocrotaline, aflatoxin B₁, and allyl alcohol into markedly hepatotoxic doses (Roth *et al.*, 2003). Moreover, in rats pretreated with LPS, unlike in untreated animals, chlorpromazine, ranitidine, and trovafloxacin caused liver injury. These drugs (and many others) when given to patients can induce rare, unexpected, and not obviously dose-related liver injury. Therefore, it is hypothesized that such idiosyncratic drug reactions develop when some endotoxin exposure decreases the threshold for drug toxicity by priming the Kupffer cells that produce ROS and inflammatory mediators discussed above. Manifest or subclinical infection, GI disturbance, or alcohol consumption (which greatly increases the intestinal permeability for endotoxin) may be the source of endotoxin. It is not surprising that most idiosyncratic drug reactions affect the liver, because this organ contains 80% to 90% of the body’s fixed macrophages (ie, Kupffer cells), because the liver is the first organ to be exposed to LPS translocating from the intestinal lumen, and because the Kupffer cells not only are activated by LPS but also remove it from the circulation, thereby protecting other organs from its inflammatory effects (Roth *et al.*, 2003). However, the causative relationship between inflammation and idiosyncrasy needs further substantiation.

Altered Protein Synthesis: Acute-Phase Proteins Cytokines released from macrophages and endothelial cells of injured tissues also alter protein synthesis, predominantly in the liver (Baumann and Gauldie, 1994) (Fig. 3-21). Mainly IL-6 but also IL-1 and TNF act on cell surface receptors and increase or decrease the transcriptional activity of genes encoding certain proteins called positive and negative acute-phase proteins, respectively, utilizing primarily the TFs NF-κB, C/EBP, and STAT (Poli, 1998; see Fig. 3-15). Many of the hepatic acute-phase proteins, such as C-reactive protein and hepcidin, are secreted into the circulation, and their elevated levels in serum are diagnostic of tissue injury, inflammation, or neoplasm. Increased sedimentation of red blood cells, which is also indicative of these conditions, is due to enrichment of blood plasma with positive acute-phase proteins such as fibrinogen.

Apart from their diagnostic value, positive acute-phase proteins may play roles in minimizing tissue injury and facilitating repair. For example, many of them, such as α₂-macroglobulin and α₁-antitrypsin, inhibit lysosomal proteases released from the injured cells and recruited leukocytes. Haptoglobin binds hemoglobin in blood, MT complexes metals in the cells, heme oxygenase oxidizes heme to biliverdin, and opsonins facilitate phagocytosis. Thus, these positive acute-phase proteins may be involved in the clearance of substances released on tissue injury. Induction of hepcidin, which triggers degradation of the iron exit channel ferroportin (see the section “Mechanisms of Adaptation”) and thus decreases the duodenal Fe²⁺ absorption and Fe²⁺ export from macrophages, may be protective by limiting iron availability in the circulation for pathogens and by minimizing the Fe²⁺-catalyzed Fenton reaction (Fig. 3-4), the source of reactive hydroxyl radicals that may cause tissue injury.

Negative acute-phase proteins include some plasma proteins, such as albumin, transthyretin, and transferrin, as well as hepatic enzymes (eg, several forms of cytochrome P450 and glutathione S-transferase), ligand-activated TFs (eg, PPARα and the bile acid receptor FXR), and transporters, such as bile acid transporters at the sinusoidal and canalicular membrane of hepatocytes (NTCP and bile salt export pump [BSEP], respectively) and the bile canalicular export pump Mrp2. Because the latter enzymes and transporters play important roles in the toxication, detoxication, and excretion of endobiotics and xenobiotics, the disposition and toxicity of bile acids and toxicants may be altered markedly during the acute phase of tissue injury.

Although the acute-phase response is phylogenetically preserved, some of the acute-phase proteins are somewhat species-specific. For example, during the acute phase of tissue injury or inflammation, C-reactive protein and serum amyloid A levels dramatically increase in humans but not in rats, whereas the concentrations of α₁-acid glycoprotein and α₂-macroglobulin increase markedly in rats but only moderately in humans.

Generalized Reactions Cytokines released from activated macrophages and endothelial cells at the site of injury also may evoke neurohumoral responses. Thus, IL-1, TNF, and IL-6 alter the temperature set point of the hypothalamus, triggering fever. IL-1 possibly also mediates other generalized reactions to tissue injury, such as hypophagia, sleep, and “sickness behavior” (Rothwell, 1991). In addition, IL-1 and IL-6 act on the pituitary to induce the release of ACTH, which in turn stimulates the secretion of cortisol from the adrenals. This represents a negative feedback loop because corticosteroids inhibit cytokine gene expression.

Mechanisms of Adaptation

Adaptation may be defined as a harm-induced capability of the organism for increased tolerance to the harm itself. It involves responses acting to preserve or regain the biological homeostasis in the face of increased harm. Theoretically, adaptation to toxicity may result from biological changes causing (1) diminished delivery of the causative chemical(s) to the target, (2) decreased size or susceptibility of the target, (3) increased capacity of the organism to repair itself, and (4) strengthened mechanisms to compensate the toxicant-inflicted dysfunction. Mechanistically, adaptation involves sensing the noxious chemical and/or the initial damage or dysfunction, and a response that typically occurs through altered gene expression. Such mechanisms will be briefly overviewed below.

Adaptation by Decreasing Delivery to the Target The first step in the development of toxicity is delivery of the ultimate

toxicant (a xenobiotic, its metabolite or xenobiotic-generated ROS and RNS) to the target (Fig. 3-2). Certain chemicals induce adaptive changes that lessen their delivery by diminishing the absorption, increasing their sequestration by intracellular binding proteins, enhancing their detoxication, or promoting their cellular export.

Repression of Iron Absorption Adaptive mechanisms triggered by iron itself adjust the intestinal absorption of this essential yet potentially harmful metal ion, a catalyst of hydroxyl radical formation by the Fenton reaction (Fig. 3-4), to its demand. Fe^{2+} is taken up from the intestinal lumen into the enterocyte by the proton-coupled divalent metal transporter 1 (DMT1) localized in the luminal membrane and is exported across the basolateral membrane of these cells through the ferroportin iron channel. High iron intake diminishes the expression of both DMT1 and ferroportin in the enterocytes, whereas low intake has the opposite effect.

The expression of DMT1 is regulated at the translational level by the intracellular iron-regulatory proteins (IRP) that contain a [4Fe-4S] cluster. Iron supply influences the Fe content of this cluster and in turn affects the capacity of IRP to bind to mRNAs containing iron response element (IRE) in their untranslated regions and to alter translation. In iron deficiency, loss of Fe from the [4Fe-4S] cluster allows the thus formed IRP1 apoprotein to bind to and protect DMT1 mRNA from enzymatic degradation. On becoming more abundant, DMT1 mRNA translates into more DMT1 protein. Conversely, iron overload saturates IRP1 with Fe, making it incapable of binding to and stabilizing the DMT1 mRNA. The consequential loss of DMT1 mRNA and its translation into less DMT1 protein then limits Fe^{2+} absorption. This physiologically important adaptive mechanism may have toxicological corollary. Since DMT1 also mediates the transport of Cd^{2+} , DMT1 overexpression in iron deficiency increases intestinal absorption of this highly toxic metal ion (Park *et al.*, 2002).

Ferroportin allows exit of iron not only from enterocytes but also from macrophages (which obtain iron from phagocytosed senescent or damaged erythrocytes) and hepatocytes (which store iron). The abundance of ferroportin in the plasma membrane of these cells is regulated directly by hepcidin, a peptide hormone secreted by the hepatocytes of the liver (Ganz, 2011). By binding to ferroportin, hepcidin triggers the internalization and lysosomal hydrolysis of ferroportin. Hepatic production of hepcidin is sensitive to iron supply. Iron deficiency decreases hepcidin secretion, precluding ferroportin degradation and thus increasing the abundance of this iron exporter in the basolateral membrane of enterocytes. This (together with the upregulated DMT1 in the apical membrane of these cells) permits increased iron absorption from the duodenum. In contrast, iron overload increases the secretion of hepcidin, which in turn induces degradation of ferroportin, thereby preventing iron export from the enterocytes. Thus, decreased synthesis of DMT1 (see above) and degradation of ferroportin act in concert to shut down iron absorption from the intestine and protect against iron excess from the diet, from lysed red blood cells, or from ferritin. The toxicological significance of this mechanism is exemplified by findings with diquat, a redox cycling hepatotoxic herbicide that (like paraquat, see Fig. 3-3) can accept an electron, forming diquat monocation radical ($\text{DQ}^{+\bullet}$), which in turn transfers the electron to O_2 , producing superoxide anion radical ($\text{O}_2^{\bullet-}$). Soon after diquat injection to rats, hepatic free iron increased dramatically (purportedly because both $\text{DQ}^{+\bullet}$ and $\text{O}_2^{\bullet-}$ had reductively released Fe^{2+} from ferritin) followed by a rise in hepatic hepcidin mRNA first, and later by a decrease in plasma iron (Higuchi *et al.*, 2011), a seemingly appropriate protective response.

Inappropriately elevated hepcidin, however, may cause iron deficiency. For example, one might speculate that elevated plasma levels of prohepcidin observed in chronic lead intoxication contribute to lead-induced anemia.

Hepcidin production by hepatocytes is transcriptionally regulated by Smad4 and STAT3 TFs through their cognate response elements in the hepcidin gene (Ganz, 2011). Two pathways converge on Smad4: one signals the amount of intracellular iron, whereas the other signals the quantity of plasma iron. Increase in intracellular iron in the liver cells is detected by unidentified sensors that induce secretion of bone morphogenetic protein (BMP6, a TGF- β -like signaling molecule) acting in an autocrine or paracrine manner on its cell surface BMP receptor that activates Smad4 by phosphorylation (like TGF- β does in pathway 8 shown in Fig. 3-12). Increase in plasma iron is detected by the transferrin receptor (TFR) of hepatocytes when activated by transferrin saturated with iron. Then TFR relays the signal through adapter proteins to the BMP receptor, which thus becomes increasingly sensitive to its ligand, BMP6. The pathway descending to STAT3 is initiated by IL-6 (see Fig. 3-12, item 1), a cytokine that triggers the acute-phase response, explaining why hepcidin is also a positive acute-phase protein (see above). In summary, the pathways initiated by transferrin and BMP receptors upregulate the hepatic production of hepcidin that reduces iron absorption in response to iron overload, whereas the pathway triggered by IL-6 has a similar effect in response to inflammation, tissue injury, or cancer, conditions with increased IL-6 production. The latter disorders may cause anemia by this mechanism.

Induction of Ferritin and Metallothionein Adaptive cellular accumulation of the binding proteins ferritin and MT is protective against their respective ligands, iron and cadmium ions. Interestingly, upregulation of ferritin by iron overload, like downregulation of DMT1, is also translationally mediated by IRP1. However, the apoIRP1 (which is formed in iron deficiency) acts oppositely on ferritin mRNA and blocks its translation. Iron overload relieves this blockade, as it yields IPR1 with the [4Fe-4S] cluster, which does not bind to the IRE in ferritin mRNA, thus causing a surge in ferritin translation. Ferritin is protective as it removes Fe^{2+} from the Fenton reaction (Fig. 3-4) and incorporates it as Fe^{3+} through its ferroxidase activity.

MT is greatly induced by cadmium and elevated levels of MT protect the liver by restricting distribution of this toxic metal ion to sensitive intracellular targets (Klaassen *et al.*, 1999). Induction of MT by Cd^{2+} is likely indirect, mediated by Zn (displaced from intracellular binding sites), which activates the metal-responsive transcription factor 1 (MTF-1) that in turn augments transcription of the MT gene by binding to the metal-responsive elements in its promoter (Lichtlen and Schaffner, 2001).

Induction of Detoxication—The Electrophile Stress Response, Part 1

Adaptive increases in detoxication (ie, elimination of xenobiotics, their reactive metabolites, harmful endobiotics, or ROS and RNS by biotransformation) and cellular export have a major role in limiting toxicity. Such adaptation is typically induced by compounds with thiol reactivity (ie, soft electrophiles, oxidants, and those generating oxidative stress), which are sensed by the cytosolic Keap1–Nrf2 protein complex. The response is initiated by the TF Nrf2, which activates genes with electrophile response element (EpRE) in their regulatory region (Fig. 3-27; Dinkova-Kostova *et al.*, 2005). Normally Nrf2 is retained in the cytoplasm by Keap1, a cysteine-rich homodimeric protein. Keap1 keeps Nrf2 inactive and at low intracellular levels by anchoring it to the cytoskeleton and also by linking it to cullin 3, a component in certain E3 ubiquitin ligase complexes, thereby initiating ubiquitination of

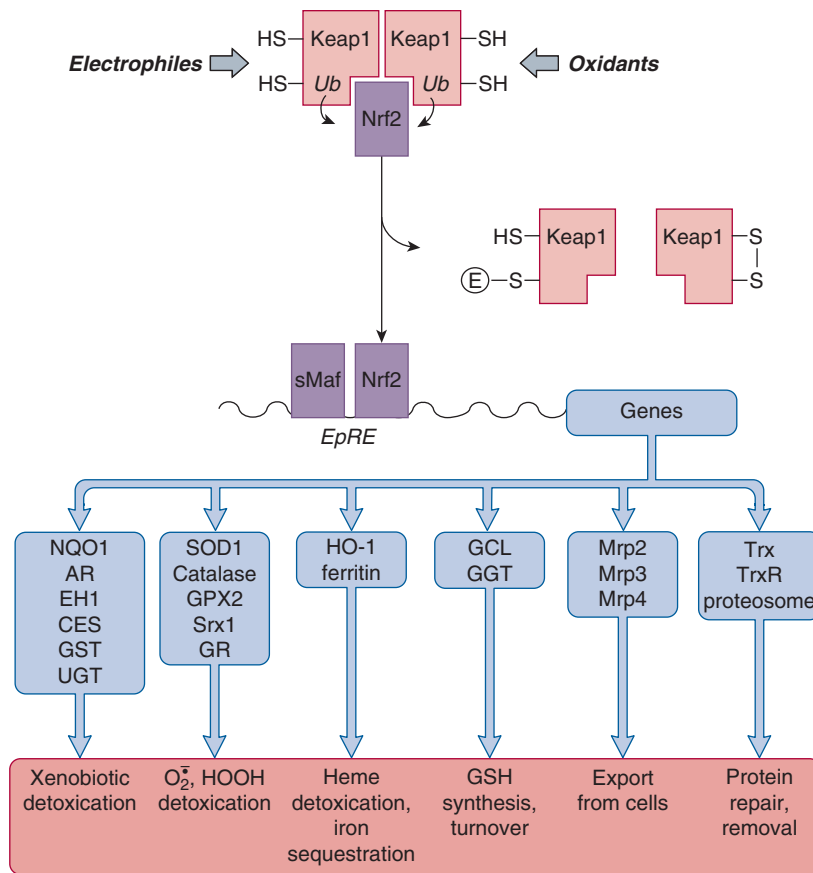

Figure 3-27. Signaling by Keap1/Nrf2 mediates the electrophile stress response. Normally NF-E2-related factor 2 (Nrf2) is kept inactive and at a low intracellular level by interacting with Keap1 that promotes its proteasomal degradation by ubiquitination. Electrophiles covalently bind to, whereas oxidants oxidize the reactive thiol groups of Keap1, causing Keap1 to release Nrf2. Alternatively, Nrf2 release may follow its phosphorylation by protein kinases. After being released from Keap1, the active Nrf2 accumulates in the cell, translocates into the nucleus, and forms a heterodimer with small Maf proteins to activate genes that contain electrophile response element (EpRE) in their promoter region. These include enzymes, binding proteins, and transporters functioning in detoxication and elimination of xenobiotics, ROS, and endogenous reactive chemicals, as well as some proteins that can repair or eliminate oxidized proteins. Induction of such proteins represents an electrophile stress response that provides protection against a wide range of toxicants. Nrf1, a transcription factor structurally related to Nrf2, also interacts with Keap1 and Maf proteins as well as EpRE and its role is partially overlapping with that of Nrf2. *Abbreviations:* AR, aldose reductase; CES, carboxylesterase; EH1, microsomal epoxide hydrolase; GCL, glutamate–cysteine ligase; GGT, gamma-glutamyl transpeptidase; GPX2, glutathione peroxidase 2; GR, glutathione reductase; GST, glutathione *S*-transferase; HO-1, heme oxygenase 1; NQO1, NAD(P)H:quinone oxidoreductase; Mrp2, Mrp3, and Mrp4, multidrug resistance protein 2, 3, and 4; SOD1, superoxide dismutase 1; Srx1, sulfiredoxin 1; UGT, UDP-glucuronosyltransferase; Trx, thioredoxin; TrxR, thioredoxin reductase.

Nrf2 for subsequent proteasomal degradation. On disruption of the Keap1–Nrf2 complex, the active Nrf2 escapes rapid degradation and accumulates in the cell. Electrophiles, such as quinones (eg, *t*-butylquinone), quinoneimines (eg, NAPBQI derived from acetaminophen), quinone methides (eg, metabolite of butylated hydroxytoluene), α,β -unsaturated aldehydes and ketones (eg, the lipid peroxidation products 4-oxonon-2-enal, 4-hydroxynon-2-enal, and 15-A₂-isoprostane), isothiocyanates (eg, ANIT), thiol-reactive metal ions (eg, Cd²⁺), and trivalent arsenicals, as well as direct and indirect oxidants (eg, HOOH, diquat, quinones) may attack Keap1 at its reactive cysteine thiol groups by binding to them covalently or oxidizing them, thereby forcing Keap1 to release Nrf2. After being released from Keap1, Nrf2 translocates into the nucleus, forms a heterodimer with small Maf proteins, and activates genes through binding to EpREs.

There are many genes with EpRE motifs that encode proteins known to be important in detoxication and export (Fig. 3-27). These include genes that code for (1) enzymes that detoxify xenobiotics (eg, NQO1, NQO2, AR, EH-1, CES1e1, CES2a6, GST, and

UGT), (2) enzymes that eliminate O₂⁻ (ie, SOD1) and HOOH (eg, GPX2, catalase, and Srx1; the latter reduces the overoxidized peroxiredoxins that in turn can reduce not only HOOH [see Fig. 3-5] but also lipid hydroperoxides and peroxinitrite), (3) proteins that detoxify heme (HO-1) and Fe²⁺ (ferritin), (4) enzymes involved in the synthesis of GSH and its regeneration from GSSG (eg, GCL and the NADPH-forming G6PDH), and (5) transporters that pump xenobiotics and their metabolites out of cells (eg, Mrp2, 3, and 4). Other Nrf2-induced proteins of known toxicological relevance will be mentioned later.

As demonstrated in Fig. 3-28 through the example of *t*-butylhydroquinone (*t*BHQ), these Nrf2-mediated adaptive changes facilitate elimination and detoxication of electrophilic chemicals, as well as ROS that may be generated by them, and assist in repairing or removing damaged proteins (to be discussed later); therefore, Nrf2 conveys protection against a wide range of toxicants. Indeed, Nrf2 knockout mice are more sensitive to the hepatotoxicity of acetaminophen, pentachlorophenol, and carbon tetrachloride, the pulmonary toxicity of butylated hydroxytoluene, hyperoxia, or cigarette smoke,

Figure 3-28. Adaptive changes in response to the *t*-butylhydroquinone (*t*BHQ)–induced electrophile stress that influence the metabolic fate and some effects of *t*BHQ and of superoxide anion radical generated in the course of *t*BHQ biotransformation. This figure illustrates the numerous proteins (ie, enzymes, exporters, repair proteins) that, when induced in response to the *t*BHQ–induced electrophile stress, facilitate the detoxication and export of *t*BHQ and/or its metabolites, the detoxication of ROS formed during the biotransformation of *t*BHQ, and repair or removal of proteins damaged by the reactive metabolites. Proteins induced by Nrf2 as a result of adaptation to the electrophile stress are marked with an asterisk.

*t*BHQ (1) can be detoxified by UDP-glucuronosyltransferase to form *t*BHQ glucuronide (2) and toxified by cytochrome P450–catalyzed dehydrogenation to *t*-butylquinone (*t*BQ; 3), which contains electrophilic carbon atoms (+), and is believed to be the actual inducer of electrophile stress response. *t*BQ can undergo 3 biotransformations. First, it can be detoxified by conjugation with glutathione (GSH) to form *t*BHQ-SG (4), which, together with *t*BHQ-glucuronide, is exported from the cell by Mrp2, 3, and 4. Second, *t*BQ can covalently bind to SH groups in proteins (5), including Keap1. Third, by accepting an electron (e^-), *t*BQ can form *t*-butylsemiquinone radical (6), which can pass the electron to molecular oxygen to form superoxide anion radical ($O_2^{\bullet-}$), completing a redox cycle. In a process catalyzed by superoxide dismutase (SOD), $O_2^{\bullet-}$ can form HOOH, which is detoxified by GSH-peroxidase (GPX), using GSH (whose synthesis is rate-limited by GCL), or toxified by Fe^{2+} -catalyzed Fenton reaction to form hydroxyl radical (HO^\bullet). HO^\bullet can react with proteins to form oxidized proteins (Prot-C=O, Prot-S-S), which can be degraded in the proteasome, or Prot-S-S can also be repaired through reduction by the thioredoxin (Trx)–thioredoxin reductase (TrxR) system. HO^\bullet can also react with lipid (L) and form lipid hydroperoxide (LOOH), which can be reduced to lipid alcohol (LOH) by GPX at the expense of GSH. This results in formation of glutathione disulfide (GSSG), which can be reduced back to GSH by glutathione reductase (GR) at the expense of NADPH generated by glucose-6-phosphate dehydrogenase (G6PDH). Virtually all of these processes become more effective after the electrophile stress response.

the neurotoxicity of 3-nitropropionic acid, and the carcinogenicity of benzo[*a*]pyrene (Klaassen and Reisman, 2010). Conversely, liver-specific deletion of Keap1 constitutively activates Nrf2 in hepatocytes, causing them to overexpress many detoxifying enzymes and become resistant to acetaminophen-induced hepatotoxicity.

Nrf2 can be activated by treatment with several chemicals of low toxicity that are thiol-reactive as soft electrophiles or oxidants.

These include *t*BHQ, butylated hydroxyanisole (BHA), sulfaphane (a compound in broccoli with an electrophilic isothiocyanate group), curcumin (a compound in turmeric containing 2 α,β -unsaturated ketone groups), resveratrol (a hydroquinone-type compound in red grapes that may undergo oxidation to a quinone and redox cycling, like shown for *t*BHQ in Fig. 3-28), derivatives of oleoanolic acid, such as 2-cyano-3,12-dioxooleana-1,9(11)-dien-28-oi-

acid (CDDO, which contains 2 electrophilic enone groups), and oltipraz (a dithiolene compound whose metabolites can form mixed disulfides with thiols, probably also with those on Keap1). These chemicals induce Nrf2 target genes (Fig. 3-27) and protect from toxicant-induced tissue injury and cancer. For example, treatment with oleanolic acid or CDDO ameliorates acetaminophen-induced hepatotoxicity and aflatoxin-induced hepatocarcinogenesis (Klaassen and Reisman, 2010). The superpotent Nrf2 agonist CDDO is now tested clinically for use in chronic kidney diseases. Of these chemopreventive agents, some (eg, *t*BHQ, BHA, and resveratrol) are antioxidants; hence the inappropriate names “antioxidant response” and “antioxidant response element” (ARE) for the Nrf2-mediated adaptive alterations and the cognate DNA-binding site for Nrf2, respectively. It became apparent only later that the electrophilic quinone metabolites of these chemicals are the inducers and not the antioxidants.

Adaptation by Decreasing the Target Density or Responsiveness Decreasing the density and sensitivity of the xenobiotic target is an adaptation mechanism for several cell surface receptors. Such alterations underlie the tolerance induced by opioids, abused drugs of considerable clinical toxicological interests.

Induction of Opioid Tolerance The main target of opioids (eg, morphine, heroin, methadone) is the μ -opioid receptor. Stimulation of this G_i protein-coupled inhibitory receptor by an agonist results in adenylyl cyclase inhibition (causing decline in cyclic AMP levels and PKA activity) and K^+ channel opening (causing hyperpolarization) (Fig. 3-15) in neurons with opioid receptors, such as those in the midbrain periaqueductal gray. Even brief stimulation induces adaptive alterations: the receptor is desensitized by G-protein receptor kinase-mediated phosphorylation and β -arrestin binding, and then becomes uncoupled from the G protein and internalized via a clathrin-dependent pathway. Whereas some receptors are recycled to the cell membrane, others are degraded in the lysosomes, causing receptor downregulation (Bailey and Connor, 2005). On prolonged stimulation, adenylyl cyclase signaling undergoes a compensatory increase. Tolerance to opioids, though far from being clarified mechanistically, may result from downregulation of the receptors and upregulation of adenylyl cyclase signaling. These changes would require increasing doses of agonist to produce an effect (ie, inhibition of adenylyl cyclase signaling) as intensive as after its first application. These adaptive changes could also explain the withdrawal reaction, that is, appearance of clinical symptoms (dysphoria, excitement, pain sensation), contrasting with the pharmacologic effects of opioids (euphoria, sedation, analgesia), on abrupt termination of drug treatment, because withdrawal of the opioid would disinhibit the reinforced signaling it had inhibited. Nevertheless, mechanistic relationships between tolerance and the withdrawal reaction remain controversial (Bailey and Connor, 2005). An important clinical feature of opioid tolerance is that the tolerance to the respiratory depressive effect is short-lived and sensitivity returns after some abstinence. Therefore, abusers often kill themselves with a dose tolerated earlier.

Adaptation by Increasing Repair There are several repair mechanisms that can be induced after toxicant exposure. Some of these may aid in repairing damaged molecules, proteins, and DNA, others in regenerating the injured tissue.

Induction of Enzymes Repairing Oxidized Proteins—The Electrophile Stress Response, Part 2 After sublethal exposure to chemicals, such as *t*BHQ, 4-hydroxynon-2-enal, and Cd^{2+} , not

only enzymes functioning in xenobiotic detoxication but also some of those mediating protein repair become overexpressed as part of the above-described electrophile response. The induced proteins include thioredoxin 1 (Trx1) and thioredoxin reductase 1 (TR1), which can reduce oxidized proteins (protein disulfides, -sulfenic acids, and -methionine sulfoxides) (Fig. 3-22), and several subunits of the proteasome complex, which hydrolyzes damaged proteins. These repair proteins are transcribed from genes containing EpRE, and their transcription is controlled by Nrf2 (Fig. 3-27). As Trx1 and TR1 are reduction partners for ribonucleotide reductase, they support this enzyme in forming deoxyribonucleotides for DNA synthesis. Thus, induction of Trx1 and TR1 also assists DNA repair.

Induction of Chaperones Repairing Misfolded Proteins—The Heat-Shock Response The cellular abundance of many molecular chaperones, which can disaggregate and refold denatured proteins, also increases after physical and chemical stresses (eg, heat, ionizing radiation, oxidants, electrophile reactants, and metal ions). Two adaptive reactions involving overexpression of chaperones are known; they are the heat-shock response and the EPR stress response.

Although first observed as a result of hyperthermia, the heat-shock response is an adaptive mechanism also triggered by various pathologic conditions (eg, trauma, tissue ischemia) and by virtually all reactive chemicals and/or their metabolites (eg, electrophiles, oxidants, lipid peroxidation products, metal ions, arsenite) that denature proteins. Thus, it takes place simultaneously with the electrophile response discussed above. This reaction, however, is governed by heat-shock transcription factors (HSF), mainly HSF1, which transactivate genes that encode Hsp through heat-shock response elements (HSE) within the promoter region. HSF1, like Nrf2, normally resides in the cytoplasm, where it associates with Hsp90, Hsp70, and Hsp40. On heat- or chemical-induced protein damage, these Hsps are purportedly sequestered by damaged proteins, allowing HSF1 to be released. HSF1 then migrates into the nucleus, trimerizes, undergoes phosphorylation, and stimulates the transcription of Hsp genes. As described in the section “Repair of Proteins,” the chaperones Hsp90 and Hsp70, together with co-chaperone proteins, are especially important in maintaining the integrity of hundreds of proteins (Pratt *et al.*, 2010). The client proteins include not only those carrying out housekeeping functions but also those involved in signaling and apoptosis. Therefore, induction of Hsps has pleiotropic effects besides increased protection from cytotoxicity. However, when the proteotoxic stress induces excessive protein unfolding, Hsp70 and Hsp40 recruit the ubiquitin system (Fig. 3-23) to tag the aberrant proteins for proteasomal degradation (Bedford *et al.*, 2011).

Induction of Chaperones Repairing Misfolded Proteins—The Endoplasmic Reticulum Stress and the Unfolded Protein Response All proteins that are destined for export or insertion into cellular membranes pass through the EPR. In this Ca^{2+} -rich oxidative environment, they may be subjected to *N*-glycosylation at asparagine residues by oligosaccharyltransferase, formation of disulfide bonds by protein disulfide isomerases, and folding assisted by EPR-resident chaperones, such as the glucose-regulated proteins Grp78 (also called binding immunoglobulin protein [BiP]) and Grp94 as well as the Ca^{2+} -binding proteins calreticulin and calnexin. Damage of proteins being processed in the EPR by reactive metabolites produced *in situ* by CYP enzymes (eg, the quinonimine metabolite of acetaminophen, Cl_3C^{\bullet} and Cl_3COO^{\bullet} radicals formed from CCl_4 , and ROS generated by CYP2E1 during oxidation of ethanol) and/or depletion of Ca^{2+} in the EPR lumen (eg,

by inactivation of the EPR Ca^{2+} -ATPase by reactive metabolites) causes accumulation of unfolded or misfolded proteins, a condition known as EPR stress (Cribb *et al.*, 2005; Nagy *et al.*, 2007; Malhi and Kaufman, 2011). Protein folding disorder can also be experimentally induced by some natural compounds that disturb the homeostasis of EPR at specific steps, such as thapsigargin (which blocks SERCA-mediated Ca^{2+} uptake into EPR; see Table 3-7), tunicamycin (which inhibits *N*-glycosylation of proteins), castanospermine (which interferes with maturation of nascent glycoproteins by deglycosylation), and brefeldin A (which inhibits transport of proteins from EPR to Golgi).

When the load of unfolded or misfolded proteins in the EPR exceeds the capacity of EPR-resident chaperones, these proteins trigger a complex adaptive response, called unfolded protein response (UPR). This may constrain exacerbation of the disorder (1) by attenuation of mRNA translation to decrease the functional load on the EPR, (2) by increased transcription of EPR chaperones to boost the folding capacity, (3) by initiating the translocation of aberrant proteins via translocon peptide channels from the EPR into the cytosol for proteasomal degradation, and (4) by eliminating the affected cell via apoptosis, if the EPR stress is sustained or massive. The eukaryotic translation initiation factor 2α (eIF2 α) and TFs X-box binding protein 1 (XBP1), ATF6, ATF4, and C/EBP homologous protein (CHOP) (or Gadd153) are the major executioners of this adaptive response.

Three transmembrane EPR proteins sense the overload of the EPR lumen with misfolded proteins and transduce this signal to initiate the UPR. These are (1) PERK, (2) inositol-requiring enzyme 1 α (IRE1 α), a protein with kinase and endoribonuclease (RNase) activities, and (3) the precursor form ATF6 (activating TF 6). Normally, these sensor proteins are turned off by being associated at their luminal domain with the EPR-resident soluble chaperone BiP (or Grp78). However, when EPR stress occurs, the unfolded proteins that accumulate in the lumen of the EPR sequester BiP away from these sensors, thereby turning them on to signal for the UPR. PERK stripped off BiP is activated by dimerization and trans-autophosphorylation. With its kinase activity thus raised, PERK catalyzes the phosphorylation of the eIF2 α , with the phosphorylated eIF2 α causing a global translation attenuation and decreased synthesis of most (but not all) proteins. The second EPR stress sensor IRE1 α also undergoes dimerization and trans-autophosphorylation on dissociation from BiP. These changes boost the RNase activity of IRE1 α , enabling it to cleave and process a mRNA into one that translates into XBP1, an active TF, another executioner of UPR. The third sensor ATF6 resides as a 90 kDa precursor protein in the EPR with its Golgi localization sequences masked by BiP. On dissociation from BiP, ATF6 translocates to the Golgi, undergoes a so-called regulated intramembrane proteolysis (by site-1 and site-2 proteases), yielding a 50 kDa fragment, the active TF ATF6. XBP1 and ATF6 bind alone or as heterodimers to cognate DNA sequences, such as EPR response element (ERSE) and unfolded protein response element (UPRE), and activate the transcription of genes coding for chaperone proteins that promote protein folding (eg, Grp78, Grp94, Mdg1/Erdj4, Herp) and for proteins that assist in degradation of misfolded proteins (eg, EPR degradation-enhancing α -mannosidase-like protein [EDEM]).

On excessive EPR stress, the three activated sensors, that is, PERK, ATF6, and IRE1 α , may act in concert to initiate apoptosis (Malhi and Kaufman, 2011). While PERK-catalyzed phosphorylation of eIF2 α decreases the synthesis of most proteins (as stated above), it increases the synthesis of some, including that of ATF4. This TF (as well as ATF6) promotes the expression of CHOP, yet another TF. CHOP in turn can transcriptionally induce

the expression of the proapoptotic Bim protein and the cell surface death receptor TRAIL-2, while inhibiting the expression of the antiapoptotic Bcl-2 protein (see Fig. 3-19). The activated IRE1 α may initiate cell death via recruiting the adaptor protein TNF receptor-associated factor-2 (TRAF2), with subsequent activation of apoptosis signal-regulating kinase 1 (ASK1) and JNK. By phosphorylation, JNK can activate the proapoptotic Bim and inactivate the antiapoptotic Bcl-2 proteins (Malhi and Kaufman, 2011). The IRE1 α -TRAF2 complex may also recruit and activate procaspase 12. Alternatively, Ca^{2+} released from the EPR can activate calpains, which cleave the EPR-associated procaspase 12 into active caspase 12. The latter then engages the caspase cascade (see Fig. 3-19) by activating effector caspases therein to sacrifice the cell by apoptosis. Several toxicants have been shown to induce EPR stress in experimental animals and in isolated cells by demonstrating expression of some elements of the UPR on toxicant exposure (Cribb *et al.*, 2005; Nagy *et al.*, 2007; Malhi and Kaufman, 2011).

Induction of Enzymes Repairing DNA—The DNA Damage Response (DDR)

DDR is initiated by detection of the DNA damage. Double-stranded DNA breaks are recognized by the MRN complex (the trimer of Mre11, Rad50, and Nbs1 proteins) or the Ku protein (the dimer of Ku70 and Ku80; see the section “Repair of DNA”) that bind and activate protein kinases ataxia telangiectasia mutated (ATM) and DNA-PKcs, respectively. A third kinase, ataxia telangiectasia and Rad3-related (ATR), is activated in response to persistent single-stranded DNA coated with replication protein A (RPA), an intermediate during nucleotide excision or recombination DNA repair processes. Directly or through checkpoint kinases (Chk1, Chk2), these kinases phosphorylate p53 (Christmann *et al.*, 2003; McGowan and Russell, 2004), a protein that can play the role of a TF regulating gene expression and the role of an associate protein affecting the function of its interacting protein partner. Normally, p53 is kept inactive and at low levels by its binding protein mdm2 (see Fig. 3-33), which ubiquitinates p53, facilitating its proteasomal degradation. On phosphorylation, p53 escapes from mdm2, allowing its activation and stabilization. Indeed, the levels of p53 protein in cells increase dramatically in response to DNA damage caused by UV or gamma irradiation or genotoxic chemicals. p53 then facilitates DNA repair by a number of mechanisms. For example, mainly by transcriptionally upregulating the cyclin-dependent kinase inhibitor protein p21, p53 arrests cells in G1 phase of the cell cycle (see Fig. 3-33), allowing more time for DNA repair. As a TF, p53 also increases expression of proteins directly involved in DNA repair (Harms *et al.*, 2004). Such proteins include (a) growth arrest and DNA damage inducible (gadd45), which interacts with histones and facilitates access of proteins (eg, topoisomerase) to DNA, (b) XPE and XPC, members of the xeroderma pigmentosum group of proteins important in UV-induced DNA damage recognition before nucleotide excision repair, (c) MSH2 operating in mismatch repair, (d) PCNA that holds DNA polymerase- δ to DNA during DNA replication as well as reparative DNA synthesis in the excision and the recombination repair processes, and (e) a form of ribonucleotide reductase that provides deoxyribonucleotides for sealing DNA gaps. As a partner protein, p53 supports the function of several proteins of the nucleotide excision machinery (eg, TFIH, XPB, XPD). (Other roles p53 plays in apoptosis and in carcinogenesis as a tumor suppressor protein are illustrated in Figs. 3-19 and 3-33 and discussed elsewhere in this chapter.) The DNA-damage-activated protein kinases (ATM, ATR, and DNA-PK) also phosphorylate histone H2AX adjacent to the damage, which then becomes ubiquitinated. These markings in turn recruit repair proteins (including BRCA1) and induce chromatin

relaxation for better access of repair enzymes to the lesion. The DDR-initiating kinases have numerous other protein substrates, including other kinases; therefore, DDR may extend to diverse cellular functions. It is important to realize that while both the complex DDR and distinct DNA repair mechanisms (eg, direct repair by MGMT) protect normal cells that suffered DNA damage from transformation into cancer cells (a process to be discussed below), these mechanisms, if remain operative in cancer cells, can protect them from mortal DNA damage inflicted by radiotherapy or chemotherapy, and thereby DDR and DNA repair can contribute to resistance of tumor cells to anticancer treatments.

Adaptive Increase in Tissue Repair—A Proliferative Response

Many toxicants potentially injurious to cells, for example, electrophiles, oxidants, and those inducing oxidative stress, can initiate mitogenic signaling as a prelude to tissue repair via cell replacement. It appears that the need for mitogenesis is sensed by PTP (eg, PTP1B) and the lipid phosphatase PTEN, which contains reactive cysteine thiols at their active site (Rhee *et al.*, 2005). These phosphatases serve as brakes on the growth factor receptor–initiated mitogenic signaling, as PTPs dephosphorylate (and inactivate) the receptors themselves (eg, EGFR, PDGFR, IGF1R) as well as some protein kinases (eg, Src and JAK), whereas PTEN dephosphorylates PIP₃, an important second messenger in the PI3K–Akt–IKK–NF- κ B pathway (Fig. 3-12). Electrophiles covalently bind to essential cysteine-SH groups in these phosphatases. HOOH can oxidize the critical -SH group in PTEN to an intramolecular disulfide, whereas it oxidizes the -SH group of PTP1B, through sulfenic acid (-S-OH), to a 5-membered cyclic sulfenyl amide species in which the sulfur atom is covalently linked to the nitrogen of the neighboring serine (Rhee *et al.*, 2005). Inactivation of PTPs and PTEN, which decrease the proliferative signal transduction, amplifies intracellular signaling for mitosis and survival.

It has been known for some time that oxidative stress, if not severe, activates the TF NF- κ B (Dalton *et al.*, 1999). For example, silica, which can produce ROS on its surface, activates NF- κ B as well as PI3K when added to various cells (Castranova, 2004). In light of new information discussed above, NF- κ B activation is now attributed to the fact that this TF is situated downstream of growth factor receptors (which are negatively controlled by the ROS-sensitive PTP) and PIP₃ (which is eliminated by ROS-sensitive PTEN) (Fig. 3-12). Furthermore, NF- κ B is at the focal point of proliferative and prolife signaling, as it transactivates genes producing cell cycle accelerators (eg, cyclin D1 and c-Myc) and apoptosis inhibitors (eg, antiapoptotic Bcl proteins and the caspase IAPs) (Karin, 2006). In addition, NF- κ B also transactivates the genes of ferritin, GST, SOD1, HO-1, a proteasome subunit, and gadd45, facilitating detoxication and molecular repair. All these roles of NF- κ B explain its involvement in tolerance to chemically induced tissue injury, resistance against cholestatic liver injury caused by bile acids, adaptation to ionizing radiation, as well as the phenomenon termed preconditioning. This is a tolerance to ischemic tissue injury (eg, myocardial infarction), a tolerance induced by temporarily enhanced ROS formation evoked by hyperoxia or brief periods of ischemia–reperfusion.

In addition to signaling for cell replacement in damaged tissue—in which NF- κ B plays a leading role—the growing cells need to boost protein synthesis. This is done under the control of the protein kinase mTOR. As shown in Fig. 3-29, mTOR activation results from signaling through both pathways coupled to growth factor receptors, that is, the MAPK pathway leading to phosphorylation of the MAPK isoform Erk and the PI3K pathway leading to phosphorylation of Akt (see Fig. 3-12). Importantly,

these pathways are subject to activation in response to oxidant or electrophile exposure as they are controlled by PTPs and PTEN (Fig. 3-12). Erk and Akt protein kinases activate mTOR through a complex mechanism (Fig. 3-29), and mTOR in turn phosphorylates and regulates effectors of protein synthesis, such as the translation repressor protein 4EBP1 and the protein kinase S6K, which modifies ribosomes increasing their translational efficiency (Shaw and Cantley, 2006). As described in the sections “Adaptation to Hypoxia—The Hypoxia Response” and “Adaptation to Energy Depletion—The Energy Stress Response,” mTOR signaling is switched off in the cell to save energy as a measure to adapt to the energy shortage caused by hypoxia or toxic impairment of ATP synthesis.

Adaptation by Compensating Dysfunction Dysfunctions caused by toxicants or drug overdose manifested at the level of organism (eg, hypoxia), organ system (eg, hypotension and hypertension), or organ (eg, renal tubular dysfunction) may evoke compensatory mechanisms.

Adaptation to Hypoxia—The Hypoxia Response When O₂ delivery is impaired and hypoxia persists for more than a few minutes, a response involving gene expression alteration is initiated. This reaction is mainly orchestrated by hypoxia-inducible factor-1 α (HIF-1 α), a ubiquitous TF whose activity and cellular abundance is greatly increased in response to hypoxia (Maxwell and Salnikow, 2004; Pouyssegur *et al.*, 2006). HIF-1 α is maintained at very low intracellular levels because of continuous hydroxylation of its 2 proline residues by HIF-prolyl hydroxylases. This permits a ubiquitin ligase subunit (called von Hippel Lindau protein [VHL]) to capture HIF-1 α and initiate its destruction by proteasomal degradation. Indeed, HIF-1 α is one of the shortest lived proteins with a half-life of less than 5 minutes. In addition, HIF-1 α is kept transcriptionally inactive by hydroxylation at one of its asparagine residues by HIF-asparagine hydroxylases, which prevents interaction of HIF-1 α with transcriptional coactivators, such as p300 and CREB-binding protein (CBP). These two types of HIF hydroxylases are O₂ sensors: they use O₂ as a substrate to carry out proline/asparagine hydroxylations with concomitant oxidative decarboxylation of 2-oxoglutarate to succinate, with the K_m of O₂ being close to the ambient O₂ concentration. As the O₂ concentration falls, decreases in the hydroxylation rate of HIF-1 α as well as its VHL-mediated ubiquitination and proteasomal degradation occur, and this increases its abundance and transcriptional activity. HIF hydroxylases belong to the Fe²⁺ and ascorbate-dependent dioxygenases (the largest group of non-heme oxidases); therefore, not only hypoxia but also Fe²⁺ deficiency impairs their activity. The latter feature explains why iron chelators (eg, deferoxamine) or Fe²⁺-mimicking metal ions (eg, Co²⁺ and Ni²⁺) also induce and activate HIF-1 α (Maxwell and Salnikow, 2004). When induced after hypoxic conditions, HIF-1 α dimerizes with HIF-1 β (also called Arnt, which, coincidentally, is the dimerization partner for the Ah receptor as well). The HIF complex transactivates a vast array of genes with hypoxia response element (HRE) in their promoter. Many of the gene products assist in acclimatization to hypoxia (Pouyssegur *et al.*, 2006). These include (1) erythropoietin (EPO) that is produced largely in kidney and activates erythropoiesis in bone marrow, (2) proteins involved in iron homeostasis (eg, transferrin, TFR, ceruloplasmin, and heme oxygenase) that may increase availability of iron for erythropoiesis, (3) vascular endothelial growth factor (VEGF) and angiopoietin-2 that stimulate blood vessel growth (ie, angiogenesis), (4) proteins facilitating anaerobic ATP synthesis from glucose (ie, glycolysis), such as the glucose transporter GLUT1 and

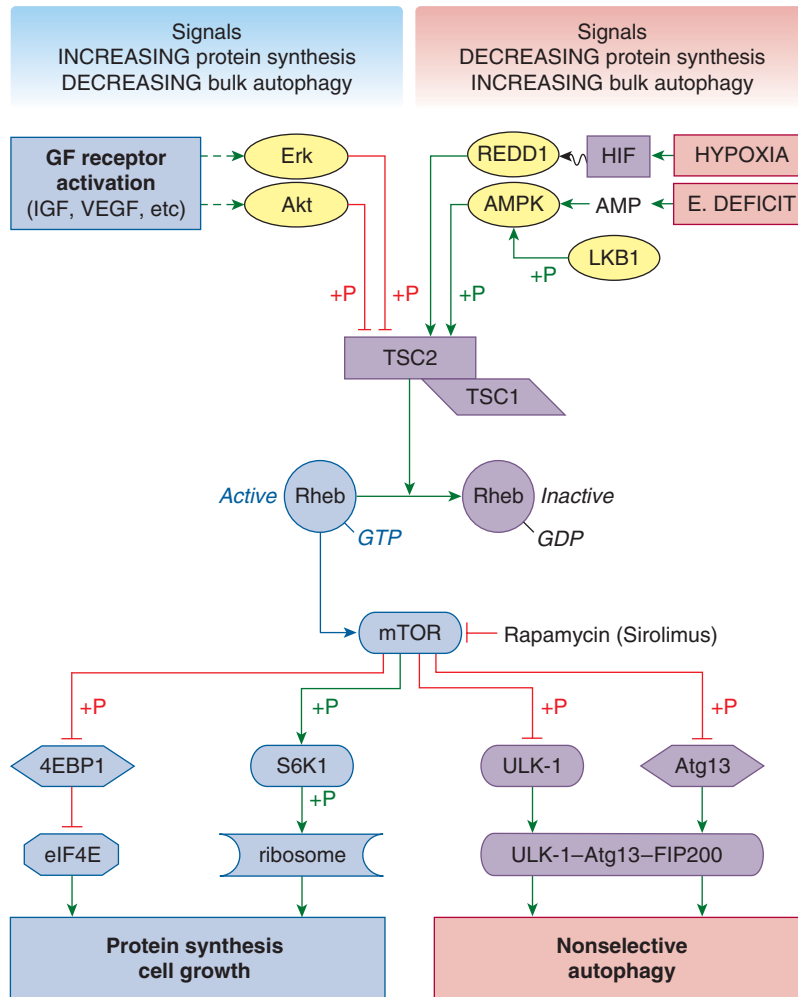

Figure 3-29. Modulation of protein synthesis and autophagy by signaling through the mTOR kinase pathway as a means for cellular adaptation—increased signaling via mTOR promotes protein synthesis at translational level and suppresses autophagy, thereby permitting cell growth and proliferation, whereas attenuated signaling via mTOR permits energy saving (by halting protein synthesis) and a desperate attempt for energy generation (by starting autophagy) when hypoxia, nutrient shortage, or toxic injury causes energy deficit. Growth factor receptors signaling via either the MAPK pathway (leading to phosphorylation of Erk) or the PI3K pathway (leading to phosphorylation of Akt) (see Fig. 3-12) activate the serine/threonine kinase, mammalian target of rapamycin (mTOR; rapamycin is also called sirolimus) by an indirect mechanism. The protein kinases Erk and Akt catalyze inactivating phosphorylation of TSC2, a member of TSC1/2 complex. TSC2 is a GTPase-activating protein whose substrate is Rheb, a small G protein (Ras homologue), which is active in the GTP-bound form and inactive in the GDP-bound form. With its GTPase activating capacity blocked by Erk or Akt, TSC2 cannot convert Rheb-GTP into inactive Rheb-GDP, and thus Rheb-GTP activates mTOR. In turn, mTOR phosphorylates 2 substrates that are necessary to initiate translation of mRNA into proteins, that is: (1) eukaryotic initiation factor 4E-binding protein-1 (4EBP1), which thus releases the translational initiation factor eIF4E, and (2) ribosomal protein S6 kinase-1 (S6K1), which phosphorylates ribosomal protein S6, thereby increasing translational efficiency of mRNAs that encode ribosomal proteins (“ribosomal biogenesis”). Simultaneously, mTOR phosphorylates and inactivates unc-51-like kinase-1 (ULK-1) and Atg13, thereby preventing nonselective or bulk autophagy that is dependent on formation of the stable complex of ULK-1, Atg13, and focal adhesion kinase family-interacting protein of 200 kDa (FIP200).

Protein synthesis for cell growth and proliferation is halted, whereas bulk autophagy is facilitated in times of energy deficit resulting from hypoxia, nutrient shortage, or toxic impairment of ATP production. Then AMP levels increase and AMP binds to the AMP-activated protein kinase (AMPK), facilitating its phosphorylation by protein kinase LKB1. Activated AMPK phosphorylates TSC2 (at a site different from that targeted by Akt and Erk), thereby increasing the GTPase-activating capacity of TSC2. This in turn switches Rheb off, making mTOR inactive. This suspends mRNA translation and starts autophagy. Hypoxia can initiate this process in a more specific way as well, that is, via stabilization of the hypoxia-inducible factor (HIF). This transcription factor induces the synthesis of REDD1 (by a mechanism that is not completely understood), which activates TSC2. See text for further details on cellular responses to hypoxia and energy deficit.

some glycolytic enzymes, (5) proteins that correct acidosis caused by glycolytic overproduction of lactate (eg, a monocarboxylate transporter and a Na^+/H^+ exchanger for export of lactate and H^+ , respectively), (6) the REDD1 signal transducer protein that initiates a complex signaling pathway that leads to suspension of the ATP-consuming protein synthesis via inactivation of the protein kinase mTOR (Fig. 3-29), and (7) many other proteins, such as

those that promote ECM remodeling (eg, matrix metalloproteinase-2) and cell migration (perhaps to facilitate access of the cells to the blood vessel), as well as BNIP3, a proapoptotic MOM protein that is also involved in autophagy of mitochondria in reticulocytes (perhaps to induce apoptosis of cells subjected to extreme hypoxia and to facilitate the terminal differentiation of red blood cells). Experiments on mice kept in low O_2 environment (hypoxic

preconditioning) demonstrated that HIF-1 α became stabilized in the retina of these animals, hypoxia-responsive genes (EPO, VEGF) were induced, and the retina became resistant to light toxicity (Grimm *et al.*, 2005). Adaptation to hypoxia also occurs, for example, in response to high-altitude hypoxia, chronic cardiorespiratory dysfunction, and ischemic preconditioning, along with other adaptive responses discussed above. The hypoxia response is also expected to develop as a result of toxicities causing hypoxia acutely or subacutely (eg, respiratory muscle weakness after organophosphate intoxication, diquat-induced pulmonary injury) or as a delayed sequel (eg, respiratory surface restriction in hard metal disease).

Adaptation to Energy Depletion—The Energy Stress Response

Cells try to maintain their adenosine nucleotide pool in triphosphorylated, energized state, which is in the form of ATP. When the rephosphorylation rate of AMP and ADP to ATP does not keep up with the rate of ATP use, because, for example, oxidative phosphorylation is impaired or ATP use for muscle contraction or ion pumping is excessive, the ratio of AMP to ATP increases. A cellular mechanism has evolved to sense this menacing energy deficit and, in order to compensate, boosts ATP production and curtails ATP consumption (Hardie *et al.*, 2006). The sensor is a ubiquitous heterotrimeric intracellular protein complex called AMP-activated protein kinase (AMPK). AMP strongly activates AMPK allosterically, and also by making it susceptible for phosphorylation by protein kinase LKB1 (or by the calmodulin-dependent protein kinase kinase [CaMKK] in neurons). The phosphorylated, and thus activated AMPK, targets 2 sets of proteins. One set includes those whose activation facilitates ATP production from catabolism of glucose and fatty acids as well as by promoting the biogenesis of mitochondria. For example, AMPK activation increases (a) glucose uptake (via recruiting to the cell membrane or activating glucose transporters GLUT4 and GLUT1), (b) glycolysis (via phosphorylation and activation of 6-phosphofructo-2-kinase [PFK-2] whose product, fructose-2,6-bisphosphate, is a glycolytic activator), and (c) fatty acid oxidation in mitochondria (via phosphorylation and inactivation of acetyl-CoA-carboxylase, whose product, malonyl-CoA, is an allosteric inhibitor of carnitine palmitoyltransferase-1 [CPT-1], which mediates uptake of long-chain fatty acid CoA esters into mitochondria). Another set of proteins, which are inactivated by AMPK (directly or indirectly), includes those that are involved in biosynthetic ATP-consuming reactions. Thus, AMPK inhibits (a) glycogen synthesis via phosphorylation and inactivation of glycogen synthase, (b) lipid synthesis by phosphorylating and inactivating acetyl-CoA-carboxylase, whose product, malonyl-CoA, is an essential substrate for fatty acid synthesis, (c) cholesterol synthesis by phosphorylating and inactivating HMG-CoA reductase, (d) glucose synthesis via inactivating phosphorylation of a transcriptional coactivator, TORC2, which then decreases expression of key gluconeogenic enzymes, such as phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase, and (e) protein synthesis, and thus cell growth, by inhibiting the protein kinase mTOR (Fig. 3-29). AMPK-mediated modulation of cellular energy supply and consumption involves mainly kinase reactions rather than new protein synthesis. Therefore, this adaptation is a rapid process. It can be a response to any harmful condition that compromises oxidative phosphorylation, such as hypoxia, hypoglycemia (especially in neurons), and chemically induced mitochondrial toxicity. For example, cells exposed to arsenite exhibit rapid increases in the AMP/ATP ratio and AMPK activity, with concomitant declines in HMG-CoA reductase activity as well as fatty acid and cholesterol synthesis (Corton *et al.*, 1994).

Apart from the above-described rapid AMPK-dependent reprogramming of the cell's intermediary metabolism from energy-consuming operation to the energy-producing mode, there is an ultimate means for the cell to generate fuel for ATP production in case of nutrient shortage. This slower process involves consumption of the cell's own constituents (lipid droplets, glycogen particles, proteins, and organelles) by nonselective or bulk autophagy (Rabinowitz and White, 2010) involving their lysosomal hydrolysis in order to gain fuel (amino acids, fatty acids, nucleosides, and carbohydrates). An essential actor in this form of autophagy is a protein complex of unc-51-like kinase-1 (ULK-1), autophagy-related protein 13 (Atg13), and focal adhesion kinase family-interacting protein of 200 kDa (FIP200), which is an initiator of autophagosome formation (Fig. 3-29). When nutrients are abundant, the ULK-1–Atg13–FIP200 complex associates with mTOR complex 1 (mTORC1), with both ULK-1 and mTOR kinase being bound by Raptor, a scaffolding protein in mTORC1. Then mTOR phosphorylates and inactivates ULK-1 and Atg13, thus inhibiting autophagy. In nutrient shortage, signaling pathways, such as those activated by AMP and hypoxia (see Fig. 3-29), inactivate mTOR kinase, thereby forcing mTORC1 to release the complex of ULK-1–Atg13–FIP200, which in turn initiates autophagosome nucleation (Hosokawa *et al.*, 2009).

In summary, mTOR kinase is a key regulator of the cell's energy homeostasis, permitting or limiting cell growth according to availability of resources, the use of which can also be controlled by mTOR through switching autophagy on and off. In the presence of abundant nutrients and growth factors, mTOR is activated, thereby promoting cell growth and metabolic activity while suppressing nonselective autophagy. In nutrient deprivation or stress (eg, energetic failure, hypoxia), signaling pathways inactivate mTOR kinase activity. This both suppresses cell growth to reduce energy demand and induces autophagy to enable stress adaptation and survival (Fig. 3-29).

After surveying the major cellular adaptation mechanisms to toxicants, it is easy to recognize that one noxious effect may initiate several adaptive responses. For example, cells exposed to a hypoxic environment can rapidly respond with both AMPK-mediated program of energy stabilization and HIF-1 α -directed adaptation to oxygen shortage. Theoretically, an electrophile toxicant that can bind covalently to cellular macromolecules and can also generate oxidative stress, such as a redox cycling quinone, would be expected to induce a number of adaptive processes, including the electrophile response, the heat-shock response, the EPR stress response, the DDR, and the proliferative response, and if it compromises ATP synthesis as well, it even induces the energy stress response.

Adaptation by Neurohumoral Mechanisms There are numerous adaptive responses to dysfunctions of organs or organ systems that are mediated by humoral or neuronal signals between cells located in the same or different organs. For example, the rapid hyperventilation evoked by acute hypoxia or HCN inhalation is mediated by a neural reflex initiated by glomus cells in the carotid body. These chemosensitive cells generate a Ca²⁺ signal via the above-described AMP sensor, AMPK, which becomes activated by hypoxia or CN⁻ through impairment of oxidative phosphorylation in these cells, causing rise in the AMP/ATP ratio (Evans *et al.*, 2005). Besides CN⁻, mitochondrial electron transport inhibitors (eg, rotenone, antimycin A, myxothiazole), uncouplers (eg, 2,4-dinitrophenol), or ATP-synthase inhibitors (eg, oligomycin) (see Table 3-6 and Fig. 3-16) as well as AMPK activators mimic the response to hypoxia in these cells. There are numerous other neurohumoral adaptive mechanisms

in the body, such as the sympathetic reflex as well as activation of the renin–angiotensin–aldosterone system in response to hypotension, and the feedback systems between endocrine glands and the hypothalamus–hypophysis, which correct abnormal hormone levels. For information on these and other mechanisms, the reader is referred to textbooks of physiology.

When Repair and Adaptation Fail

When Repair Fails Although repair mechanisms operate at molecular, cellular, and tissue levels, for various reasons they often fail to provide protection against injury. First, the fidelity of the repair mechanisms is not absolute (eg, the nonhomologous end joining that restores DNA DSB), making it possible for some lesions to be overlooked or erroneously fixed. However, repair fails most typically when the damage overwhelms the repair mechanisms, as when protein thiols are oxidized faster than they can be reduced. In other instances, the capacity of repair may become exhausted when necessary enzymes or cofactors are consumed. For example, alkylation of DNA may lead to consumption of MGMT (a self-sacrificing enzyme), lipid peroxidation can deplete α -tocopherol, and overproduction of oxidized or otherwise damaged proteins can exhaust the pool of ubiquitin. Sometimes the toxicant-induced injury adversely affects the repair process itself. For example, ethanol generates ROS via CYP2E1 that impairs the proteasomal removal of damaged proteins. Autophagic removal of cell constituents may be compromised by lysosomotropic drugs (lipophilic amines) that increase the pH in these organelles, thus decreasing the activity of lysosomal hydrolases. This may underlie the mechanism of chloroquine-induced myopathy in rats. Thiol-reactive chemicals may inactivate ubiquitin-activating enzymes (E1), ubiquitin-conjugating enzymes (E2), and the HECT domain-containing ubiquitin ligases (E3), each of which contains a catalytically active cysteine, as well as the lysosomal cysteine proteases (eg, cathepsins B, H, and L), thereby compromising the clearance of damaged proteins by both the UPS and autophagy. Indeed, diminished proteolysis occurs in hepatocytes exposed to toxic concentrations of acetaminophen. These repair mechanisms are especially important in neurons, as genetic deletion of proteins mediating UPS and autophagy causes accumulation of intraneuronal inclusions, neuronal loss, or neurodegeneration. In fact, human neurodegenerative diseases can be directly attributed to some dysfunction of the UPS and/or autophagy (Bedford *et al.*, 2011). The finding that individual overexpression of some E2 and E3 enzymes confers resistance to methylmercury toxicity in yeast (Hwang *et al.*, 2006) lends some support to the speculation that impairment of the UPS and/or autophagy might contribute to the neurotoxicity of methylmercury. After exposure to necrogenic chemicals, mitosis of surviving cells may be blocked and restoration of the tissue becomes impossible (Mehendale, 2005). Finally, some types of toxic injuries cannot be repaired effectively, as occurs when xenobiotics are covalently bound to proteins or when protein carbonyls are formed. Thus, toxicity is manifested when repair of the initial injury fails because the repair mechanisms become overwhelmed, exhausted, or impaired or are genuinely inefficient.

It is also possible that repair contributes to toxicity. This may occur in a passive manner, for example, if excessive amounts of NAD⁺ are cleaved by PARP when this enzyme assists in repairing broken DNA strands, or when too much NAD(P)H is consumed for the repair of oxidized proteins and endogenous reductants. Either event can compromise oxidative phosphorylation, which is also dependent on the supply of reduced cofactors (see Fig. 3-16), thus causing or aggravating ATP depletion that contributes to cell injury.

Excision repair of DNA and reacylation of lipids also contribute to cellular deenergization and injury by consuming significant amounts of ATP. However, repair also may play an active role in toxicity. This is observed after chronic tissue injury, when the repair process goes astray and leads to uncontrolled proliferation instead of tissue remodeling. Such proliferation of cells may yield neoplasia, whereas overproduction of ECM results in fibrosis. A specific case is when the cellular repair processes that normally degrade damaged proteins, such as the UPS and the autophagy pathway, become inappropriately stimulated by adverse signaling, causing degradation of ordinary intracellular proteins. This occurs in muscle wasting induced by glucocorticoids, such as cortisol and dexamethasone. This condition appears to be secondary to suppression of the growth-promoting IGF-1–PI3K–Akt signaling that leaves FoxO TFs unchecked, which in turn increase the expression of muscle-specific ubiquitin ligases (MAFbx, also called atrogin-1, and MuRF1) as well as several components of the autophagy–lysosome pathway (Fig. 3-30).

When Adaptation Fails Although adaptation mechanisms, such as the Nrf2-mediated electrophile response and the NF- κ B-induced proliferative reaction, boost the capacity of the organism to withstand toxicant exposure and damage, excessive exposure can overwhelm these protective responses. Moreover, toxicants may impair the adaptive process. For example, moderate oxidative stress activates NF- κ B, AP-1, and Nrf2 to initiate adaptive protection. However, extensive oxidant exposure aborts this program because it leads to oxidation of thiol groups in the DNA-binding domain of these TFs (Hansen *et al.*, 2006). Similarly, Hg²⁺ can incapacitate NF- κ B, thus inhibiting the prolife program activated by this TF. This promotes Hg²⁺-induced renal tubular cell injury (Dieguez-Acuna *et al.*, 2004).

Some adaptive mechanisms may be harmful under extreme conditions. For example, acute tubular injury, which impairs tubular reabsorption and causes polyuria, triggers a tubuloglomerular feedback mechanism that reduces glomerular blood flow and filtration. Ultimately, this may precipitate anuric renal failure. It is possible that an adaptive mechanism that is beneficial in the short term may become harmful when forced to operate for a prolonged period of time. Bulk autophagy likely contributes to lethal wasting syndrome induced by TCDD in experimental animals. Chronic inflammation, tissue injury, or cancer may lead to iron deficiency and anemia because IL-6 (the acute-phase-triggering cytokine overproduced in these conditions) upregulates hepcidin secretion from the liver, which in turn reduces intestinal iron absorption. As discussed earlier, NF- κ B activation is indispensable for repair via proliferation of the acutely injured tissue. However, NF- κ B also targets cytokine genes, and the cytokines (eg, TNF, IL-1 β) in turn activate NF- κ B through their receptors (see Fig. 3-12). This vicious cycle may lead to chronic inflammation and cancer when repetitive tissue injury maintains NF- κ B signaling (Karin, 2006). This occurs after occupational exposure to silica (Castranova, 2004). Sustained activation of HIF-1 α in tumors facilitates invasiveness, in part by increasing VEGF expression and angiogenesis. In the kidney, HIF-1 α may be involved in fibrogenesis, as it targets critical genes, such as tissue inhibitor of metalloproteinase-1 (TIMP-1).

Toxicity Resulting from Inappropriate Repair and Adaptation

Like repair, dysrepair occurs at the molecular, cellular, and tissue levels. Some toxicities involve dysrepair at an isolated level. For example, hypoxemia develops after exposure to methemoglobin-forming chemicals if the amount of methemoglobin produced overwhelms

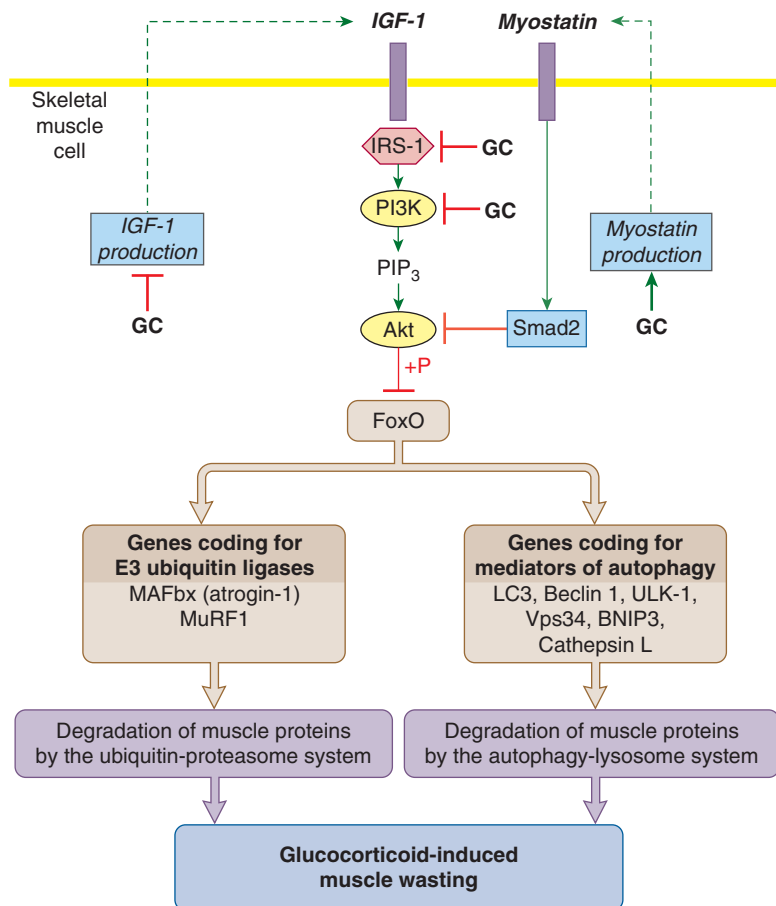

Figure 3-30. A model of glucocorticoid-induced muscle wasting: by attenuating the IGF-1–PI3K–Akt growth signaling pathway, glucocorticoids dis-inhibit FoxO transcription factors that upregulate the degradation of muscle proteins by both the ubiquitin–proteasome system and the autophagy–lysosome pathway. The trophic condition of the skeletal muscle is positively regulated by IGF-1, a muscle anabolic growth factor. IGF-1 acts in autocrine and paracrine manner on its tyrosine kinase receptor to trigger signaling through insulin receptor substrate 1 (IRS-1), phosphatidylinositol 3-kinase (PI3K), and the lipid mediator phosphatidylinositol (3,4,5)-trisphosphate (PIP₃), causing activation of the serine/threonine protein kinase Akt (see also Fig. 3-12). As shown in Fig. 3-29, Akt activation leads to activation of mTOR, which boosts protein translation and halts bulk autophagy. In addition, the active Akt also phosphorylates and inactivates Forkhead box O transcription factors (eg, FoxO1 and FoxO3), thereby preventing them from translocating into the nucleus and activating the expression of genes whose products would mediate degradation of muscle proteins. These mechanisms collectively contribute to muscle hypertrophy.

Glucocorticoids (GC) induce muscle atrophy mainly by suppressing the IGF-1–PI3K–Akt signaling pathway in the skeletal muscle. Under this condition the phosphorylation of FoxO by Akt ceases, and then the nonphosphorylated FoxO translocates into the nucleus and activates the transcription of its target genes. Among these are the genes coding for muscle-specific E3 ubiquitin ligases, that is, muscle atrophy F-box (MAFbx, also called atrogen-1) and muscle ring finger 1 (MuRF1). By ubiquitinating their substrates, which include structural proteins (eg, myosin heavy chain) and regulatory proteins (eg, the transcription factor MyoD and the translation initiation factor eIF3f), these ubiquitin ligases promote their proteasomal degradation. FoxO also turns on the other degradative machinery, the autophagy–lysosome system (Mehrpour *et al.*, 2010), by increasing the expression of a number of its components, such as LC3, Beclin 1, ULK-1, Vps34, BNIP3, and cathepsin L (see more details in the sections “Cellular Repair” and “Adaptation to Energy Depletion—The Energy Stress Response”).

GC suppress the IGF-1–PI3K–Akt signaling by multiple mechanisms. They decrease production of IGF-1 by the muscle, downregulate the expression of IRS-1, and inhibit PI3K activity (apparently by direct interaction of the activated GC receptor with the regulatory subunit of PI3K). In addition, GC upregulate the expression of myostatin in the muscle probably by downregulating the expression of miRNA-27a and b, which target myostatin mRNA (see elsewhere). Myostatin is a TGF- β family member protein, which is a negative regulator of muscle mass. It acts by both endocrine and paracrine fashion on its receptor (similar to item 8 in Fig. 3-12) and activates Smad2, which inhibits Akt (Glass, 2010). Other mechanisms may also contribute to GC-induced muscle wasting (Hasselgren *et al.*, 2010).

the capacity of methemoglobin reductase. Because this repair enzyme is deficient at early ages, neonates are especially sensitive to chemicals that cause methemoglobinemia. Formation of cataracts purportedly involves inefficiency or impairment of lenticular repair enzymes, such as the endopeptidases and exopeptidases, which normally reduce oxidized crystalline and hydrolyze damaged proteins to their constituent amino acids. Dysrepair also is thought to contribute to the formation of Heinz bodies, which are protein aggregates formed in oxidatively stressed and aged red blood cells. Defective proteolytic degradation of the immunogenic

trifluoroacetylated proteins may make halothane-anesthetized patients victims of halothane hepatitis.

Several types of toxicity involve failed and/or derailed repairs at different levels before they become apparent. This is true for the most severe toxic injuries, such as tissue necrosis, fibrosis, and chemical carcinogenesis.

Tissue Necrosis As discussed above, several mechanisms may lead to cell death. Most or all involve molecular damage that is potentially reversible by repair mechanisms. If repair mechanisms

operate effectively, they may prevent cell injury or at least retard its progression. For example, prooxidant toxicants cause no lipid fragmentation in microsomal membranes until α -tocopherol is depleted in those membranes. Membrane damage ensues when this endogenous antioxidant, which can repair lipids containing peroxy radical groups (Fig. 3-24), becomes unavailable (Scheschonka *et al.*, 1990). This suggests that cell injury progresses toward cell necrosis if molecular repair mechanisms are inefficient or the molecular damage is not readily reversible.

Progression of cell injury to tissue necrosis can be intercepted by 2 repair mechanisms working in concert: apoptosis and cell proliferation. As discussed above, injured cells can initiate apoptosis, which counteracts the progression of the toxic injury. Apoptosis does this by preventing necrosis of injured cells and the consequent inflammatory response, which may cause injury by releasing cytotoxic mediators. Indeed, the activation of Kupffer cells, the source of such mediators in the liver, by the administration of bacterial LPS (endotoxin) greatly aggravates the hepatotoxicity of galactosamine. In contrast, when the Kupffer cells are selectively eliminated by pretreatment of rats with gadolinium chloride, the necrotic effect of carbon tetrachloride is markedly alleviated (Edwards *et al.*, 1993). Blockade of Kupffer cell function with glycine (via the inhibitory glycine receptor; see item 4 in Fig. 3-15) also protects the liver from alcohol-induced injury (Yin *et al.*, 1998).

Another important repair process that can halt the propagation of toxic injury is proliferation of cells adjacent to the injured cells. This response is initiated soon after cellular injury. A surge in mitosis in the liver of rats administered a low (non-necrogenic) dose of carbon tetrachloride is detectable within a few hours. This early cell division is thought to be instrumental in the rapid and complete restoration of the injured tissue and the prevention of necrosis. This hypothesis is corroborated by the finding that in rats pretreated with chlordecone, which blocks the early cell proliferation in response to carbon tetrachloride, a normally non-necrogenic dose of carbon tetrachloride causes hepatic necrosis (Mehendale, 2005). The sensitivity of a tissue to injury and the capacity of the tissue for repair are apparently two independent variables, both influencing the final outcome of the effect of injurious chemical—that is, whether tissue restitution ensues with survival or tissue necrosis occurs with death. For example, variations in tissue repair capacity among species and strains of animals appear to be responsible for certain variations in the lethality of hepatotoxicants (Soni and Mehendale, 1998).

It appears that the efficiency of repair is an important determinant of the dose–response relationship for toxicants that cause tissue necrosis. Following chemically induced liver or kidney injury, the intensity of tissue repair increases up to a threshold dose, restraining injury, whereupon it is inhibited, allowing unrestrained progression of injury (Mehendale, 2005). Impaired signaling to mitosis (see Fig. 3-12), caused by high tissue concentrations of toxicants (eg, acetaminophen in the liver or *S*-(1,2-dichlorovinyl)-L-cysteine in the kidney) and their reactive metabolites may account for lagging tissue repair (Boulares *et al.*, 1999; Vaidya *et al.*, 2003), but maintenance of DNA and protein synthesis, mitotic machinery, and energy supply may also be impaired at high-dose chemical exposures. That is, tissue necrosis is caused by a certain dose of a toxicant not only because that dose ensures sufficient concentration of the ultimate toxicant at the target site to initiate injury but also because that quantity of toxicant causes a degree of damage sufficient to compromise repair, allowing for progression of the injury. Experimental observations with hepatotoxicants indicate that apoptosis and cell proliferation are operative with latent tissue injury caused by low (non-necrogenic) doses of toxicants, but

are inhibited with severe injury induced by high (necrogenic) doses. For example, 1,1-dichloroethylene, carbon tetrachloride, and thioacetamide all induce apoptosis in the liver at low doses, but cause hepatic necrosis after high-dose exposure (Corcoran *et al.*, 1994). Similarly, there is an early mitotic response in the liver to low-dose carbon tetrachloride, but this response is absent after administration of the solvent at necrogenic doses (Mehendale, 2005). This suggests that tissue necrosis occurs because the injury overwhelms and disables the repair mechanisms, including (1) repair of damaged molecules, (2) elimination of damaged cells by apoptosis, and (3) replacement of lost cells by cell division.

As in tissues and organs several types of cells are integrated and support the function of each other, toxic injury to different cell types may exacerbate the tissue damage and promote its progression to tissue necrosis. This principle is exemplified by the acetaminophen-induced hemorrhagic hepatic necrosis. Even before causing manifest injury to the parenchymal liver cells, acetaminophen overdose in mice has a deleterious effect on the sinusoidal endothelial cells (McCuskey, 2008). These cells swell and lose normal function (eg, endocytosis); their fenestrae coalesce into gaps that permit red blood cells to penetrate into the space of Disse. The subsequent collapse of sinusoids reduces blood flow, thus impairing oxygen and nutrient supply of hepatocytes that also endure direct damage by the reactive metabolite of acetaminophen.

Fibrosis Fibrosis is a pathologic condition characterized by excessive deposition of an ECM of abnormal composition. Hepatic fibrosis, or cirrhosis, results from chronic consumption of ethanol or high-dose retinol (vitamin A), treatment with methotrexate, and intoxication with hepatic necrogens such as carbon tetrachloride and iron. Pulmonary fibrosis is induced by drugs such as bleomycin and amiodarone and prolonged inhalation of oxygen or mineral particles. Doxorubicin may cause cardiac fibrosis, whereas drugs acting as agonists on 5-HT_{2B} receptors of human valvular interstitial cells, such as bromocriptine, ergotamine, methysergide, and fenfluramine after long-term use as well as 5-HT itself when overproduced in carcinoid syndrome, induce proliferative valve disease with fibrosis. Exposure to high doses of ionizing radiation induces fibrosis in many organs. Most of these agents generate free radicals and cause chronic cell injury.

Fibrosis is a specific manifestation of dysrepair of the chronically injured tissue. As discussed above, cellular injury initiates a surge in cellular proliferation and ECM production, which normally ceases when the injured tissue is remodeled. If increased production of ECM is not halted, fibrosis develops.

The cells that manufacture the ECM during tissue repair (eg, stellate cells and myofibroblasts in liver, mesangial cells in the kidney, fibroblast-like cells in lungs and skin) are the ones that overproduce the matrix in fibrosis. These cells are controlled and phenotypically altered (“activated”) by cytokines and growth factors secreted by nonparenchymal cells, including themselves (see Fig. 3-26). TGF- β appears to be the major mediator of fibrogenesis, although other factors are also involved. These include growth factors, such as connective tissue growth factor (CTGF, a TGF- β -induced growth factor) and PDGF, vasoactive peptides, such as endothelin-1 and angiotensin-II, and the adipocyte-derived hormone leptin (Lotersztajn *et al.*, 2005). The evidence is compelling to indicate that TGF- β , acting through its receptor (item 8 in Fig. 3-12), and receptor-activated TFs (Smad2 and 3), is a highly relevant causative factor of fibrosis. For example, subcutaneous injection of TGF- β induces local fibrosis, whereas overexpression of TGF- β in transgenic mice produces hepatic fibrosis. Smad3-null mice are relatively resistant to radiation-induced cutaneous fibrosis,

bleomycin-induced pulmonary fibrosis, and CCl_4 -induced hepatic fibrosis. TGF- β antagonists, such as anti-TGF- β immunoglobulin and decorin, as well as Smad3 antagonists, such as halofuginone and overexpressed Smad7 protein (which is antagonistic to Smad2 and 3), ameliorate chemically induced fibrogenesis (Flanders, 2004). In several types of experimental fibrosis and in patients with active liver cirrhosis, overexpression of TGF- β in affected tissues has been demonstrated. Specific factors may also be involved in the pathomechanism of chemically induced fibrosis. For example, in alcoholic liver cirrhosis stellate cells may be activated directly by acetaldehyde (formed by alcohol dehydrogenase), by ROS (generated by the ethanol-induced CYP2E1), and by bacterial endotoxin (LPS), which is increasingly absorbed from the gut, the permeability of which is enhanced by chronic alcohol exposure. LPS can stimulate stellate cells both directly and indirectly through Kupffer cells (see Fig. 3-26) because both cells express TLR through which LPS acts.

The increased expression of TGF- β is a common response mediating regeneration of the ECM after an acute injury. However, whereas TGF- β production ceases when repair is complete, this does not occur when tissue injury leads to fibrosis. Failure to halt TGF- β overproduction could be caused by continuous injury or a defect in the regulation of TGF- β . Indeed, after acute CCl_4 -induced liver injury, hepatic stellate cells exhibit a TGF- β -mediated induction of Smad7 (which purportedly terminates the fibrotic signal by inhibiting activation of Smad2 and Smad3 by TGF- β receptor); however, after chronic injury, Smad7 induction fails to occur (Flanders, 2004).

The fibrotic action of TGF- β is due to increased production and decreased degradation of ECM components. TGF- β stimulates the synthesis of individual ECM components (eg, collagens) by specific target cells via the Smad pathway (see Fig. 3-12) and also by downregulation of the transcription of miR-29 miRNA family members, which inhibit the translation of collagen. Downregulation of miR-29 family members occurs in murine hepatic stellate cells exposed to TGF- β , in the stellate cells of mice with hepatic fibrosis induced by CCl_4 or bile duct ligation, and in the liver of patients with advanced liver cirrhosis (Roderburg *et al.*, 2011). TGF- β inhibits ECM degradation by disproportionately increasing the expression of inhibitor proteins that antagonize ECM-degrading enzymes, such as TIMP-1 and plasminogen activator inhibitor-1 (PAI-1), compared with the expression of ECM-degrading metalloproteinases (Arthur *et al.*, 1999; Flanders, 2004). Interestingly, TGF- β induces transcription of its own gene in target cells (Flanders, 2004), suggesting that the TGF- β produced by these cells can amplify in an autocrine manner the production of the ECM. This positive feedback (autoinduction) may facilitate fibrogenesis.

Fibrosis involves not only excessive accumulation of the ECM but also changes in its composition. The basement membrane components, such as collagen IV and laminin, as well as the fibrillar-type collagens (collagen I and III), which confer rigidity to tissues, increase disproportionately during fibrogenesis (Gressner, 1992).

Fibrosis is detrimental in a number of ways:

1. The scar compresses and may ultimately obliterate the parenchymal cells and blood vessels.
2. Deposition of basement membrane components between the capillary endothelial cells and the parenchymal cells presents a diffusional barrier that contributes to malnutrition of the tissue cells.
3. An increased amount of ECM and its rigidity unfavorably affect the elasticity and flexibility of the whole tissue,

compromising the mechanical function of organs such as the heart and lungs.

4. Furthermore, the altered extracellular environment is sensed by integrins. Through these transmembrane proteins and the coupled intracellular signal transducing networks (see Fig. 3-12), fibrosis may modulate several aspects of cell behavior, including polarity, motility, and gene expression (Raghow, 1994).

Carcinogenesis Chemical carcinogenesis involves malfunctions in various repair and adaptive mechanisms. At the molecular level, a crucial feature of carcinogenesis is altered expression of critical proteins, that is, proto-oncogenic proteins and tumor suppressor proteins. This may result (1) from mutation of critical genes due to insufficient adaptive response to DNA damage and missed DNA repair or (2) from inappropriate transcriptional control at the regulatory regions of critical genes that gives rise to overexpression or underexpression of their products. (Note that the genes that we designate here as “critical” include those that are transcribed into mRNAs that in turn translate into proto-oncogenic or tumor suppressor proteins, as well as those that are transcribed into miRNAs that in turn regulate the translation of proto-oncogenic or tumor suppressor proteins. These proteins will be defined below.) At the cellular level, the fundamental feature of tumorigenesis is proliferation of cells, which may result (1) from failure to execute apoptosis and/or (2) from failure to restrain cell division.

As to be described in more detail later, carcinogenesis entails gene expression alterations initiated by two fundamentally distinct types of mechanisms that often work simultaneously and in concert, that is, genetic and epigenetic mechanisms. Genetic mechanisms bring about a *qualitative* change in gene expression, that is, expression of an altered gene product, a mutant protein, or miRNA, with gain or loss in activity. In contrast, epigenetic mechanisms cause *quantitative* change in gene expression resulting in more or less gene product. Whereas genetic mechanisms alter the coding sequences of critical genes, epigenetic mechanisms eventually influence the regulatory (promoter) region of genes. Thus, chemical and physical insults may induce neoplastic transformation of cells by affecting critical genes through genotoxic and nongenotoxic (ie, epigenetic) mechanisms. However, either mechanism ultimately induces cancer by causing cellular failures in executing apoptosis and/or restraining cell division, thereby giving rise to an uncontrollably proliferating cell population.

Genotoxic Mechanisms of Carcinogenesis: Chemical Damage and Disrepair in the Coding Region of Critical Genes Leading to Mutation

Chemicals that react with DNA may cause damage such as adduct formation, oxidative alteration, and strand breakage. In most cases, these lesions are repaired or the injured cells are eliminated. If neither event occurs, a lesion in the parental DNA strand may induce a heritable alteration, or mutation, in the daughter strand during replication. The mutation may remain silent if it does not alter the protein encoded by the mutant gene or if the mutation causes an amino acid substitution that does not affect the function of the protein. Alternatively, the genetic alteration may be incompatible with cell survival. The most unfortunate scenario for the organism occurs when the altered genes express mutant proteins that reprogram cells for multiplication and escaping apoptosis (ie, immortalization). When such cells undergo mitosis, their descendants also have a similar propensity for proliferation. Moreover, because enhanced DNA replication and cell division increases the likelihood of mutations (for reasons discussed below), these cells eventually acquire additional mutations that may further augment their growth advantage over their normal

Figure 3-31. The process of carcinogenesis initiated by genotoxic carcinogens. The figure indicates that activating mutation of proto-oncogenes that encode permanently active oncoproteins and inactivating mutation of tumor suppressor genes that encode permanently inactive tumor suppressor proteins can cooperate in neoplastic transformation of cells. It is important to realize that overexpression of normal proto-oncogenes (eg, by hypomethylation of their promoter) and underexpression (silencing) of normal tumor suppressor genes (eg, by hypermethylation of their promoter) may also contribute to such transformation (see text for explanation).

counterparts. The final outcome of this process is a nodule, followed by a tumor consisting of rapidly proliferating transformed cells (Fig. 3-31).

The critical role of DNA repair in preventing carcinogenesis is attested by the human heritable disease xeroderma pigmentosum. Affected individuals lack excision repair proteins of the XP series and exhibit a greatly increased incidence of sunlight-induced skin cancers. Cells from these patients are also hypersensitive to DNA-reactive chemicals, including aflatoxin B₁, aromatic amines, polycyclic hydrocarbons, and 4-nitroquinoline-1-oxide (Lehmann and Dean, 1990). Also, mice with ablated PARP gene are extremely sensitive to γ -rays and *N*-methyl-*N*-nitrosourea and show genomic instability, as indicated by sister chromatid exchanges and chromatid breaks following genotoxic insult (D'Amours *et al.*, 1999).

A small set of cellular genes is the target for genetic alterations that initiate neoplastic transformations. Included are proto-oncogenes and tumor suppressor genes (Barrett, 1992).

Mutation of Proto-Oncogenes Proto-oncogenes are highly conserved genes encoding proteins that stimulate the progression of cells through the cell cycle, or oppose apoptosis (Smith *et al.*, 1993). The products of proto-oncogenes that accelerate the

cell division cycle include (1) growth factors; (2) growth factor receptors; (3) intracellular signal transducers such as G proteins, protein kinases, cyclins, and cyclin-dependent protein kinases; and (4) nuclear TFs (see Figs. 3-12 and 3-32). A notable proto-oncogene product that inhibits apoptosis is Bcl-2 (see Fig. 3-19).

Fig. 3-32 depicts several proto-oncogene products that are closely involved in initiating the cell division cycle. The legend of that figure outlines some important details on the function of these proteins and their interaction with tumor suppressor proteins (to be discussed below). Transient increases in the production or activity of proto-oncogene proteins are required for regulated growth, as during embryogenesis, tissue regeneration, and stimulation of cells by growth factors or hormones. In contrast, permanent activation and/or overexpression of these proteins favor neoplastic transformation. One mechanism whereby genotoxic carcinogens induce neoplastic cell transformation is by producing an activating mutation of a proto-oncogene. Such a mutation is so named because the altered gene (then called an oncogene) encodes a permanently active protein that forces the cell into the division cycle.

An example of mutational activation of an oncogene protein is that of the Ras proteins. Ras proteins are G-proteins with GTP/GDP-binding capacity as well as GTPase activity (Anderson *et al.*, 1992). They are localized on the inner surface of the plasma membrane and function as crucial mediators in the signaling pathways initiated by growth factors (see Figs. 3-12 and 3-32). Ras is located downstream from growth factor receptors and nonreceptor protein tyrosine kinases and upstream from mitogen-activated protein kinase (MAPK) cascade whose activation finally upregulates the expression of cyclin D and initiates the mitotic cycle (Fig. 3-32). In this pathway, Ras serves as a molecular switch, being active in the GTP-bound form and inactive in the GDP-bound form. Some mutations of the Ras gene (eg, a point mutation in codon 12) dramatically lower the GTPase activity of the protein. This in turn locks Ras in the permanently active GTP-bound form. Continual rather than signal-dependent activation of Ras can lead eventually to uncontrolled cell division and transformation. Indeed, microinjection of Ras-neutralizing monoclonal antibodies into cells blocks the mitogenic action of growth factors as well as cell transformation by several oncogenes. Ionizing radiation and carcinogenic chemicals (eg, *N*-methyl-*N*-nitrosourea, polycyclic aromatic hydrocarbons, benzidine, aflatoxin B₁) induce mutations of Ras proto-oncogenes that lead to constitutive activation of Ras proteins (Anderson *et al.*, 1992). Most of these chemicals induce point mutations by transversion of G₃₅ to T in codon 12.

Another example for activating mutation of a proto-oncogene is B-Raf mutation, although Ras and Raf mutations are mutually exclusive (Shaw and Cantley, 2006). Raf proteins are protein kinases, lying just downstream from Ras and being the first signal transducers in the MAP kinase pathway (see Fig. 3-12). After recruitment by Ras to the cell membrane, Raf is activated by the growth factor receptor (see item 4 in Fig. 3-12) through phosphorylation in its activating segment. B-Raf mutations occur in mouse liver tumors induced by diethylnitrosamine (Jaworski *et al.*, 2005) in 66% of malignant melanomas and a wide range of human cancers. All mutations are within the activation segment of B-Raf, with a single amino acid substitution (V599E) accounting for the majority. The mutant B-Raf protein has elevated kinase activity probably because substitution of the nonpolar valine with the negatively charged glutamate mimics an activating phosphorylation. Thus, the constitutively active B-Raf continually sends Ras-independent proliferative signal down the MAPK pathway. Indeed, transfection of the mutant B-Raf gene into cells induced neoplastic transformation even in the absence of Ras proteins (Davies

Figure 3-32. Key regulatory proteins controlling the cell division cycle with some signaling pathways and xenobiotics affecting them. Proteins on the left, represented by brown symbols, accelerate the cell cycle and are oncogenic if permanently active or expressed at high level. In contrast, proteins on the right, represented by blue symbols, decelerate or arrest the cell cycle and thus suppress oncogenesis, unless they are inactivated (eg, by mutation).

Accumulation of cyclin D (cD) is a crucial event in initiating the cell division cycle. cD activates cyclin-dependent protein kinases 4 and 6 (cdk4/6), which in turn phosphorylate the retinoblastoma protein (pRb) causing dissociation of pRb from transcription factor E2F (Johnson and Walker, 1999). Then the unleashed E2F is able to bind to and transactivate genes whose products are essential for DNA synthesis, such as dihydrofolate reductase (DHFR), thymidine kinase (TK), thymidylate synthetase (TS), and DNA polymerase (POL), or are regulatory proteins, such as cyclin E (cE), cyclin A (cA), and cyclin-dependent protein kinase 1 (cdk1), which promote further progression of the cell cycle. Expression of cD is increased, for example, by growth factors signaling through Ras proteins and the MAPK pathway (see Fig. 3-12) as well as by Wnt and Hedgehog (Hh) ligands that ultimately signal through B-cat and Gli transcription factors, respectively (see Figs. 3-13 and 3-14). Some carcinogens, for example, benzpyrene (BP) and reactive oxygen species (ROS), and diethylnitrosamine (DENA) may cause mutation of the *Ras* or *Raf* gene that results in permanently active mutant Ras or Rab protein, but BP as well as TCDD may also induce simple overexpression of normal Ras protein.

Cell cycle progression is counteracted, for example, by pRb (which inhibits the function of E2F), by cyclin-dependent protein kinase inhibitors (such as p15, p16, and p21), by p53 (which transactivates the *p21* gene), and by ARF (also called p14 that binds to mdm2, thereby neutralizing the antagonistic effect of mdm2 on p53). Signals evoked by DNA damage and TGF- β will ultimately result in accumulation of p53 and p15 proteins, respectively, and deceleration of the cell cycle. In contrast, mutations that disable the tumor suppressor proteins facilitate cell cycle progression and neoplastic conversion and are common in human tumors. Aflatoxin B₁ (ATX), BP, and UV light cause such mutations of the *p53* gene (Bennett *et al.*, 1999), whereas *pRb* mutations occur invariably in methylcholanthrene (MC)-induced transplacental lung tumors in mice (Miller, 1999).

et al., 2002). Another proto-oncogene product that often undergoes activating mutation in breast and colon tumors is p110- α , the catalytic subunit of PI3K (Shaw and Cantley, 2006). This can cause permanent proliferative signaling via the GF receptor–PI3K–Akt pathway (see Fig. 3-12).

Whereas constitutive activation of oncogene proteins, as a result of point mutation, is a common initiator of chemical carcinogenesis, permanent overexpression of such proteins also can contribute to neoplastic cell transformation. Overexpression of proto-oncogene proteins may result from amplification of the proto-oncogene, that is, the formation of more than one copy (Anderson *et al.*, 1992). Such an event may be initiated by DNA strand breaks, and therefore often observed after exposure to ionizing radiation; however, proto-oncogene amplification also occurs in spontaneous human cancer. An example for a proto-oncogene protein that is overexpressed in response to gene damage is the antiapoptotic Bcl-2 protein (see Fig. 3-19). The aberrantly increased expression of Bcl-2 is caused by a chromosomal translocation and is responsible for B-cell lymphoma, a spontaneous human malignancy (see later). Overexpression of proto-oncogene proteins as a result of nongenotoxic, epigenetic mechanisms will be discussed later.

Mutation of Tumor Suppressor Genes Tumor suppressor genes encode proteins that inhibit the progression of cells in the division cycle, or promote DNA repair or apoptosis on DNA damage. Fig. 3-32 depicts such proteins, which include, for example, cyclin-dependent protein kinase inhibitors (eg, p15, p16, and p21), TFs (eg, p53 and Smad) that activate genes encoding cyclin-dependent protein kinase inhibitors, proteins (eg, pRb) that block TFs involved in DNA synthesis and cell division, and proteins (eg, ARF) that block inhibitors of tumor suppressor proteins. Other notable tumor suppressor gene products include, for example, the protein kinases (eg, ATM, ATR) that sense the DNA damage and signal for the p53-controlled response shown in Fig. 3-33, proteins involved in DNA repair, such as *O*⁶-methylguanine-DNA methyltransferase (which removes alkyl groups adducted to guanine) as well as BRCA1 and BRCA2 proteins (which contribute to recombinational DNA repair), proapoptotic proteins (eg, Bax, Puma, Noxa, and Bim) induced after DNA damage (Fig. 3-33), the suppressor of cytokine signaling (Socs) protein (Fig. 3-12), the phosphatase PTEN (which dephosphorylates the membrane lipid PIP₃, an essential intermediate in the PI3K–Akt pathway) that turns off the PI3K–Akt pathway-mediated proliferative signaling (Fig. 3-12), and the tuberous sclerosis complex-2 (TSC2) that prevents activation of mTOR (Fig. 3-29). Uncontrolled proliferation can occur when the mutant tumor suppressor gene encodes a protein that cannot suppress cell division. Inactivating mutations of specific tumor suppressor genes in germ cells are responsible for the inherited predisposition to cancer, as in familial retinoblastoma (pRb; see Fig. 3-32), Wilms tumor (WT1, WTX, and β -catenin; see Fig. 3-13), familial polyposis (Smad4; see Figs. 3-12 and 3-32), and Li–Fraumeni syndrome (p53; see Figs. 3-19, 3-32, and 3-33). Mutations of tumor suppressor genes in somatic cells contribute to nonhereditary cancers. The genes of p16, PTEN, and pRb are frequently mutated in human cancer. The best known tumor suppressor gene involved in both spontaneous and chemically induced carcinogenesis is p53.

The p53 tumor suppressor gene encodes a 53 kDa protein with multiple functions (Fig. 3-33). Acting as a transcriptional modulator, the p53 protein (1) activates protein-coding genes whose products arrest the cell cycle (eg, p21 and gadd45), repair damaged DNA (eg, XPE, MSH2), or promote apoptosis (eg, Bax, Puma, and Fas receptor); (2) activates miRNA-coding genes whose products (eg,

miR-34a) repress the translation of mitogenic TFs and cell cycle accelerator proteins (eg, Myc, E2F3, cyclin D, and CDK4/6); and (3) represses protein-coding genes that encode cell cycle accelerators (eg, cyclin B1, Cdk1), or antiapoptotic proteins (eg, Bcl-2 and IGF-1 receptor) (Bennett *et al.*, 1999; Liu and Chen, 2006). DNA damage activates protein kinases (ATM, ATR, Chk1, Chk2) to phosphorylate and stabilize the p53 protein, causing its accumulation (Fig. 3-33). The accumulated p53 may induce cell cycle arrest and apoptosis of the affected cells. Thus, p53 eliminates cancer-prone cells from the replicative pool, counteracting neoplastic transformation; therefore, it is commonly designated as guardian of the genome.

Indeed, cells that have no p53 are a million times more likely to permit DNA amplification than are cells with a normal level of this suppressor gene. Furthermore, mice with the p53 gene deleted develop cancer by 6 to 9 months of age, attesting to the crucial role of the p53 tumor suppressor gene in preventing carcinogenesis.

Mutations in the p53 gene are found in 50% of human tumors and in a variety of induced cancers. The majority are “missense mutations” that change an amino acid and result in a faulty or altered protein (Bennett *et al.*, 1999). The faulty p53 protein forms a complex with endogenous wild-type p53 protein and inactivates it. Thus, the mutant p53 not only is unable to function as a tumor suppressor protein but also prevents tumor suppression by the wild-type p53.

Carcinogens may cause characteristic mutations in the p53 tumor suppressor gene. An example is the point mutation in codon 249 from AGG to AGT, which changes amino acid 249 in the p53 protein from arginine to serine. This mutation predominates in hepatocellular carcinomas in individuals living where food is contaminated with aflatoxin B₁ (Bennett *et al.*, 1999). Because in human hepatocytes the CYP-activated metabolites of aflatoxin B₁ induce the transversion of G to T in codon 249 of the p53 tumor suppressor gene (Aguilar *et al.*, 1993), it appears likely that this mutation in primary human liver cancer is indeed caused by this mycotoxin. Although the incriminated mutation probably contributes to the hepatocarcinogenicity of aflatoxin B₁ in humans, it is not involved in aflatoxin B₁-induced hepatocarcinogenesis in rats, as the transformed liver cells from the toxin-exposed rats do not show this mutation.

Another example for inactivating mutation of a tumor suppressor gene of environmental origin is that of Patched, which often occurs in basal cell carcinoma of the skin that may be induced by UV and ionizing radiation, as well as arsenic exposure (Tang *et al.*, 2007). Normal Patched, the membrane receptor of the Hh ligand, suppresses the mitogenic Hh pathway in absence of Hh ligand, which would inhibit Patched (Fig. 3-14). Mutant Patched loses its power to restrain this signaling network, which thus promotes cell division even in absence of its inhibitor ligand.

In addition to aberrations in critical protein-coding genes, damage in genes coding for miRNA (which repress the translation of critical proteins; see Fig. 3-11) may also contribute to carcinogenesis. For example, amplification of miR-21 (which is oncogenic by repressing the translation of PTEN; see Fig. 3-12) and deletion of miR-15 and miR-16 (which is tumor suppressive by repressing the translation of *cdc25A*; see Fig. 3-25) occur in spontaneous human malignancies. Therefore, miRNA gene damage may also underlie the mechanism of chemical carcinogenesis. The role of altered miRNA expression as an epigenetic mechanism of chemical carcinogenesis will be discussed below.

Epigenetic Mechanisms in Carcinogenesis: Inappropriate Activation or Responsiveness of the Regulatory Region of Critical Genes Whereas some chemicals cause cancer by reacting with DNA and inducing a mutation, others do not damage DNA,

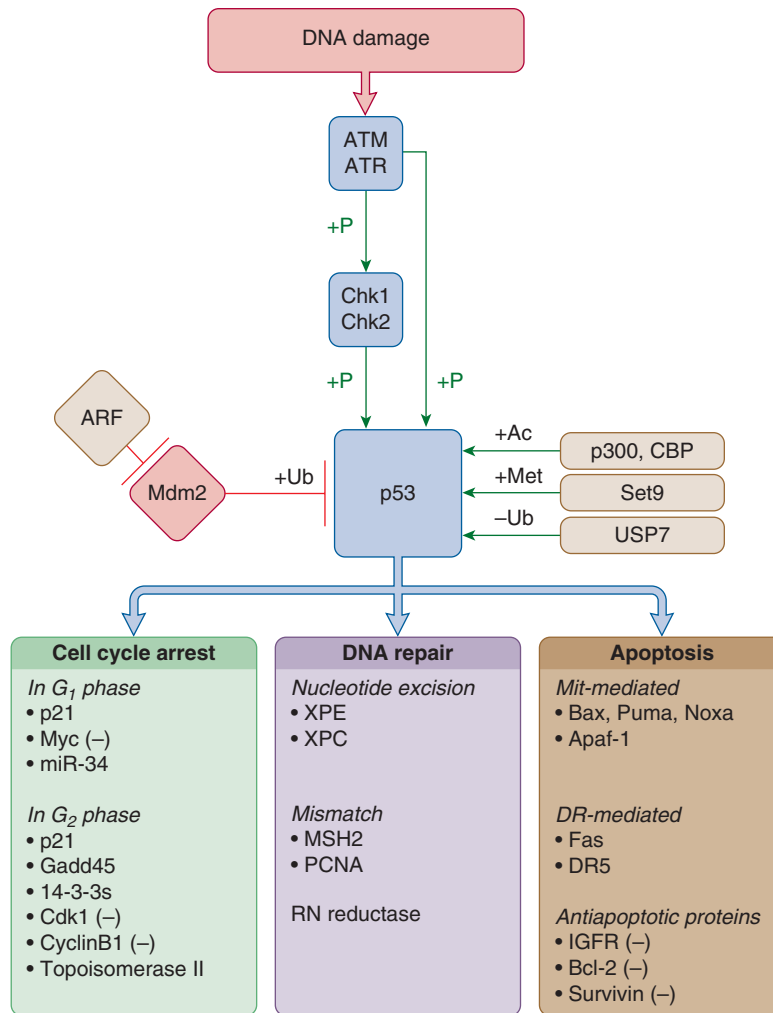

Figure 3-33. *The guardian of the genome: p53 tumor suppressor protein—its role and regulation.* When activated on DNA damage, the p53 protein may mediate cell cycle arrest, DNA repair, and apoptosis. When inducing these effects, p53 acts chiefly as a transcription factor that can activate the transcription of most target genes, while repressing some of others, such as those marked with (-) in the figure (Liu and Chen, 2006). For example, p53 transactivates *p21* and *gadd45* genes (whose products are inhibitors of cyclin–cyclin-dependent protein kinase complexes) and arrest the cell cycle in G₁ and G₂ phases, respectively, but p53 represses the *Cdk1* and *cyclin B1* genes (whose products are indispensable for the cells to transit from G₂ phase to M) (see Fig. 3-25). p53 also induces the expression of miR-34 (a microRNA), which in turn represses the translation of cyclin D, CDK4/6, and E2F, important cell cycle accelerator proteins (see Fig. 3-32) (Chen *et al.*, 2010). p53 also transactivates the genes of some DNA repair proteins and proapoptotic proteins (eg, bax and fas; see Fig. 3-19) and represses the genes of antiapoptotic proteins (eg, Bcl-2 and IGF-1 receptor), whereby it promotes apoptosis. These (and other) p53-induced proapoptotic mechanisms may be cell-specific, that is, all are not necessarily occurring in the same cell at the same time.

The intracellular level and activity of p53 depends primarily on the presence of mdm2 protein, which inactivates p53 by ubiquitinating it; monoubiquitination causes export of p53 from the nucleus, whereas polyubiquitination promotes its proteasomal degradation. The influence of mdm2 on p53 may be disrupted by overexpression of the ARF (or p14) protein (which binds to mdm2 and removes it from p53) or by post-translational modification of p53 through phosphorylation by protein kinases (see below), acetylation by acetyltransferases (eg, p300 and CBP), methylation by methyltransferases (eg, Set9) and deubiquitination by ubiquitin-specific-processing protease 7 (USP7, also called HAUSP) (Liu and Chen, 2006). These mechanisms release p53 from mdm2 and stabilize the p53 protein, thereby greatly increasing its abundance and activity. Phosphorylation of p53 is induced by DNA damage. This is sensed by kinases, such as ataxia telangiectasia mutated (ATM) and ataxia telangiectasia related (ATR), which directly or through checkpoint kinases (Chk1, Chk2) phosphorylate p53 to induce cell cycle arrest, DNA repair, or apoptosis (McGowan and Russell, 2004).

It is important to emphasize that there is also a p53-independent mechanism to arrest the cells suffering DNA damage before mitosis. Like induction of p53, this is also initiated by the activated Chk1, which phosphorylates and inactivates cdc25A, a protein phosphatase, which normally would dephosphorylate Cdk1 and activate the Cdk1–cyclin B complex (see Fig. 3-25). Thus, when cdc25A is inactivated, Cdk1 stalls and mitosis is delayed. Interestingly, p53 assists in keeping Cdk1, this mitosis-driving molecular motor, off track as it induces 14-3-3 σ , a cytoplasmic binding protein, which associates with both cdc25A and the Cdk1–cyclin B complex and sequesters them in the cytoplasm.

By arresting division of cells with potentially mutagenic DNA damage, facilitating the DNA repair or eliminating such cells, p53 protein counteracts neoplastic development. *p53*-null mice, like *ARF*-null mice, develop tumors with high incidence. Mutational inactivation of the p53 protein is thought to contribute to the carcinogenic effect of aflatoxin B₁, sunlight, and cigarette smoke in humans. Overexpression of mdm2 can lead to constitutive inhibition of p53 and thereby promotes oncogenesis even if the *p53* gene is unaltered. See the text for more details.

yet induce cancer after prolonged exposure (Barrett, 1992). These chemicals are designated *nongenotoxic* (or epigenetic) *carcinogens* and include (1) xenobiotic mitogens, that is, chemicals that promote proliferative signaling, such as the PKC activator phorbol esters and fumonisin B₁, as well as the protein phosphatase inhibitor okadaic acid (see Fig. 3-12); (2) endogenous mitogens, such as growth factors (eg, TGF- α) and hormones with mitogenic action on specific cells, for example, estrogens on mammary gland or liver cells, TSH on the follicular cells of the thyroid gland, and luteinizing hormone on Leydig cells in testes; (3) toxicants that, when given chronically, cause sustained cell injury (such as chloroform and D-limonene); (4) xenobiotics that are nongenotoxic carcinogens in rodents but not in humans, such as phenobarbital, DDT, TCDD, and peroxisome proliferators (eg, fibrates, WI-14643, dihalogenated and trihalogenated acetic acids); and (5) ethionine and diethanolamine, which interfere with formation of the endogenous methyl donor *S*-adenosyl methionine (Poirier, 1994). Because several of the listed chemicals promote the development of tumors after neoplastic transformation has been initiated by a genotoxic carcinogen, they are referred to as *tumor promoters*. Despite the initial belief that promoters are unable to induce tumors by themselves, studies suggest that they can do so after prolonged exposure.

It appears that nongenotoxic chemicals, like the genotoxic ones, eventually also influence the expression of proto-oncogenes and/or tumor suppressor genes, but in a different manner. When continuously present, nongenotoxic carcinogens can permanently induce the synthesis of normal proto-oncogene proteins and/or repress the synthesis of normal tumor suppressor proteins, rather than inducing the synthesis of permanently active mutant proto-oncogene proteins or permanently inactive mutant tumor suppressor proteins, as the mutagenic genotoxic carcinogens do.

Carcinogens may alter the synthesis of proto-oncogene proteins and tumor suppressor proteins at transcriptional and/or translational levels. Chemicals may modify transcription of the genes into mRNAs for proto-oncogene and tumor suppressor proteins by perturbing the signal transduction to the promoter region of these genes and/or by altering the signal receptivity of this gene region by DNA methylation and histone modifications. Translation of proto-oncogene proteins and tumor suppressor proteins from their mRNA may be controlled by specific miRNAs, which repress this process (Fig. 3-11). Carcinogen-induced perturbations in signaling and promoter alterations may not only influence transcription of protein-coding genes but also affect the transcription of miRNA-coding genes. The resultant changes in the abundance in miRNAs in turn alter, in a reciprocal (inverse) manner, the synthesis of proto-oncogene proteins and tumor suppressor proteins, provided the miRNA in question targets the mRNA of such a protein. The forthcoming discussion deals with the importance of signaling, DNA as well as histone modifications, and miRNA expression in carcinogenesis.

Role of Signaling in Carcinogenesis An important target of nongenotoxic carcinogens is the promoter region of critical genes where they can act via two distinct modes. First, they may alter the abundance and/or activity of TFs, typically by influencing upstream signaling elements ranging from extracellular signaling molecules (eg, TSH) to intracellular transducer proteins (eg, PKC). Obviously both xenobiotic and endogenous mitogens mentioned above can thus activate proliferative pathways (see Fig. 3-12) that descend to TFs (eg, Myc) that act on the promoter of proto-oncogenes coding for mRNAs of proto-oncogene proteins (eg, cyclins), and, as to be discussed below, on the promoter of genes coding for oncogenic miRNAs (eg, miR-17-92). It is easy to recognize that

even nongenotoxic carcinogens of the cytotoxic type act in this manner. As described under tissue repair, cell injury evokes the release of mitogenic growth factors such as HGF and TGF- α from tissue macrophages and endothelial cells. Thus, cells in chronically injured tissues are exposed continuously to endogenous mitogens. Although these growth factors are instrumental in tissue repair after acute cell injury, their continuous presence is potentially harmful because they may ultimately transform the affected cells into neoplastic cells. Indeed, transgenic mice that overexpress TGF- α develop hepatomegaly at a young age and tumors by 12 months (Fausto *et al.*, 2006). Mitogenic cytokines secreted by Kupffer cells are apparently involved in hepatocyte proliferation and, possibly, tumor formation induced by peroxisome proliferators in rats (Rose *et al.*, 1999) and in the formation of the endothelial cell-derived hepatic hemangiosarcoma in mice exposed to 2-butoxyethanol (Corthals *et al.*, 2006).

Role of DNA Methylation and Histone Modification in Carcinogenesis As a second mode of action, nongenotoxic carcinogens may alter expression of critical genes by modifying the responsiveness of the promoter region of these genes to TFs. Promoter responsiveness is typically controlled by DNA methylation. This takes place at C₅ of specific cytosine residues located in CpG islands (ie, clusters of CpG dinucleotides) in the promoter and is catalyzed by DNA cytosine methyltransferases (eg, DNMT1, DNMT3a, and DNMT3b) using *S*-adenosyl methionine as the methyl donor. It is well known that promoter methylation decreases the transcriptional activity of genes. For example, tissue-specific genes (eg, the genes of GI TFFs) are hypermethylated in tissues where they are not expressed, but are typically hypomethylated in tissues where they are expressed.

Promoter methylation can silence genes because it weakens binding of TFs to the promoter and because it triggers secondary alterations in histone proteins that reduce the accessibility of the promoter for TFs (Esteller, 2005). The latter mechanism involves modification of the protruding amino-terminal tails of core histone proteins by deacetylation and methylation of lysine residues. This makes the histone more compact, thereby diminishing access of TFs and other proteins involved in transcription initiation to the gene promoter. Histone deacetylases that remove the acetyl group from histone tails may be recruited by DNMTs directly, or through proteins that recognize and bind to the methylated CpG dinucleotides (eg, MeCP1, MeCP2, MBD2, MBD3). Some of these methyl-CpG-binding domain-containing proteins (eg, MBD2, MBD3) also have histone deacetylase activity. Finally, both DNMTs and MBDs can recruit histone methyltransferases to methylate histone tail lysines.

While methylation of CpG dinucleotides codes for gene silencing via histone deacetylation and methylation ("histone code"), hypomethylated genes are alert. In fact, CpG islands in the 5'-end region (promoter, untranslated region, exon 1) of genes are relatively hypomethylated in normal tissues, except for tissue- or germline-specific genes, and genomically imprinted genes (see earlier). Thus, if the appropriate TFs are available for a particular gene, and if the CpG island remains hypomethylated, the histones acetylated and hypomethylated, then the gene will be transcribed (Esteller, 2005). Histones are acetylated by histone acetyltransferases, such as p300 and CBP, which also acetylate other proteins, including p53 (see Fig. 3-33), and are also transcriptional coactivators.

It is well documented that the normal methylation pattern of DNA is disrupted in cancer cells. Such cells are characterized by global (average) hypomethylation, that is, decreased content of genomic 5'-methylcytosine. Paradoxically, DNA hypomethylation occurs in the face of hypermethylation of the CpG islands in

the promoter region tumor suppressor genes, which are normally demethylated (Esteller, 2005). The frequently hypermethylated tumor suppressor genes in human cancers are, for example, the Cdk inhibitor p15 and p16, the mdm2-binding protein ARF, pRb that tethers E2F (see Fig. 3-30), the DNA repair enzyme MGMT, and the lipid phosphatase PTEN (see Fig. 3-12). Importantly, both global hypomethylation and tumor suppressor gene hypermethylation intensify with increased malignancy of the tumor. Relevance of hypermethylation-induced silencing of tumor suppressor genes in carcinogenesis is supported by the finding that inhibitors of DNMTs (such as 5-aza-2'-deoxycytidine) can stop the growth of cancer cells and induce their differentiation by demethylating the dormant tumor suppressor genes, thereby restoring their expression (Esteller, 2005). The consequence of global hypomethylation of DNA is less clear. Nevertheless, hypomethylation of proto-oncogenes and increased expression of their products is a plausible mechanism (Goodman and Watson, 2002), although others have also been proposed (eg, chromosomal instability, reactivation of transposable DNA elements, and loss of genomic imprinting). On comparing mouse strains, it has been suggested that their sensitivity to chemical carcinogens may be related inversely to their capacity to maintain normal patterns of DNA methylation. It is worth noting that DNA methylation is more stable in human cells than in rodent cells (Goodman and Watson, 2002).

It appears that some of the nongenotoxic carcinogens alter DNA methylation. Inhibition of DNA methylation is a plausible mechanism that underlies tumorigenesis induced by ethionine, which depletes S-adenosyl-methionine (the methyl donor for DNMTs), and diethanolamine, which inhibits cellular uptake of choline, a dietary methyl group source for methylation of homocysteine to methionine. On prolonged administration, virtually all nongenotoxic rodent liver carcinogens listed above decrease DNA methylation. In addition to global DNA hypomethylation, promoter hypomethylation of the following proto-oncogenes have been observed in mouse or rat liver: Ras or Raf, following phenobarbital treatment, c-Jun, c-Myc, and IGF-2, after treatment with dichloroacetic acid, dibromoacetic acid, or trichloroacetic acid, and c-Myc after WY-14643 dosing. Long-term arsenic exposure of mice also induces hypomethylation of hepatic DNA globally and in the promoter of ER α , a hormone-activated TF. This is associated with an increase of cyclin D, a potentially ER α -linked gene (Chen *et al.*, 2004). In contrast, in human keratinocytes TCDD induces promoter hypermethylation in the tumor suppressor genes p16 and p53 as well as immortalization of these cells (Ray and Swanson, 2004). Although the mechanisms that initiate altered promoter methylation are currently unknown, it is possible that that altered promoter methylation plays a role in tumor promotion by these nongenotoxic carcinogens.

Role of MicroRNAs in Carcinogenesis As miRNAs almost always repress the translation of proteins from their mRNAs (Fig. 3-11), a miRNA plays an oncogenic role if it represses the translation of tumor suppressor proteins, that is, proteins that counter cell division, repair DNA, or promote apoptosis. For example, the miR-17-92 cluster is considered oncogenic, because its members promote mitosis by repressing the translation of PTEN (an inhibitor of the mitogenic PI3K–Akt signaling; see Fig. 3-12) and p21 (a cyclin-dependent kinase inhibitor; see Fig. 3-32) and because they inhibit apoptosis by repressing the translation of the proapoptotic protein Bim. Other examples for oncogenic miRNAs include miR-29b (which also targets the mRNAs of p21 and Bim), as well as miR-221/222, the targets of which include mRNAs translating into tumor suppressor proteins, such as PTEN, p27, p57, FOXO3 (see Fig. 3-30), TIMP3 (metalloproteinase inhibitor 3), and Bim

(Chen *et al.*, 2010; Garofalo and Croce, 2011). Overexpression of such oncogenic miRNAs promotes neoplastic cell transformation, whereas their underexpression opposes it.

Conversely, a miRNA has tumor suppressive role if it represses the translation of proto-oncogene proteins, that is, proteins that facilitate cell division or oppose apoptosis. For example, the let-7 family of miRNAs is regarded tumor suppressive as they silence the translation of Ras and Myc proteins, components of proliferative signaling (see Fig. 3-12). Furthermore, miR-15a and miR-16-1 repress the translation of protein phosphatase cdc25, which dephosphorylates and thus activates CDK1 and 2 that drives the cell cycle (see Fig. 3-25), and of Bcl-2, which inhibits apoptosis (see Fig. 3-19). Another tumor suppressor miRNA is miR-34, whose targets include the mRNAs that translates into the mitogenic TFs Myc and E2F3, as well as the cell cycle accelerator proteins cyclin D and CDK4/6 (see Figs. 3-25 and 3-32) (Chen, 2010; Garofalo and Croce, 2011). Upregulation of such tumor suppressive miRNAs counters neoplastic cell transformation, whereas their downregulation stimulates it.

Expression of miRNAs, like that of mRNAs coding for proteins, can be regulated at the promoter region of their genes by TFs as well as DNA methylation and histone modification. For example, Myc activates the transcription of the oncogenic miR-17-92, whereas p53 activates the transcription of the tumor suppressive miR-34. Therefore, the latter event is part of the adaptive DNA damage stress response discussed earlier and depicted in Fig. 3-33. Indeed, genotoxic carcinogens such as *N*-ethyl-*N*-nitrosourea and tamoxifen (which forms a DNA-reactive metabolite in rats, but not in humans) as well as ionizing radiation typically induce overexpression of mi-34.

The role of miRNAs in tumorigenesis induced by nongenotoxic carcinogens is well exemplified by the rodent hepatocarcinogenesis induced by the PPAR α -activator WY-14643. This process involves transcriptional downregulation of the gene coding for let-7c and consequential derepression of the translation of c-Myc mRNA into c-Myc protein. Due to its increased abundance, this TF (see Figs. 3-12 and 3-32) increasingly activates the gene coding for cyclin D, a mitogenic protein, as well as the gene coding for miR-17-92, an oncogenic miRNA. miR-17-92 in turn represses the translation of proteins that counter mitosis (eg, PTEN and p21) and promote apoptosis (eg, Bim), thus forcing hepatocytes to proliferate (Gonzalez and Shah, 2008).

Cooperation of Genotoxic and Epigenetic Mechanisms in Carcinogenesis Genotoxic and epigenetic mechanisms most likely complement and amplify each other in chemical carcinogenesis. One chemical may exert both genotoxic and epigenetic effects. For example, estrogens produce mutagenic free radicals via redox cycling of their quinone and hydroquinone metabolites and induce receptor-mediated proliferative effect (Newbold, 2004). Well-known genotoxic carcinogens can also cause epigenetic alterations. For example, 2-acetylaminofluorene does not only form DNA adducts but also induces DNA methylation in the promoter of Rassf1a and p16 genes as well as histone methylation around the promoter of Rassf1a, p16, Socs1, Cdh1, and Cx26 genes, thereby silencing all these genes that encode tumor suppressor proteins (Pogribny *et al.*, 2011). The p16, ARF, and MGMT tumor suppressor genes are also hypermethylated in aflatoxin B₁-induced mouse lung tumor and in 7,12-dimethylbenzanthracene-induced skin tumor. The antiestrogen tamoxifen, a hepatocarcinogen in rats (but not in humans), exerts genotoxic effect and induces global hypomethylation of DNA and histones in rat liver (Tryndyak *et al.*, 2006). Thus, epigenetic alterations evoked by genotoxic carcinogens may drive the process of carcinogenesis after the initiating

genotoxic event (Pogribny *et al.*, 2011). Conversely, global DNA hypomethylation and tumor suppressor gene hypermethylation may increase the occurrence of mutations in cells exposed to nongenotoxic carcinogens. In this sense, epigenetic mechanisms may also initiate carcinogenesis (Goodman and Watson, 2002).

Failure to Execute Apoptosis Promotes Mutation and Clonal Growth As discussed earlier, in cells suffering DNA damage, the stabilized p53 protein may induce cell death by apoptosis (Fig. 3-33). Apoptosis thus eliminates cells with DNA damage, preventing mutations to initiate carcinogenesis. Initiated preneoplastic cells have much higher apoptotic activity than do normal cells (Bursch *et al.*, 1992) and this can counteract their clonal expansion. In fact, facilitation of apoptosis can induce tumor regression. This occurs when hormone-dependent tumors are deprived of the hormone that promotes growth and suppresses apoptosis. This is the rationale for the use of tamoxifen, an antiestrogen, and gonadotropin-releasing hormone analogues to combat hormone-dependent tumors of the mammary gland and the prostate gland, respectively (Bursch *et al.*, 1992).

Thus, inhibition of apoptosis is detrimental because it facilitates both mutations and clonal expansion of preneoplastic cells. Indeed, apoptosis inhibition plays a role in the pathogenesis of human B-cell lymphomas, in which a chromosomal translocation results in aberrantly increased expression of Bcl-2 protein, which overrides programmed cell death after binding to and inactivating the proapoptotic Bax protein (see Fig. 3-19). Increased levels of Bcl-2 are also detected in other types of cancer, and a high Bcl-2/Bax ratio in a tumor is a marker for poor prognosis (Jäättelä, 1999). Other antiapoptotic proteins, such as Hsp27, Hsp70, and Hsp90 (Sreedhar and Csermely, 2004) and IAP family members, may also contribute to progression of neoplasia. Survivin, a member of the IAP family, is expressed in all cancer cells but not in adult differentiated cells (Jäättelä, 1999).

Inhibition of apoptosis is one mechanism by which the rodent tumor promoter phenobarbital promotes clonal expansion of preneoplastic cells. This has been demonstrated in rats given a single dose of *N*-nitrosomorpholine followed by daily treatments with phenobarbital for 12 months to initiate and promote, respectively, neoplastic transformation in liver (Schulte-Hermann *et al.*, 1990). From 6 months onward, phenobarbital did not increase DNA synthesis and cell division in the preneoplastic foci, yet it accelerated foci enlargement. The foci grow because phenobarbital lowers apoptotic activity, allowing the high cell replicative activity to manifest itself. The peroxisome proliferator nafenopin, a nongenotoxic hepatocarcinogen, also suppresses apoptosis in primary rat hepatocyte cultures (Bayly *et al.*, 1994). Based on a recent study with WY-14643, another peroxisome proliferator (Gonzalez and Shah, 2008), it may be suggested that miR-17-92 upregulation and consequential suppression of Bim translation accounts for apoptosis inhibition.

Failure to Restrain Cell Division Promotes Mutation, Proto-Oncogene Expression, and Clonal Growth Enhanced mitotic activity, whether it is induced by oncogenes inside the cell or by external factors such as xenobiotic or endogenous mitogens, promotes carcinogenesis for a number of reasons:

1. First, the enhanced mitotic activity increases the probability of mutations. This is due in part to activation of the cell division cycle, which invokes a substantial shortening of the G₁ phase, allowing less time for the repair of injured DNA before replication, thus increasing the chance that the damage will yield a mutation. Although repair still may be feasible after

replication, postreplication repair is error-prone. In addition, activation of the cell division cycle increases the proportion of cells that replicate their DNA at any given time. During replication, DNA becomes unpacked and its amount doubles, greatly increasing the effective target size for DNA-reactive mutagenic chemicals, including ROS.

2. Enhanced mitotic activity may compromise DNA methylation, which occurs in the early postreplication period and is carried out by DNMTs that copy the methylation pattern of the parental DNA strand to the daughter strand (maintenance methylation). Limitation of DNMTs by shortened G₂ phase or by presence of other transacting factors might impair methylation and may contribute to overexpression of proto-oncogenes, starting a vicious cycle.
3. During cell division, the cell-to-cell communication through gap junctions (constructed from connexins) and AJ (constructed from cadherins) is temporarily disrupted. Several tumor promoters, such as phenobarbital, phorbol esters, and peroxisome proliferators, decrease gap junctional intercellular communication. It has been hypothesized that this contributes to neoplastic transformation. Increased susceptibility of connexin-knockout mice to spontaneous and chemically induced liver tumors supports this hypothesis (Chipman *et al.*, 2003). Lack of the AJ contributes to the invasiveness of tumor cells (see below).
4. Another mechanism by which proliferation promotes the carcinogenic process is through clonal expansion of the initiated cells to form nodules (foci) and tumors.

In summary, transformation of normal cells with controlled proliferative activity to malignant cells with uncontrolled proliferative activity is driven by 3 major forces: (1) accumulation of genetic damage in the form of mutant proto-oncogenes (which encode permanently activated cell cycle accelerator and/or antiapoptotic proteins) and mutant tumor suppressor genes (which encode permanently inactivated cell cycle decelerator and/or proapoptotic proteins); (2) increased transcription and/or translation of normal proto-oncogenes (causing expression of more cell cycle accelerator and/or antiapoptotic proteins); and (3) silencing of normal tumor suppressor genes at transcriptional and/or translational level (causing expression of less cell cycle decelerator and/or proapoptotic proteins). Uncontrolled proliferation results from offset of the balance between mitosis and apoptosis (Fig. 3-34).

Genotoxic carcinogens appear to induce cancer primarily by inducing activating mutations in proto-oncogenes or inactivating mutations in tumor suppressor genes, and secondarily by causing inappropriate expression rate of these critical genes. In contrast, nongenotoxic carcinogens cause cancer primarily by transcriptional or translational upregulation of the synthesis of proto-oncogene proteins or downregulation of the synthesis of tumor suppressor proteins. Secondarily, however, nongenotoxic carcinogens may also increase mutation of critical genes, which is initiated by genotoxic agents or spontaneous DNA damage. In human cells, spontaneous DNA damage may give rise to mutation at a frequency of 1 out of 10⁸ to 10¹⁰ base pairs (Barrett, 1992). Genotoxic carcinogens increase this frequency 10- to 1000-fold. Nongenotoxic carcinogens also increase the rate of spontaneous mutations through a mitogenic effect (see above) and increase the number of cells with DNA damage and mutations by facilitating their division and inhibiting their apoptosis. Both enhanced mitotic activity and decreased apoptotic activity expand the population of transformed cells.

According to an emerging theory, cancers may form by genotoxic and/or epigenetic mechanisms in pluripotent stem cell

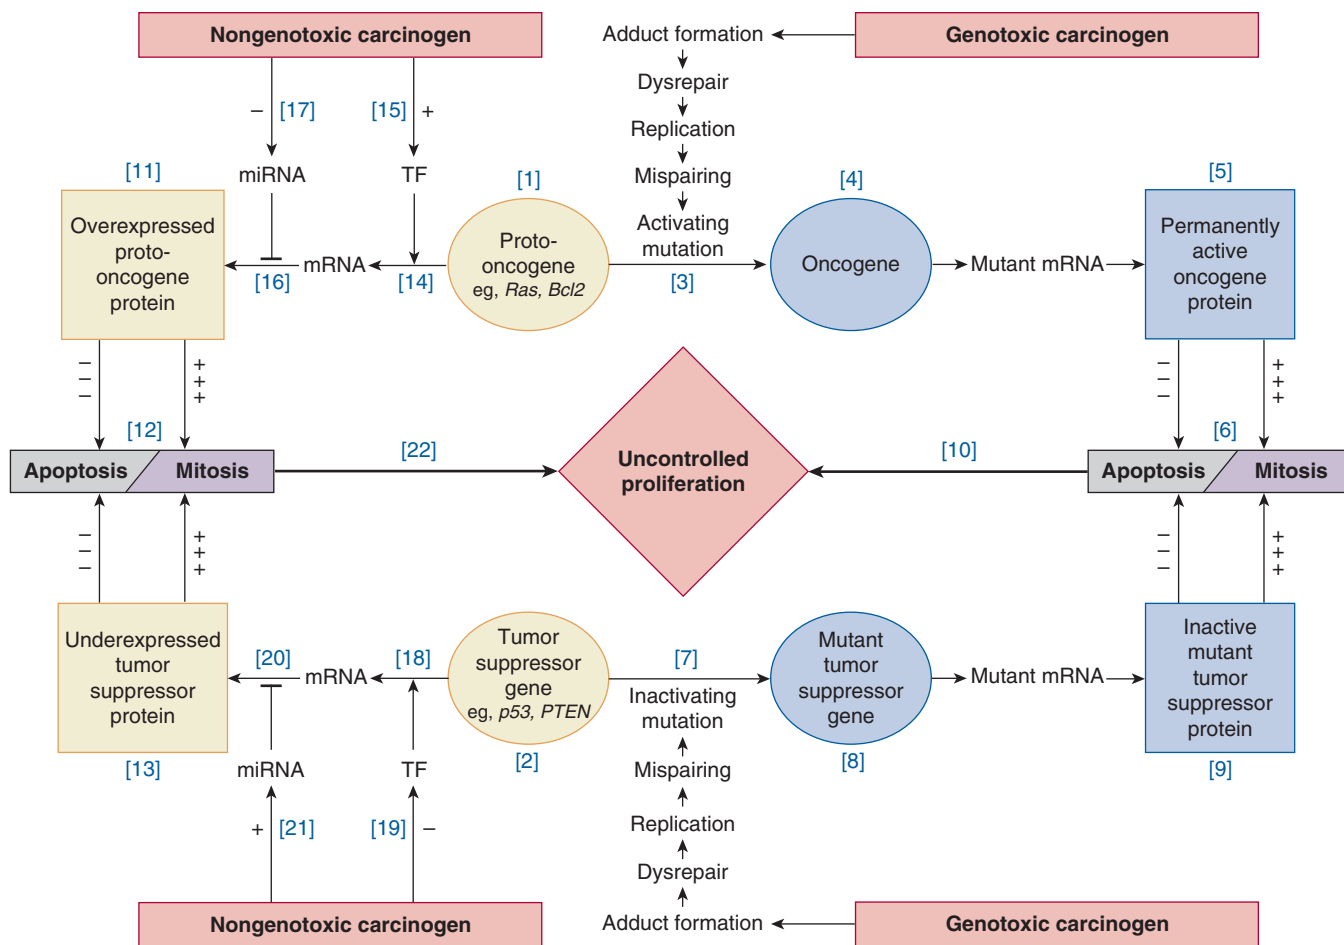

Figure 3-34. A model depicting the modes of action of genotoxic and nongenotoxic carcinogens and the cooperation between proto-oncogenes and tumor suppressor genes in transformation of normal cells with controlled proliferation into neoplastic cells with uncontrolled proliferation. When produced in appropriate quantities, the normal proteins encoded by proto-oncogenes [1] and tumor suppressor genes [2] reciprocally influence mitosis and apoptosis and thus ensure controlled cell proliferation. However, the balance between the effects of these 2 types of proteins on the fate of cells is offset by carcinogens via genotoxic and nongenotoxic mechanisms resulting in uncontrolled proliferation.

A genotoxic (or DNA-reactive) carcinogen may induce cell proliferation in 2 ways. In the first way, it inflicts DNA damage (eg, by forming DNA adducts) that ultimately brings about an activating mutation [3] in a proto-oncogene [1] and the mutant proto-oncogene (then called an oncogene) [4] in turn encodes a constitutively (ie, permanently) active oncogene protein [5] that continuously signals for mitosis or against apoptosis [6], depending on its function. In the second way, the DNA-reactive chemical produces DNA damage that eventually yields an inactivating mutation [7] in a tumor suppressor gene [2], with the mutant gene [8] encoding an inactive tumor suppressor protein [9] that cannot restrain mitosis or evoke apoptosis (eg, in response to DNA damage). In both instances, the rate of mitosis will exceed the rate of apoptosis [6] and uncontrolled proliferation of the affected cells will ensue [10]. Such a scenario may underlie the carcinogenicity of aflatoxin B₁, which induces mutation sometimes in the *Ras* proto-oncogene and often in the *p53* tumor suppressor gene (see text for details).

Nongenotoxic (epigenetic) carcinogens may also induce cell proliferation by 2 modes of action: first, by causing the overexpression of normal proto-oncogenes [1], yielding increased quantity of their protein products [11], which in turn excessively stimulate mitosis or inhibit apoptosis [12]. The second mode involves the underexpression of normal tumor suppressor genes [2], yielding diminished quantity of their protein products [13], which thus fail to restrain mitosis or promote apoptosis appropriately [12]. Nongenotoxic carcinogens may induce the synthesis of proto-oncogene proteins [11] at transcriptional and/or translational levels. They may facilitate the transcription of a proto-oncogene [1] into its mRNA [14] either by increasing the abundance of active transcription factors (TFs) at the promoter region of the gene or by facilitating the accessibility of TFs to the promoter (eg, by hypomethylation of this region) [15]. Nongenotoxic carcinogens may promote the translation of the mRNA into proto-oncogene protein [16] by decreasing the expression of microRNA (miRNA) [17] that normally represses the translation of this protein [16]. (Such miRNAs have tumor suppressor roles.) Nongenotoxic (also called epigenetic) carcinogens also may reduce the synthesis of tumor suppressor proteins [13] at transcriptional and/or translational levels. They may diminish the transcription of a tumor suppressor gene [2] into its mRNA [18] either by decreasing the abundance of active TFs at the promoter region of the gene or by impeding the accessibility of TFs to the promoter (eg, by hypermethylation of this region) [19]. Nongenotoxic carcinogens may downregulate the translation of the mRNA into a tumor suppressor protein [20] by increasing the expression of a miRNA [21] that normally represses the translation of this protein [20]. (Such miRNAs have oncogenic roles.) Eventually, overexpression of proto-oncogene proteins and/or underexpression of tumor suppressor proteins produce mitosis rate that exceeds the rate of apoptosis [12], thereby leading to uncontrolled proliferation of the affected cells [22]. Examples for nongenotoxic carcinogens acting by these mechanisms are given in the text.

In effect, the modes of action of these 2 types of chemical carcinogens are more complex: genotoxic carcinogens may also exert epigenetic effects and nongenotoxic carcinogens may increase the frequency of spontaneous mutations as well as the division and survival of cells carrying mutations (see the text for details).

populations. Such cells are characterized by quiescence, self-renewal, and conditional immortality, thus would potentially supply a lifelong, latent neoplastic population after carcinogen attack. Stem cells may be an especially likely target for transplacental carcinogens, such as DES or arsenic (Tokar *et al.*, 2011), because they are abundant during fetal development and have the longevity to carry the molecular lesion to the adult period of life.

Finally, further changes in gene expression may occur in these proliferating cells making them capable of invading the tissue and forming metastasis. These alterations confer the cells capacity for increased mobility by (1) their transdifferentiation into a mobile fibroblastoid phenotype (called epithelial-to-mesenchymal transition [EMT]), (2) disruption of the AJ that anchor cells to their neighbor (by downregulation of E-cadherin expression), and (3) degradation of the surrounding ECM (by upregulation of matrix metalloproteinases). Signaling systems that orchestrate EMT include those triggered by TGF- β (Fig. 3-12), the Wnt ligand (see Fig. 3-13), and the Hh ligand (see Fig. 3-14) (Katoh and Katoh, 2008).

CONCLUSIONS

This overview systematically surveys the mechanisms of the potential events that follow toxicant exposure and contribute to toxicity.

This approach is also useful in the search for mechanisms responsible for (1) selective toxicity, that is, differences in the sensitivity to toxicants of various organisms, such as different species and strains of animals, organs, and cells, and (2) alteration of toxicity by exogenous factors such as chemicals and food and physiologic or pathologic conditions such as aging and disease. To identify the mechanisms that underlie selective toxicity or alterations in toxicity, all steps where variations might occur must be considered systematically. Selective or altered toxicity may be due to different or altered (1) exposure; (2) delivery, thus resulting in a different concentration of the ultimate toxicant at the target site; (3) target molecules; (4) biochemical processes triggered by the reaction of the chemical with the target molecules; (5) repair at the molecular, cellular, or tissue level; or (6) altered gene expression-based stress responses as well as circulatory and thermoregulatory reflexes by which the affected organism can adapt to some of the toxic effects.

In this chapter, a simplified scheme has been used to give an overview of the development of toxicity (Fig. 3-1). In reality, the route to toxicity can be considerably more diverse and complicated. For example, one chemical may yield several ultimate toxicants, one ultimate toxicant may react with several types of target molecules, and reaction with one type of target molecule may have a number of consequences. Thus, the toxicity of one chemical may involve several mechanisms that can interact with and influence each other in an intricate manner.

This chapter has emphasized the significance of the chemistry of a toxicant in governing its delivery to and reaction with the target molecule as well as the importance of the biochemistry, molecular and cell biology, immunology, and physiology of the affected organism in its response to the action of the toxicant. An organism has mechanisms that (1) counteract the delivery of toxicants, such as detoxication; (2) reverse the toxic injury, such as repair mechanisms; and (3) offset some dysfunctions, such as adaptive responses. Thus, toxicity is not an inevitable consequence of toxicant exposure because it may be prevented, reversed, or compensated for by such mechanisms. Toxicity develops if the toxicant exhausts or impairs the protective mechanisms and/or overrides the adaptability of biological systems.

Summary

INTRODUCTION AND HISTORICAL CONTEXT

In the 1970s Congress established a basic plan for environmental laws that authorized regulatory actions to protect public health and the environment. These science-based actions provided the foundation for environmental and human health risk assessment. Toxicological research and toxicity testing constitute the scientific core of risk assessment, which is used for evaluating potential adverse health impacts from chemical exposures. However, such considerations for risk evaluation were not new, since for decades the American Conference of Governmental Industrial Hygienists (ACGIH) set threshold limit values for occupational exposures and the US Food and Drug Administration (FDA) established acceptable daily intakes (ADIs) for pesticide residues and food additives. In 1958, the US Congress instructed the FDA in the Delaney Clause to prohibit the addition of all substances found to cause cancer in animals or humans to the food supply. Pragmatically, this policy allowed food sources that had nondetectable levels of these additives to be declared “safe.” As advances in analytical chemistry revealed that “nondetects” were not equivalent to “not present,” regulatory agencies were forced to develop “tolerance levels” and “acceptable risk levels.” Risk assessment methodologies blossomed in the 1970s with the rising need to address these issues and statutes and to provide a common framework for considering human and ecological health effects (Albert, 1994).

Risk assessment was defined as a specific activity in 1983 in the National Research Council (NRC) publication *Risk Assessment*

in the Federal Government: Managing the Process (Red Book). This book detailed steps for hazard identification, dose–response assessment, exposure analysis, and characterization of risks (NRC, 1983). These 4 basic framework steps now form the foundation framework for risk assessment and risk management approaches for many contexts such as children’s health and ecological health and they provide a consistent context for risk assessment frameworks across agencies nationally and worldwide. Risk assessment frameworks have been used by the Health and Safety Executive Risk Assessment Policy Unit of the United Kingdom (Great Britain and Health and Safety Executive, 1999) and by the World Health Organization (NRC, 2009; WHO, 2010) and all of these build from these common components. Fig. 4-1 illustrates a framework with bidirectional arrows demonstrating an ideal situation where mechanistic research feeds directly into risk assessments and critical data uncertainty drives research. The common elements of the basic risk assessment framework are shown in red highlight. Initially, attention in risk assessment was focused on cancer risks; in subsequent years, noncancer end points were examined with similar methods and risk assessments were performed across life stages and for ecosystems. Continuing advances in toxicology, epidemiology, exposure assessment, biologically based modeling of adverse responses, and modeling of variability and uncertainty, as well as the rapidly growing area of genomics, have contributed to improvements in risk assessment. Risk assessment links with the public policy objectives from risk management often require extrapolations that go far beyond the observation of actual effects. Extrapolating data to address risks continues to generate controversy.

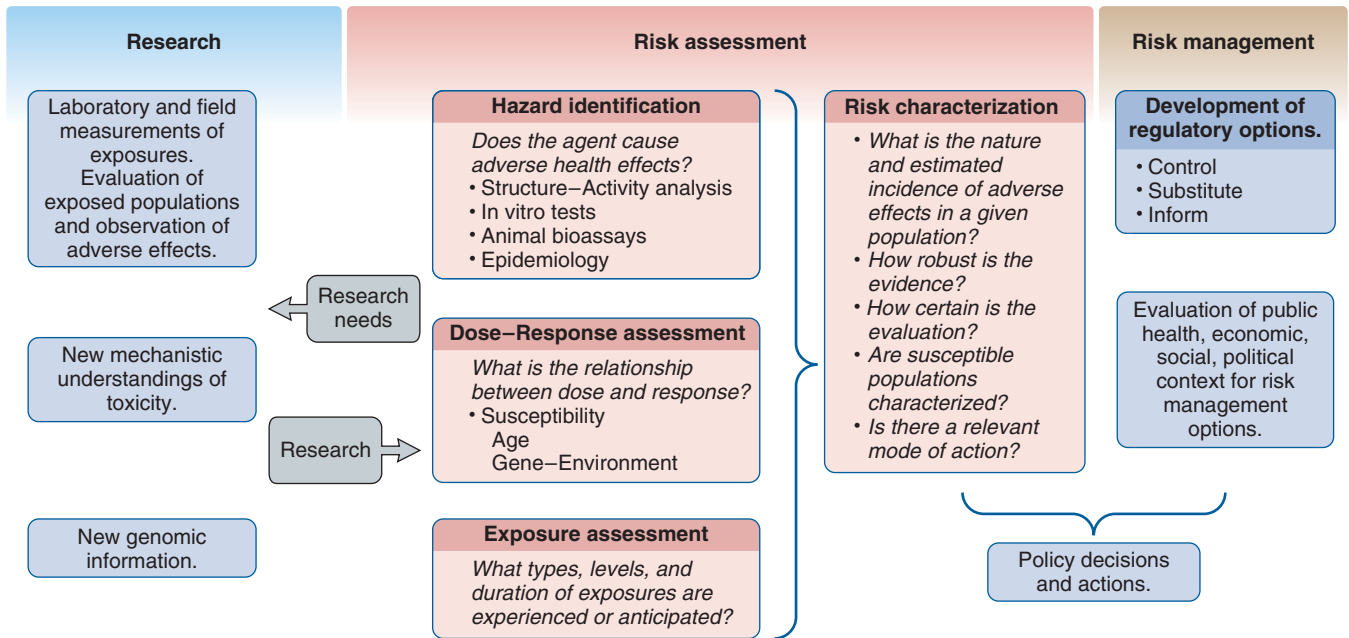

Figure 4-1. Risk assessment/risk management framework. This framework shows, under the red highlight, the 4 key steps of risk assessment: hazard identification, dose–response assessment, exposure assessment, and risk characterization. It shows an interactive, 2-way process where research needs from the risk assessment process drive new research, and new research findings modify risk assessment outcomes. (Adapted from Calkins *et al.* (1980), NRC Committee on Risk Assessment Methodology (1993), NRC (1994), Faustman and Omenn (1996), Risk Commission (1997), and Gargas *et al.* (1999); reprinted with permission from the National Academic Press, National Academy of Sciences.)

The National Academy of Sciences (NAS) 1994 report entitled *Science and Judgment in Risk Assessment* captured in its title the combination of qualitative and quantitative approaches essential for effective assessment of risks (NRC, 1994). The report discussed in detail the challenges and provided approaches for incorporating new scientific findings into the risk assessment process. It also highlighted ways to deal with uncertainty when insufficient scientific information was available. To address these challenges, the Presidential/Congressional Commission on Risk Assessment and Risk Management (Risk Commission, 1997) formulated a comprehensive framework that (1) placed each environmental problem or issue into public health and/or ecological context and (2) proactively called for engaging relevant stakeholders, often affected or potentially affected community groups, from the very beginning of the 6-stage process shown in Fig. 4-2. This report emphasized that particular exposures and potential health effects must be evaluated across sources and exposure pathways and in light of multiple end points, not just one chemical, in one environmental medium (air, water, soil, food, products), for one health effect at a time. The single-chemical, single-exposure approach had been the general approach up to this time. The importance of defining the risk problem based on this initial input is critical to risk assessment. Problem formulation and scoping has now been defined as Phase 1 for risk-based decision making and has been outlined by the US Environmental Protection Agency (EPA) (US EPA, 2011b) and reinforced by Science and Decisions, the *Silver Book* (NRC, 2009).

DEFINITIONS

Risk assessment is the systematic scientific evaluation of potential adverse health effects resulting from human exposures to hazardous agents or situations (NRC, 1983, 1994; Omenn, 2000). Risk is defined as the probability of an adverse outcome based

on the exposure and potency of the hazardous agent(s). Although historically there have been differences in how the term hazard has been used, international risk harmonization activities have allowed for current consensus on hazard as reference to intrinsic

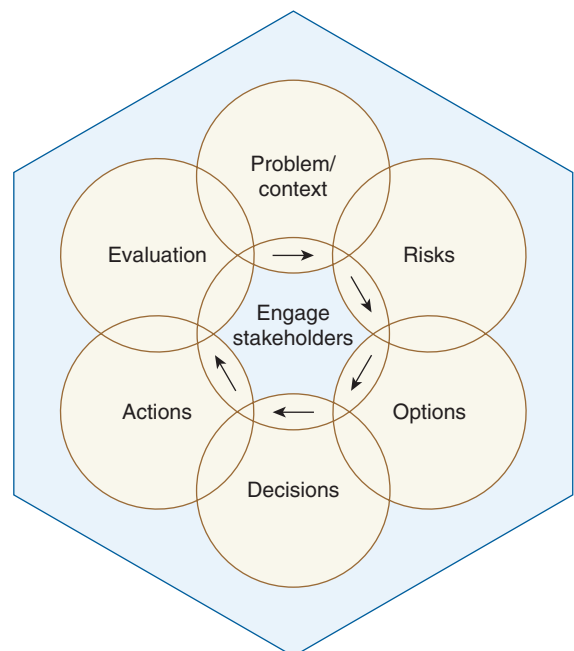

Figure 4-2. Risk management framework for environmental health from the US Commission on Risk Assessment and Risk Management. The framework comprises 6 stages: (1) formulating the problem in a broad public health context; (2) analyzing the risks; (3) defining the options; (4) making risk reduction decisions; (5) implementing those actions; and (6) evaluating the effectiveness of the actions taken. Interactions with stakeholders are critical and thus have been put at the center of the framework (Charnley and Omenn, 1997; Risk Commission, 1997).

Table 4-1

Objectives of Risk Assessment

1. Protect human and ecological health
 - Toxic substances
2. Balance risks and benefits
 - Drugs
 - Pesticides
3. Set target levels of risk
 - Food contaminants
 - Water pollutants
4. Set priorities for program activities
 - Regulatory agencies
 - Manufacturers
 - Environmental/consumer organizations
5. Estimate residual risks and extent of risk reduction after steps are taken to reduce risks

toxic properties, whereas exposure becomes an essential consideration along with hazard for risk. Risk assessment requires an integration of both qualitative and quantitative scientific information. For example, qualitative information about the overall evidence and nature of the end points and hazards is integrated with quantitative assessment of the exposures, host susceptibility factors, and the magnitude of the hazard. A description of the uncertainties and variability in the estimates is a significant part of risk characterization and an essential component of risk assessment. Analogous approaches are applied to ecological risks, as demonstrated by EPA's ecological risk assessment guidelines (US EPA, 2011b). The objectives of risk assessment are outlined in Table 4-1.

The phrase "characterization of risk" reflects the combination of qualitative and quantitative analysis. Increasingly, the use of the term "hazard characterization" versus "hazard identification" has been seen in both the US EPA (2012a) and WHO (1999) documents. This shift recognizes the difficulties in evaluating only hazard information without dose–response information. Unfortunately, many users equate risk assessment with quantitative risk assessment, generating a number for an overly precise risk estimate, while ignoring crucial information about the uncertainties of the risk assessment, mode of action (MOA), and type of effect across species or context.

Risk management refers to the process by which policy actions are chosen to control hazards identified in the risk assessment stage of the framework (Fig. 4-2). Risk managers consider scientific evidence and risk estimates—along with statutory, engineering, economic, social, and political factors—in evaluating alternative options and choosing among those options (Risk Commission, 1997).

Risk communication is the challenging process of making risk assessment and risk management information comprehensible to the public, community groups, lawyers, local elected officials, judges, business people, labor, environmentalists, etc (Morgan, 1993; Sandman, 1993; Fischhoff *et al.*, 1996; NRC, 1996). Such communication requires an understanding of level of risk response needed, how and which individuals and organizations should be informed, and what the audience hears versus what was intended as the risk communication message. Involving stakeholders in the initial problem formulation, as well as in the translation of the bottom line has become an essential part of risk management. Part of this analytical–deliberative process is the crucial, too-often neglected or delayed need for considering the fears, perceptions, priorities, and

proposed remedies of these stakeholders (Risk Commission, 1997; Drew *et al.*, 2003, 2006; Judd *et al.*, 2005; Kramer *et al.*, 2006; Cullen *et al.*, 2008). Underestimating potential public and media attitudes toward local polluters, other responsible parties, and relevant government agencies may lead to what has been labeled "the outrage factor" (Sandman, 1993), greatly influencing the communication process and the choices for risk management. Sometimes the decision makers and stakeholders simply want to know the "bottom line": whether a substance or a situation is "safe" or not. Others will be keenly interested in knowing how and why the risk estimates are uncertain and may be well prepared to challenge underlying assumptions about context and methodology. Stakeholders can also be part of a risk management solution (Judd *et al.*, 2005; Drew *et al.*, 2006). Perception of risk is further discussed at the end of this chapter.

DECISION MAKING

Risk management decisions are reached under diverse statutes in the United States. Table 4-2 lists examples of major environmental statutes and the year of initial enactment. Some statutes specify reliance on risk alone, whereas others require a balancing of risks and benefits of the product or activity. Risk assessments provide a valuable framework for priority setting within regulatory and health agencies, in the chemical development process within companies, and in resource allocation by environmental organizations. Similar approaches for risk assessment have been developed in many other countries and through such international organizations as the International Programme on Chemical Safety (IPCS) within the WHO. Currently within the IPCS, there are significant efforts toward a global harmonization of risk assessment methodology (WHO, 2006). The *WHO Human Health Risk Assessment Toolkit: Chemical Hazards* is an example (WHO, 2010). Their goals include use of a common risk assessment framework and development of confidence and acceptance of different risk assessment approaches through a common understanding and agreement on basic principles of testing and evaluation.

A major challenge for risk assessment, risk communication, and risk management is to work across disciplines to demonstrate the biological plausibility and clinical significance of the conclusions from epidemiologic studies, animal bioassays, short-term in vitro and in vivo tests, and structure–activity studies of chemicals thought to have potential adverse effects. Biomarkers of exposure, effect, or individual susceptibility can link the presence of a chemical in various environmental compartments to specific sites of potential action in target organs and to host health impacts (NRC, 1989a,b, 1992a,b; Adami *et al.*, 2011). Mechanistic investigations of the actions of specific chemicals can help us penetrate the "black box" approach of simply counting tumors, for example, in exposed animals in routine bioassays. Greater appreciation of the mechanisms and extent of individual variation in susceptibility to adverse health impacts among humans can improve protection of susceptible populations and better relate findings in animals to the characterization of risk for humans. Identifying individual behavioral and social risk factors can be critically important both to the characterization of risk and to the reduction of risk.

HAZARD IDENTIFICATION

Assessing Toxicity of Chemicals—Introduction

In order to assess the toxicity of chemicals, information from four types of studies is used: structure–activity relationships (SAR), in vitro or short-term studies, in vivo animal bioassays, and

Table 4-2

Examples of Major Toxic Chemical Laws in the United States by Responsible Agency and Year of Initial Enactment

EPA	Air pollutants	Clean Air Act, 1970		
	Water pollutants	Federal Water Pollution Control Act, 1948		
	Drinking water	Safe Drinking Water Act, 1974		
	Pesticides	Fungicides, Insecticides & Rodenticides Act (FIFRA), 1947 Food Quality Protection Act (FQPA), 1996		
	Ocean dumping	Marine Protection, Research and Sanctuaries Act (MPRSA) or Ocean Dumping Act, 1972		
	Toxic chemicals	Toxic Substances Control Act (TSCA), 1976		
	Hazardous wastes Abandoned hazardous wastes	Resource Conservation and Recovery Act (RCRA), 1976 Superfund (CERCLA), 1980		
CEQ	Environmental impacts	National Environmental Policy Act (NEPA), 1969		
OSHA	Workplace	Occupational Safety and Health (OSH) Act, 1970		
FDA	Foods, drugs, and cosmetics	Food and Drugs Act, 1906 Food, Drugs and Cosmetics Act (FDC), 1938 FDA Modernization Act, 1997		
		CPSC	Dangerous consumer products	Consumer Product Safety Act (CPSA), 1972
		DOT	Transport of hazardous materials	Hazardous Materials Transportation Act (HMTA), 1975

EPA, Environmental Protection Agency; CEQ, Council for Environmental Quality (now Office of Environmental Policy); OSHA, Occupational Safety and Health Administration; FDA, Food and Drug Administration; CPSC, Consumer Product Safety Commission; DOT, Department of Transportation.

information from human epidemiologic studies. In many cases, toxicity information for chemicals is limited. For example, in 1998, the EPA evaluated high production volume (HPV) chemicals (those produced in excess of one million lb per year) to ascertain the availability of chemical hazard data. Their study found that for 43% of these HPV chemicals, there were no publicly available studies for any of the basic toxicity end points (US EPA, 1998a). In response, EPA established a voluntary program called the HPV Challenge Program (US EPA, 2011c). Industry participants in this program committed to filling the data gaps for HPV chemicals. Since its inception, there have been over 2200 chemicals sponsored for additional testing. International efforts such as the Organization for Economic Cooperation and Development's screening information data set (OECD/SIDS) program are also addressing data needs related to HPV, highlighted by the publication of their *Manual for Investigation of HPV Chemicals* (OECD, 2011).

Data requirements for specific chemicals can vary greatly by compound type and applicable regulatory statutes. Introduced in 2003 and approved in 2006, the European Union released a regulatory framework for Registration, Evaluation and Authorisation of Chemicals (REACH) (REACH, 2011). Under the REACH framework, since 2007, all stakeholders submit dossiers that include physical, chemical, and toxicological data as well as risk assessment studies for all chemicals in use in Europe. Such chemical safety assessments are submitted prior to approval in approaches similar to premanufacturing notices (PMNs) in the United States for the US EPA (US EPA, 2011d). Table 4-3 shows requirements and costs for one example class of agents, pesticides (Stevens, 1997; US EPA, 1998b; EPA, 2000), in the United States (40 CFR 158.340). It also illustrates current international efforts to align these testing guidelines by listing examples of the harmonized 870 test guidelines (US EPA, 2010a). The emphasis in REACH is on non-in vivo animal tests. Also, REACH has brought about new international labeling laws for hazard identification.

Assessing Toxicity of Chemicals—Approaches

Structure–Activity Relationships Given the cost of two to four million dollars and the three to five years required for testing a single chemical in a lifetime rodent carcinogenicity bioassay, initial decisions on whether to continue development of a chemical, to submit PMN, or to require additional testing may be based largely on results from SARs and limited short-term assays.

A chemical's structure, solubility, stability, pH sensitivity, electrophilicity, volatility, and chemical reactivity can be important information for hazard identification. Historically, certain key molecular structures have provided regulators with some of the most readily available information on the basis of which to assess hazard potential. For example, 8 of the first 14 occupational carcinogens were regulated together by the Occupational Safety and Health Administration (OSHA) as belonging to the aromatic amine chemical class. The EPA Office of Toxic Substances relies on SARs to meet deadlines to respond to PMN for new chemical manufacture under the Toxic Substances Control Act (TSCA). Structural alerts such as *N*-nitroso or aromatic amine groups, amino azo dye structures, or phenanthrene nuclei are clues to prioritize chemicals for additional evaluation as potential carcinogens. SAR information for specific noncancer health end points can be challenging. The database of known developmental toxicants limits SARs to a few chemical classes, including chemicals with structures related to those of valproic acid, retinoic acid, phthalate esters, and glycol ethers (NRC, 2000). More recently, omic technologies have been used to supplement SAR relationship databases, as seen with the creation of the National Cancer Institute's (NCI) gene expression database (<http://dtp.nci.nih.gov/>) and the US EPA Computational Toxicity Program Screening Database (ToxCast™) (US EPA ACToR, 2011).

SARs have been used for assessment of complex mixtures of structurally related compounds. A prominent application has been the assessment of risks associated with 2,3,7,8-tetrachloro-dibenzo-*p*-dioxin (TCDD), related chlorinated and brominated

Table 4-3

Example EPA/FIFRA Requirements for Hazard Evaluation of Pesticides

GUIDELINE NO.	REVISED 870 GUIDELINE	TYPE OF TOXICITY STUDY	TEST SYSTEM	OBJECTIVE	APPROXIMATE COST/STUDY* (US\$)
81-1	1100	Acute oral	Rats	Define toxic dose by ingestion	2700
81-2	1200	Acute dermal	Rabbits	Define toxic dose by absorption through skin	2000
81-3	1300	Acute inhalation	Rats	Define toxic dose by inhalation	6800
81-4	2400	Ocular	Rabbits	Assess eye irritation/injury	2000
81-5	2500	Skin irritation	Rabbits	Assess skin irritation/injury	130
81-6	2600	Sensitization	Guinea pigs	Assess allergic potential	4000
81-7	6100–6855	Neurotoxicity ^{†,‡}	Hens/rats	Assess nervous system injury	34,000 [‡]
84-2	5100–5915	Mutagenicity [§]	In vivo/in vitro	Determine genotoxic potential; screen for carcinogenicity	6800
82-1	3050–3465	Range-finding [§] Subacute (28- to 90-day*)	Rats	Determine effects following repeated doses; set dose level	95,000
			Mice		95,000
			Dogs	For longer studies	136,000
			Rabbits		101,000
			Rats		258,000
Mice	Identify target organs; set dose levels for chronic studies	258,000			
83-5	4200–4300	Carcinogenicity/ chronic toxicity	Rats	Determine potential to induce tumors; define dose–response relationships (lifetime)	1,900,000
			Mice		1,087,000
			Dogs	Determine long-term toxic effects (1 year)	543,000
83-3	3550–3800	Reproduction and teratogenicity	Rats	Determine potential to cause fetal abnormalities and effects on development, fertility, pregnancy, and development of offspring over at least 2 generations	686,000
83-4			Rabbits		
85-1	7485	Toxicokinetics	Rats, mice	Determine and quantitate the metabolic fate of a pesticide	135,000

*Indicates per assay cost using Consumer Price Index (CPI) conversion factors to determine 2010 value (oregonstate.edu/cla/polisci/sahr/sahr). Estimates were provided using guideline 81 series.

[†]Required for organophosphate insecticides only.

[‡]Additional neurotoxicity tests 81-7, 81-8, 82-6, 82-7, and 83-6 have been added to requirements for certain materials and can include tests such as functional observational battery, motor activity, developmental landmarks, and learning and memory assessments (Sette, 1991). Costs listed for this type of study are only those for the initial study, not additional testing.

[§]Range-finding studies are not required, but provide justification for setting dose levels in required studies. EPA-required studies can include reverse mutation assays in *Salmonella*, forward mutation assays in mammalian cells—for example, Chinese hamster ovary cells and mouse lymphoma L5178Y (the locus cells)—and in vivo cytogenetics (Dearfield, 1990).

SOURCE: Adapted from Stevens (1997), and updated with newly revised EPA 870 guideline information (US EPA, 2010a). For details on changes in the health effects test guidelines reflective of the harmonization of the toxicology guidelines between the Office of Pollution Prevention and Toxics (OPPT) and the Office of Pesticide Programs (OPP), within the EPA and with the Organization for Economic Cooperation and Development (OECD) guidelines, see EPA (US EPA, 2010a, 2011a) (http://www.epa.gov/OPPTS_Harmonized/870_Health_Effects_Test_Guidelines).

dibenzo-*p*-dioxins, dibenzofurans, and planar biphenyls, and chemicals generally present as mixtures in the environment. Toxicity equivalence factors (TEFs) are used to evaluate health risks associated with closely related chemicals. For the TCDD class, this is based on a common mechanism of aryl hydrocarbon (Ah) receptor induction (US EPA, 1994a). The estimated toxicity of environmental mixtures containing these chemicals is calculated as the sum

of the product of the concentration of each chemical multiplied by its TEF value. The World Health Organization has organized efforts to reach international consensus on the TEFs used for polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), and polychlorinated dibenzofurans (PCDFs) for both humans and wildlife, and has updated its values and published the supporting database (Van den Berg *et al.*, 1998, 2006; Haws *et al.*,

2006). Under the auspices of WHO, the dioxin-like PCB congeners have been assigned TEFs reflecting their toxicity relative to TCDD, which itself has been assigned a TEF of 1.0.

Computerized SAR methods have, in general, given disappointing results in the National Toxicology Program (NTP) rodent carcinogenicity prediction challenges (Ashby and Tennant, 1994; Omenn *et al.*, 1995; Benigni and Zito, 2004). More successes are those of pharmaceutical companies using combinatorial chemistry and 3-dimensional (3D) molecular modeling approaches to design ligands (new drugs) that can sterically fit into the “receptors of interest.” However, for environmental pollutants where selective binding to specific receptors is rare, these applications of SAR have had limited success within risk assessment. A renewed interest in quantitative SAR (QSAR) approaches has resulted from the need to evaluate nano-engineered materials where the tremendous number of unique new products has highlighted the necessity of using QSAR approaches to handle the avalanche of novel untested materials (Maynard *et al.*, 2006; Liu *et al.*, 2011).

Efforts within REACH have also emphasized the potential for use of SAR as similar chemicals are collectively evaluated using a concept of “read-across.” Substances whose physicochemical, toxicological, and ecotoxicological properties are similar can be grouped as a “category” of substances when they have a common functional group, common precursor or breakdown product, or a common pattern of potency.

In Vitro and Short-Term Tests The next level of biological information obtained within the hazard identification process includes assessment of the test chemical in *in vitro* or short-term tests, ranging from bacterial mutation assays performed entirely *in vitro* to more elaborate short-term tests, such as skin painting studies in mice or altered rat liver foci assays conducted *in vivo*. For example, EPA mutagenicity guidelines call for assessment of reverse mutations using the Ames *Salmonella typhimurium* assay; forward mutations using mammalian cells, mouse lymphoma L5178Y, Chinese hamster ovary, or Chinese hamster lung fibroblasts; and *in vivo* cytogenetics assessment (bone marrow metaphase analysis or micronucleus tests) (US EPA, 2005). Chap. 8 discusses uses of these assays for identifying chemical carcinogens and Chap. 9 describes in detail various assays of genetic and mutagenic end points. Other assays evaluate specific health end points such as developmental toxicity (Faustman, 1988; Whittaker and Faustman, 1994; Brown *et al.*, 1995; Lewandowski *et al.*, 2000; NRC, 2000; Spielmann *et al.*, 2006), reproductive toxicity (Gray, 1988; Harris *et al.*, 1992; Shelby *et al.*, 1993; Yu *et al.*, 2009), neurotoxicity (Atterwill *et al.*, 1992; Costa, 2000), and immunotoxicity (ICCVAM, 1999, 2011a) (Chap. 12). Less information is available on the extrapolation of these test results for noncancer risk assessment than for the mutagenicity or carcinogenicity end points; however, mechanistic information obtained in these systems has been applied to risk assessment (Abbott *et al.*, 1992; US EPA, 1994b; Leroux *et al.*, 1996; NRC, 2000).

Overall, progress in developing and validating new *in vitro* assays has been slow and frustrating. The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) of NTP reinvigorated the validation process in the United States as a result of Public Law 103-43 and coordinates cross-agency issues relating to development, validation, acceptance, and national/international harmonization of toxicological test methods for use in risk assessments. The committee has put forth recommendations for over 40 alternative safety testing methods using various short-term/*in vitro* assays, such as the cell-free corrosivity test, and for the mouse local lymph node assay for assessing chemical potential to

elicit allergic reactions (ICCVAM, 1999, 2011a; NIEHS, 1999a,b). In 2006 the committee released a document that extensively reviews *in vitro* acute toxicity methods (National Toxicology Program Center for the Evaluation of Alternative Toxicological Methods (US) and Interagency Coordinating Committee on the Validation of Alternative Methods (US), 2006). The European Centre on the Validation of Alternative Methods (ECVAM) has been very active given the visibility of animal rights issues in the European Union, and this Center was originally formed to “support the development, validation, and acceptance of methods that could reduce, refine, or replace [3 Rs] the use of laboratory animals” (<http://ecvam.jrc.cec.eu.int/index.htm>). Early successes of ECVAM are described in Hartung *et al.* (2003). However, a recent report for the Center for Alternatives for Animal Testing highlights the slow progress on full replacement of animal testing, especially for repeated dose toxicity testing, carcinogenicity, or reproductive toxicity testing (Adler *et al.*, 2011; Hartung *et al.*, 2011). It does highlight numerous successes for evaluating sensitization and toxicokinetics (TK). International efforts to reduce the number of animals required for chemical safety testing have been established between ICCVAM, Korea, Japan, Canada, and ECVAM (http://iccvam.niehs.nih.gov/docs/about_docs/ICATM-MOC-Mar11.pdf).

The validation and application of short-term assays is particularly important to risk assessment because such assays can be designed to provide information about mechanisms of effects, and, moreover, they are fast and inexpensive compared with lifetime bioassays (McGregor *et al.*, 1999). Validation of *in vitro* assays, like other kinds of tests, requires determination of their sensitivity (eg, ability to identify true carcinogens), specificity (eg, ability to recognize noncarcinogens as noncarcinogens), and predictive value for the toxic end point under evaluation. The societal costs of relying on such tests, with false positives (noncarcinogens classified as carcinogens) and false negatives (true carcinogens not detected), are the subject of a value-of-information model for testing in risk assessment and risk management (Lave and Omenn, 1986; Omenn and Lampen, 1988).

Efforts to improve our ability to utilize short-term tests for carcinogenicity prediction include increased attention to improving the mechanistic basis of short-term testing. Examples of this approach include the development and application of several knock-out transgenic mouse models as shorter-term *in vivo* assays to identify carcinogens (Nebert and Duffy, 1997; Tennant *et al.*, 1999). Specific assays for evaluating mechanisms such as the function of the estrogen receptor are an example where *in vitro* test methods are used to predict endocrine disruptor actions (ICCVAM, 2011b, 2012). The primary use of short-term tests in the United States continues to be for mechanistic evaluations with the hope of informing chemical-specific information or overall MOA. In that context, results from short-term assays have impacted risk assessments. For example, evidence of nonmutagenicity in both *in vitro* and *in vivo* short-term assays plays an essential role, allowing regulators to consider nonlinear cancer risk assessment paradigms for non-genotoxic carcinogens (US EPA, 1999a). Mechanistic information from short-term *in vitro* assays can also be used to extend the range of biological observations available for dose–response assessment. In addition, for developmental toxicity assessment, assay methods that acknowledge the highly conserved nature of developmental pathways across species have accelerated the use of a broader range of model organisms and assay approaches for noncancer risk assessments (NRC, 2000). *Toxicity Testing in the 21st Century* and *Toxicity Pathway-Based Risk Assessment* emphasized such approaches for using model organisms and tiered toxicity strategies for Risk Assessment (NRC, 2007a; NRC, 2010).

Animal Bioassays Animal bioassays are a key component of the hazard identification process. A basic premise of risk assessment is that chemicals that cause tumors in animals can cause tumors in humans. All human carcinogens that have been adequately tested in animals produce positive results in at least one animal model. Thus, “although this association cannot establish that all chemicals and mixtures that cause cancer in experimental animals also cause cancer in humans, nevertheless, in the absence of adequate data on humans, it is biologically plausible and prudent to regard chemicals and mixtures for which there is sufficient evidence of carcinogenicity in experimental animals as if they presented a carcinogenic risk to humans” (IARC, 2000)—a reflection of the “precautionary principle.” The US EPA cancer guidelines (US EPA, 2005) also assume relevance of animal bioassays unless lack of relevance for human assessment is specifically determined. In general, the most appropriate rodent bioassays are those that test exposure and biological pathways of most relevance to predicted or known human exposure pathways. Bioassays for reproductive and developmental toxicity and other noncancer end points have a similar rationale. The National Toxicology Program (NTP) serves as a resource for conducting, designing, and evaluating bioassays for cancer as well as noncancer evaluation. The NTP Office of Human Health Assessment and Translation serves as a resource to the public and regulatory agencies regarding the interpretation and assessment of adverse effects of chemicals (National Toxicology Program, 2011b). The WHO International Agency for Research on Cancer (IARC) has evaluated over 900 agents “of which more than 400 have been identified as carcinogenic, probably carcinogenic or possibly carcinogenic to humans” (WHO, 2011b).

Consistent features in the design of standard cancer bioassays include testing in two species and both sexes, with 50 animals per dose group and near-lifetime exposure. Important choices include the strains of rats and mice, the number of doses, and dose levels (typically 90%, 50%, and 10%–25% of the maximally tolerated dose [MTD]), and details of the required histopathology (number of organs to be examined, choice of interim sacrifice pathology, etc). The NTP Web site lists details on study designs and protocols (National Toxicology Program, 2011a). Positive evidence of chemical carcinogenicity can include increases in number of tumors at a particular organ site, induction of rare tumors, earlier induction (shorter latency) of commonly observed tumors, and/or increases in the total number of observed tumors. Recently, NTP has added an in utero exposure period to the start of their cancer bioassays to more directly evaluate the significance of early life exposures for cancer incidence.

The cancer bioassay, originally designed for hazard identification, is frequently used to evaluate dose–response. The relatively limited number of evaluated doses and the use of high doses have caused issues for low-dose extrapolations and have limited the use of cancer bioassays as a “gold standard” for prediction of human carcinogenicity risk (McClain, 1994; Cohen, 1995; Risk Commission, 1997; Rodericks *et al.*, 1997; Capen *et al.*, 1999; Rice *et al.*, 1999). Tumors may be increased only at the highest dose tested, which is usually at or near a dose that causes systemic toxicity (Ames and Gold, 1990). Second, even without toxicity, the high dose may trigger different events than do low-dose exposures and high doses can saturate important metabolism and elimination pathways.

Rats and mice give concordant positive or negative results in approximately 70% of bioassays, so it is unlikely that rodent/human concordance would be higher (Lave *et al.*, 1988). Haseman and Lockhart (1993) concluded that most target sites in cancer bioassays showed a strong correlation (65%) between males and females—especially for forestomach, liver, and thyroid tumors—so

they suggested, for efficiency, that bioassays could rely on a combination of male rats and female mice. Even when concordant, positive results are observed, there can still be large differences in potency, as observed in aflatoxin-induced tumors in rats and mice. In this example, an almost 100,000-fold difference in susceptibility to aflatoxin B₁ (AFB₁)–induced liver tumors is seen between the sensitive rat and trout species and the more resistant mouse strains. Genetic differences in the expression of cytochrome P450 and glutathione *S*-transferases explain most of these species differences and suggest that humans may be as sensitive to AFB₁-induced liver tumors as rats (Eaton and Gallagher, 1994; Eaton *et al.*, 1995, 2001). These species differences have been supported by research results (Groopman and Kensler, 1999; Kensler *et al.*, 2011) and have been extended within epidemiologic studies to demonstrate the interaction of hepatitis C infection with AFB₁ exposure to fully explain elevated human liver cancer risks.

Lifetime bioassays have been enhanced with the collection of additional mechanistic data and with the assessment of multiple noncancer end points. It is feasible and desirable to integrate such information together with data from mechanistically oriented short-term tests and biomarker and genetic studies in epidemiology (Perera and Weinstein, 2000). In the example of AFB₁-induced liver tumors, AFB₁-DNA adducts have proved to be an extremely useful biomarker. A highly linear relationship was observed between liver tumor incidence (in rats, mice, and trout) and AFB₁-DNA adduct formation over a dose range of 5 orders of magnitude (Eaton and Gallagher, 1994). Such approaches may allow for an extension of biologically observable phenomena to doses lower than those leading to frank tumor development and help to address the issues of extrapolation over multiple orders of magnitude to predict response at environmentally relevant doses.

Table 4-4 presents some mechanistic details about rodent tumor responses that are no longer thought to be predictive of cancer risk for humans. This table lists examples of both qualitative and quantitative considerations useful for determining relevance of rodent tumor responses for human risk evaluations. An example of qualitative considerations is the male rat kidney tumors observed following exposure to chemicals that bind to α_{2u} -globulin (eg, unleaded gasoline, 1,4-dichlorobenzene, D-limonene). The α_{2u} -globulin is a male-rat-specific low-molecular-weight protein not found in female rats, humans, or other species, including mice and monkeys (McClain, 1994; Neumann and Olin, 1995; Oberdorster, 1995; Omenn *et al.*, 1995; Risk Commission, 1997; Rodericks *et al.*, 1997).

Table 4-4 also illustrates quantitative considerations important for determining human relevance of animal bioassay information. For example, doses of compounds so high as to exceed solubility in the urinary tract outflow lead to tumors of the urinary bladder in male rats following crystal precipitation and local irritation leading to hyperplasia. Such precipitates are known to occur following saccharin or nitroacetate acid exposure (Cohen *et al.*, 2000). The decision to exclude saccharin from the NTP list of suspected human carcinogens reaffirms the nonrelevance of such high-dose responses for likely human exposure considerations (Neumann and Olin, 1995; National Toxicology Program, 2005). A gross overloading of the particle clearance mechanism of rat lungs via directly administered particles, as was seen in titanium dioxide (TDO) exposures, resulted in EPA’s delisting TDO as a reportable toxicant for the Clean Air Act Toxic Release Inventory (US EPA, 1988; Oberdorster, 1995).

Other rodent responses not likely to be predictive for humans include localized forestomach tumors after gavage. Ethyl acrylate, which produces such tumors, was delisted on the basis of extensive

Table 4-4

Examples of Mechanistic Considerations for Carcinogens: Explanation for Special Cases of Rodent Bioassay Data Lacking Relevance for Human Risk Evaluation

SYSTEM	TARGET ORGAN	MECHANISM FOR SUSCEPTIBLE SPECIES	SPECIES DIFFERENCES	ILLUSTRATIVE CHEMICAL AGENTS
Urinary tract	Renal tumors in male rats	Chemicals bind to α_{2U} -globulin, accumulation in target kidney cells, increased necrosis, increased regenerative hyperplasia, renal tubular calcification neoplasia	α_{2U} -Globulin male-rat-specific low-molecular-weight protein not found in female rats, humans, mice, monkeys	Unleaded gasoline, 1,4-dichlorobenzene, δ -limonene, isophorone, dimethyl-methylphosphonate, perchloroethylene, pentachloroethane, hexachloroethane
	Bladder	Reactive hyperplasia from cytotoxic precipitated chemicals	Rodent exposure levels exceed solubility, not relevant for human exposure	Saccharin, melamine, nitrilotriacetic acid, fosetyl-A2
Gastric	Forestomach	Direct oral gavage, local cytotoxicity, hyperplasia	Rodent gavage treatment, exposure conditions not relevant for human exposure	BHA, propionic acid, ethyl acrylate
Endocrine	Thyroid gland tumors	Alteration in thyroid homeostasis, decreased thyroid hormone production, sustained increase in thyroid-stimulating hormone (TSH), thyroid tumors	Lack of thyroid-binding protein in rodents versus humans, decreased $t_{1/2}$ for T_4 , increased TSH levels in rodents	Ethylene bisdithiocarbamate, fungicides, amitrol, goitrogens, sulfamethazine
Respiratory	Rat lung	Overwhelming clearance mechanisms	High-dose effects seen with rodent models	Various particles, titanium dioxide

mechanistic studies (National Toxicology Program, 2005). In general, for risk assessment, it is desirable to use the same route of administration as the likely exposure pathway in humans to avoid such extrapolation issues. Despite the example of forestomach tumors, tumors in unusual sites—such as the pituitary gland, the eighth cranial nerve, or the Zymbal gland—should not be immediately dismissed as irrelevant, since organ-to-organ correlation is often lacking (NRC, 1994). The EPA cancer guidelines provide a good list of considerations for evaluating relevance in the sections on evaluating weight of evidence (US EPA, 2005).

In an attempt to improve the prediction of cancer risk to humans, transgenic mouse models have been developed as possible alternative to the standard 2-year cancer bioassay. Transgenic models use knockout or transgenic mice that incorporate or eliminate a gene that has been linked to human cancer. NTP evaluated some of these models and found the p53-deficient (p53+/- heterozygous) and Tg.AC (v-Ha-ras transgene) models to be particularly useful in identifying carcinogens and mechanisms of action (Bucher, 1998; Chhabra *et al.*, 2003). The use of transgenic models has the power to improve the characterization of key cellular and MOA of toxicological responses (Mendoza *et al.*, 2002; Gribble *et al.*, 2005). However, these studies have been used primarily for mechanistic characterization than for hazard identification. Transgenic models have been shown to reduce cost and time as compared with the standard 2-year assay but they have also been shown to be somewhat limited in their sensitivity (Cohen, 2001). As stated in the current EPA cancer guidelines, transgenic models should not be used to replace the standard 2-year assay, but can be

used in conjunction with other types of data to assist in the interpretation of additional toxicological and mechanistic evidence (US EPA, 2005). A series of genetically defined (fully sequenced genomes, 20 × coverage) mice referred to as the Collaborative Cross have been established to investigate genetic and environmental influences on toxicological response in mice (Chesler *et al.*, 2008) and these strains should improve our understanding of mammalian genes that predispose to cancer (Koturbash *et al.*, 2011).

Use of Epidemiologic Data in Risk Assessment The most convincing lines of evidence for human risk are well-conducted epidemiologic studies in which a positive association between exposure and disease has been observed (NRC, 1983). Environmental and occupational epidemiologic studies are frequently opportunistic. Studies begin with known or presumed exposures, comparing exposed with nonexposed individuals, or with known cases, compared with persons lacking the particular diagnosis.

Table 4-5 shows examples of epidemiologic study designs and provides clues on types of outcomes and exposures evaluated. Although convincing, there are important limitations inherent in epidemiologic studies. Robust exposure estimates are often difficult to obtain as they are frequently done retrospectively (eg, through retrospective job history records). Also, since many important health effects have long latency before clinical manifestations appear, reconsideration of relevant populations can be challenging. Another challenge for interpretation is that there are often exposures to multiple chemicals, especially when a lifetime exposure period is

Table 4-5

Example of 3 Types of Epidemiologic Study Designs

METHODOLOGICAL ATTRIBUTES	TYPE OF STUDY		
	COHORT	CASE-CONTROL	CROSS-SECTIONAL
Initial classification	Exposure–nonexposure	Disease–nondisease	Either one
Time sequence	Prospective	Retrospective	Present time
Sample composition	Nondiseased individuals	Cases and controls	Survivors
Comparison	Proportion of exposed with disease	Proportion of cases with exposure	Either one
Rates	Incidence	Fractional (%)	Prevalence
Risk index	Relative risk–attributable risk	Relative odds	Prevalence
Advantages	Lack of bias in exposure; yields incidence and risk rates	Inexpensive, small number of subjects, rapid results, suitable for rare diseases, no attrition	Quick results
Disadvantages	Large number of subjects required, long follow-up, attrition, change in time of criteria and methods, costly, inadequate for rare diseases	Incomplete information, biased recall, problem in selecting control and matching, yields only relative risk—cannot establish causation, population of survivors	Cannot establish causation (antecedent consequence), population of survivors, inadequate for rare diseases

SOURCE: Gamble and Battigelli (1978, 1991).

considered. There is frequently a trade-off between detailed information on relatively few persons and very limited information on large numbers of persons. Contributions from lifestyle factors, such as smoking and diet, are important to assess as they can have a significant impact on cancer development. Human epidemiologic studies can provide both very useful information for hazard assessment and quantitative information for data characterization. Good illustrations of epidemiologic studies and their interpretation for toxicological evaluation are available (Gill *et al.*, 2011 and Regalado *et al.*, 2006).

Three types of epidemiologic study designs—cross-sectional studies, cohort studies, and case–control studies—are detailed in Table 4-5. Cross-sectional studies survey groups of humans to identify risk factors (exposure) and disease but are not useful for establishing cause and effect. Cohort studies can evaluate individuals selected on the basis of their exposure to a chemical under study. Thus, based on exposure status, these individuals are monitored for development of disease. These prospective studies monitor over time individuals who initially are disease-free to determine the rates at which they develop disease. In case–control studies, subjects are selected on the basis of disease status: disease cases and matched cases of disease-free individuals. Exposure histories of the 2 groups are compared to determine key consistent features in their exposure histories. All case–control studies are retrospective studies.

In risk assessment, epidemiologic findings are judged by the following criteria: strength of association, consistency of observations (reproducibility in time and space), specificity (uniqueness in quality or quantity of response), appropriateness of temporal relationship (did the exposure precede responses?), dose–responsiveness, biological plausibility and coherence, verification, and analogy (biological extrapolation) (Hill, 1965; Faustman *et al.*, 1997; World Health Organization and International Programme on

Chemical Safety, 1999; Adami *et al.*, 2011). These same criteria have been used for evaluating MOAs where integrated considerations of both human and animal studies are done.

Epidemiologic study designs should also be evaluated for their power of detection, appropriateness of outcomes, verification of exposure assessments, completeness of assessing confounding factors, and general applicability of the outcomes to other populations at risk. Power of detection is calculated using study size, variability, accepted detection limits for end points under study, and a specified significance level (Healey, 1987; EGRET, 1994; Dean *et al.*, 1995). Meta-analysis is used with epidemiologic studies to combine results from different studies using weighting of results to account for sample size across studies. The importance of human studies for risk assessment is shown in evaluations with arsenic and dioxin (US EPA, 2010b).

Advance from the human genome project have increase sophistication of molecular biomarkers and have improved the mechanistic bases for epidemiologic hypotheses. This has allowed epidemiologists to get within the “black box” of statistical associations and forward our understanding of biological plausibility and clinical relevance. “Molecular epidemiology,” the integration of molecular biology into traditional epidemiologic research, is an important focus of human studies where improved molecular biomarkers of exposure, effect, and susceptibility have allowed investigators to more effectively link molecular events in the causal disease pathway. Epidemiologists can now include the contribution of potential genetic factors with environmental risk factors for the determination of the etiology, distribution, and prevention of disease. Highlighting the potential power of genetic information to epidemiologic studies, the Human Genome Epidemiology (HuGE) Network was launched in 1998, providing a literature database of published, population-based epidemiologic studies of human genes (Khouri, 1999).

With the advance of genomics, the range of biomarkers has grown dramatically and includes identification of single-nucleotide polymorphisms (SNPs), genomic profiling, transcriptome analysis, and proteomic analysis (Simon and Wang, 2006). Implications of these improvements for risk assessment are tremendous, as they provide an improved biological basis for extrapolation across the diversity of human populations and allow for improved cross-species comparisons with rodent bioassay information because of evolutionarily conserved response pathways (NRC, 2000). In addition, genomics allows for “systems-based” understanding of disease and response, moving risk assessment away from a linear, single-event-based concept and improving the biological plausibility of epidemiologic associations (Toscano and Oehlke, 2005; NRC, 2010).

Integrating Qualitative Aspects of Risk Assessment

Qualitative assessment of hazard information should include a consideration of the consistency and concordance of findings, including a determination of the consistency of the toxicological findings across species and target organs, an evaluation of consistency across duplicate experimental conditions, and a determination of the adequacy of the experiments to consistently detect the adverse end points of interest.

Qualitative assessment of animal or human evidence is done by many agencies, including the EPA and IARC. Similar evidence classifications have been used for both the animal and human evidence categories by both agencies. These evidence classifications have included levels of “sufficient, limited, inadequate, and no evidence” (US EPA, 1994b, 2005) or “evidence suggesting lack of carcinogenicity” (IARC, 2000). For both agencies, these classifications are used for an overall weight-of-evidence approach for carcinogenicity classification.

Weight of evidence is an integrative step used by the EPA to “characterize the extent to which the available data support the hypothesis that an agent causes cancer in humans” (US EPA, 2005). It is the process of “weighing” all of the evidence to reach a conclusion about carcinogenicity. With this method, the likelihood of human carcinogenic effect is evaluated within an evaluation of the conditions under which such effects may be expressed. Weight of evidence can consider both the quality and quantity of data as well as any underlying assumptions. The evidence includes data from all of the hazard assessment and characterization studies such as SAR data, in vivo and/or in vitro studies, and epidemiologic data. Using this type of information and weight-of-evidence approach, the EPA includes hazard descriptors to define carcinogenic potential and to provide a measure of clarity and consistency in the characterization narrative: “carcinogenic to humans,” “likely to be carcinogenic to humans,” “suggestive evidence of carcinogenic potential,” “inadequate information to assess carcinogenic potential,” and “not likely to be carcinogenic to humans.” In this section, approaches for evaluating cancer end points are discussed for carcinogens. Similar weight-of-evidence approaches have been proposed for reproductive risk assessment (refer to sufficient and insufficient evidence categories in EPA’s guidelines for reproductive risk [US EPA, 1996a] and considerations by NTP).

The Institute for Evaluating Health Risks defined an “evaluation process” by which reproductive and developmental toxicity data can be consistently evaluated and integrated to ascertain their relevance for human health risk assessment (Moore *et al.*, 1995; Faustman *et al.*, 2011). This evaluation process has served as the basis for US EPA’s guidelines for developmental toxicity

risk assessment (US EPA, 1991) and for NTP’s *Office of Health Assessment and Translation (Formerly CERHR)* (National Toxicology Program, 2011b). Application of such carefully deliberated approaches for assessing noncancer end points has helped avoid the tendency to list chemicals as yes or no (positive or negative) without human relevancy information.

Mode of Action The EPA has emphasized in their revised cancer guidelines the importance of using “weight of evidence” to arrive at insights to possible “MOA” (US EPA, 2005). MOA information describes key events and processes leading to molecular and functional effects that would in general explain the overall process of cancer development. In many cases these could be plausible hypothesized MOAs for specific toxicity end points, but the detailed mechanistic nuances of the pathway might not yet be fully known. EPA is using such MOA information to suggest non-default approaches for cancer risk assessments and for evaluating toxicity of compounds with common MOAs in cumulative risk assessments (US EPA, 1996a, 1998a).

Within the EPA’s carcinogenic risk assessment guidelines, the MOA framework considers evidence from animal studies, relevance to humans, and life stage or population susceptibility (US EPA, 2005). Chemical-specific adjustment factors for interspecies differences and human variability have been proposed and build upon guidance developed by the WHO’s International Programme on Chemical Safety Harmonization Project (WHO, 2000). Critical to the MOA development is the use of “criteria of causality” considerations, which build upon Hill criteria used in epidemiology (Hill, 1965; Faustman *et al.*, 1996; US EPA, 1999a; Klaunig *et al.*, 2003), and consider dose–response relationships and temporal associations, as well as the biological plausibility, coherence, strength, consistency, and specificity of the postulated MOA.

DOSE–RESPONSE ASSESSMENT

Integrating Quantitative Aspects of Risk Assessment

Quantitative considerations in risk assessment include dose–response assessment, exposure assessment, variation in susceptibility, and characterization of uncertainty. For dose–response assessment, varying approaches have been proposed for threshold versus nonthreshold end points. Traditionally, in the United States, threshold approaches have been applied for assessment of noncancer end points, and nonthreshold approaches have been used for cancer end points. As we have learned more about nongenotoxic mechanisms of carcinogenicity, these processes have been evaluated using threshold approaches. Each approach and its inherent assumptions are discussed below, as are efforts to include more detailed mechanistic considerations to harmonize these approaches (Bogdanffy *et al.*, 2001).

In general, human exposure data for prediction of human response to environmental chemicals are quite limited; thus, animal bioassay data have primarily served as the basis for most quantitative risk assessments and have required extrapolation for human health risk prediction. The risk assessor, however, is normally interested in low environmental exposures when considering human risk, exposures that are well below the experimentally observable range of responses in most animal assays. Thus, methods for extrapolating from high dose to low dose as well as extrapolating from animal risk to human risk are required and comprise a major emphasis of dose–response assessment.

The fundamental basis of the quantitative relationships between exposure to a chemical and the incidence of an adverse response is the dose–response assessment. Analysis of dose–response relationships must start with the determination of the critical effects to be quantitatively evaluated. It is usual practice to choose the most robust data sets with adverse effects occurring at the lowest levels of exposure from studies using the most relevant exposure routes. The “critical” adverse effect is defined as the significant adverse biological effect that occurs at the lowest exposure level (Barnes and Dourson, 1988). EPA has issued toxicity-specific guidelines that are useful in identifying such critical effects (for developmental toxicity [US EPA, 1991], reproductive toxicity [US EPA, 1996a], neurotoxicity [US EPA, 1998c], and cancer [US EPA, 1994b, 1996a, 1999a, 2005]). IPCS has compiled a document cited as the *Principles for Modeling Dose–Responses for the Risk Assessment of Chemicals* (International Programme on Chemical Safety, 2006). It outlines key concepts and considerations for dose–response evaluations within the context of a risk assessment.

Threshold Approaches Approaches for characterizing threshold dose–response relationships include identification of “no observed adverse effect level” (NOAEL) or “lowest observed adverse effect levels” (LOAELs). On the dose–response curve illustrated in Fig. 4-3, the doses tested in the bioassay are given as F, G, H, and I. The statistical significance of points G, H, and I is indicated using an asterisk (*). The NOAEL (F) is identified as the highest nonstatistically significant dose tested; in this example the NOAEL occurs at approximately 2 mg/kg body weight. Point G is the LOAEL (~2.3 mg/kg body weight), as it is the lowest dose tested with a statistically significant effect. Lines A to D represent possible extrapolations below the point of departure (POD), which is represented on this figure as a square (■) and is labeled as point E. The POD is used to specify the estimated dose near the

Figure 4-3. Dose–response curve. This figure is designed to illustrate a typical dose–response curve with points F to I indicating the biologically determined responses. Statistical significance of these responses is indicated with the symbol “*.” Point E (■) represents a dose near the lower end of the observed dose–response range, below which extrapolation to lower doses can occur for cancer risk estimates (US EPA, 2005). Point F is the highest nonstatistically significant response point; hence, it is the “no observed adverse effect level” (NOAEL) for this example. Point G is the “lowest observed adverse response level” (LOAEL). Curves A to D show some options for extrapolating the dose–response relationship below the range of biologically observed data points and POD.

lower end of the observed dose range, below which extrapolation to lower exposures is necessary (US EPA, 2005). In Fig. 4-3, the POD occurs at 10% effective dose or ED_{10} . The type of extrapolation below the POD is depending on the type of data available. The importance of choosing an appropriate POD and extrapolation type is discussed further in the following sections of this chapter. From these modeled approaches, model D shows a model where the threshold (T) represents the dose below which no additional increase in response is observed.

In general, most animal bioassays are constructed with sufficient numbers of test animals to detect biological responses at the 10% response range; however, this is also dependent on end point and the background rate of the end point in control animals. The risk assessor should always understand the biological significance of the responses being evaluated in order to put statistical observations in context. Significance thus usually refers to both biological and statistical criteria (Faustman *et al.*, 1994) and is dependent on the number of dose levels tested, the number of animals tested at each dose, and background incidence of the adverse response in the nonexposed control groups. The NOAEL should not be perceived as risk-free, as several reports have shown that the response of NOAELs for continuous end points averages 5% risk, and NOAELs based on quantal end points can be associated with risk of greater than 10% (Allen *et al.*, 1994a; Faustman *et al.*, 1994).

As described in Chap. 2, approaches for characterizing dose–response relationships include identification of effect levels such as LD_{50} (dose producing 50% lethality), LC_{50} (concentration producing 50% lethality), ED_{10} (dose producing 10% response), as well as NOAELs. NOAELs have traditionally served as the basis for risk assessment calculations, such as reference doses (RfDs) or ADI values. RfDs or concentrations (RfCs) are estimates of daily exposure (oral or inhalation, respectively) to a chemical that is assumed to be without adverse health impact in humans. The ADIs are used by WHO for pesticides and food additives to define “the daily intake of chemical, which during an entire lifetime appears to be without appreciable risk on the basis of all known facts at that time” (WHO, 1962; Dourson *et al.*, 1985). RfDs (first introduced in Chap. 2) and ADI values typically are calculated from NOAEL values by dividing by uncertainty factor (UF) and/or modifying factor (MF) (Dourson and Stara, 1983; Dourson and DeRosa, 1991; US EPA, 1991):

$$RfD = \frac{NOAEL}{UF \times MF}$$

$$ADI = \frac{NOAEL}{UF \times MF}$$

Tolerable daily intakes (TDI) can be used to describe intakes for chemicals that are not “acceptable” but are “tolerable” as they are below levels thought to cause adverse health effects. These are calculated in a manner similar to ADI. Historically, dividing by the UFs allows for interspecies (animal-to-human) and intraspecies (human-to-human) variability with default values of 10 each. An additional UF is used to account for experimental inadequacies—for example, to extrapolate from short-exposure-duration studies to a situation more relevant for chronic study or to account for inadequate numbers of animals or other experimental limitations. If only a LOAEL value is available, then an additional 10-fold factor is commonly used to arrive at a value more comparable to a NOAEL. For developmental toxicity end points, it has been demonstrated that the application of the 10-fold factor for LOAEL-to-NOAEL

conversion is too large (Allen *et al.*, 1994a). Traditionally, a safety factor of 100 would be used for RfD calculations to extrapolate from a well-conducted animal bioassay (10-fold factor for animal-to-human variability) and to account for human variability in response (10-fold factor for human-to-human variability).

MFs are values that can be used to adjust the UFs if data on mechanisms, pharmacokinetics, or relevance of the animal response to human risk are available. For example, if there is kinetic information suggesting there is very similar metabolism for a particular compound in rats and humans, producing the same active target metabolite, then—rather than using a 10-fold UF to divide the NOAEL from the animal toxicity study to obtain a human relevant RfD—a factor of 3 for that UF might be used. Of particular interest is the addition of an extra 10-fold factor through the Food Quality Protection Act (FQPA) to ensure protection of infants and children (US EPA, 1996b). Under this law an additional UF is added to ensure protection of children’s health and it is currently being used for determining allowable pesticide chemical residues. This factor is designed to take into account potential prenatal and postnatal toxicity and to overcome the incompleteness of toxicity and exposure data (FQPA, PL 104-170). Illustrative discussions on how such a legislatively mandated UF might be applied are available for chlorpyrifos (Schardein and Scialli, 1999; US EPA, 2000a). In this case, this uncertainty factor was reduced due to the availability of specific animal experiments assessing developmental toxicity at sensitive life stages (Zhao *et al.*, 2006; US EPA, 2011e).

To reduce uncertainty in calculating RfDs and ADIs, there has been a transition from the use of traditional 10-fold UFs to the use of data-derived and chemical-specific adjustment factors. Such efforts have included reviewing the human pharmacologic literature from published clinical trials (Silverman *et al.*, 1999) and developing human variability databases for a large range of exposures and clinical conditions (Renwick, 1991, 1999; Johnson *et al.*, 1997). Toward this goal, Renwick has separated the intraspecies and interspecies UFs into 2 components: toxicokinetics (TK) and toxicodynamic (TD) aspects (Renwick, 1991, 1999; Johnson *et al.*, 1997). Fig. 4-4 shows these distinctions. A key advantage of this approach is that it provides a structure for incorporating scientific information on specific aspects of the overall toxicological process into the RfD calculations; thus, relevant data can replace a portion of the overall “uncertainty” surrounding these extrapolations. Current WHO guidance uses a 4.0- and 2.5-fold factor for the TK and TD interspecies components, respectively (WHO, 2005), and interindividual TK and TD factors of 3.16 (Renwick and Lazarus, 1998).

The recent NAS publications (*Silver Book*) have emphasized the need to consider population variability and context in risk assessment. In examples described in this NRC report, high background incidence of cancers or other adverse health outcomes in the population should be considered before setting “acceptable” levels of additional risks (NRC, 2009).

NOAEL values have also been utilized for risk assessment by evaluating a “margin of exposure” (MOE), where the ratio of the NOAEL determined in animals and expressed as mg/kg per day is compared with the level to which a human may be exposed. For example, consider the case where human exposures to a specific chemical are calculated to be solely via drinking water, and the total daily intake of the compound is 0.04 mg/kg per day. If the NOAEL for neurotoxicity is 100 mg/kg per day, then the MOE would be 2500 for the oral exposure route for neurotoxicity. Such a large value is reassuring to public health officials. Low values of MOE indicate that the human levels of exposure are close to levels for the NOAEL in animals. There is usually no factor included in this calculation for differences in human or animal susceptibility or animal-to-human extrapolation; thus, MOE values of less than 100 have been used by regulatory agencies as flags for requiring further evaluation.

The NOAEL approach has been criticized on several points, including that (1) the NOAEL must, by definition, be one of the experimental doses tested and (2) once this is identified, the rest of the dose–response curve is ignored. Because of these limitations, an alternative to the NOAEL approach, the benchmark dose (BMD) method, was proposed (Crump, 1980). In this approach, the dose–response is modeled and the lower confidence bound for a dose at a specified response level (benchmark response [BMR]) is calculated. The BMR is usually specified at 1%, 5%, or 10%. Fig. 4-5 shows the BMD using a 10% BMR (BMD_{10}) and a 95% lower confidence bound on dose ($BMDL_{10}$). The BMD_x (with x representing the percent BMR) is used as an alternative to the NOAEL value for RfD calculations. Thus, the RfD would be:

$$RfD = \frac{BMD_x \text{ or } MBDL_x}{UF \times MF}$$

EPA has developed software for the application of BMD methods and a technical guidance document to provide guidelines for application of BMDs for both cancer and noncancer end points (EPA, 2000). It recently released an updated version (2.2) of its BMD software (<http://www.epa.gov/ncea/bmds/index.html>). The 2009 WHO

Figure 4-4. Toxicokinetic (TK) and toxicodynamic (TD) considerations inherent in interspecies and interindividual extrapolations. TK refers to the processes of absorption, distribution, elimination, and metabolism of a toxicant. TD refers to the actions and interactions of the toxicant within the organism and describes processes at organ, tissue, cellular, and molecular levels. This figure shows how uncertainty in extrapolation both across and within species can be considered as being due to 2 key factors: a kinetic component and a dynamic component. Challenges remain for extrapolating information on human variation to specific populations (NRC, 2009). Refer to the text for detailed explanations.

Figure 4-5. Illustration of benchmark dose (BMD) approach. This figure shows the $BMDL_{10}$ and BMD_{10} , the lower confidence limit and dose (ED_{10}) associated with a 10% incidence of adverse response, respectively (Kavlock *et al.*, 1995; US EPA, 2005). For reference, points are labeled as described in the legend for Fig. 4-3.

guidelines for dose–response modeling for risk assessment also discuss BMD approaches (International Programme on Chemical Safety, 2006). Both the EPA and WHO guidelines distinguish NOAEL versus BMD-based approaches. Harmonization of approaches available for assessments is discussed in the WHO documents.

The BMD approach has been applied to study noncancer end points, including developmental (Allen *et al.*, 1994a) and reproductive toxicity (Auton, 1994). The most extensive studies with developmental toxicity have shown that BMD_{05} values were similar to a statistically derived NOAEL for a wide range of developmental toxicity end points and that results from using generalized dose–response models were similar to biologically based dose–response (BBDR) models designed specifically to represent unique features of developmental toxicity testing (Faustman *et al.*, 1999).

Advantages of the BMD approach include (1) the ability to take into account the dose–response curve; (2) the inclusion of a measure of variability (confidence limit); and (3) the use of a consistent BMR level for RfD calculations across studies. Limitations in the animal bioassays in regard to minimal test doses for evaluation, shallow dose responses, and use of study designs with widely spaced test doses will limit the utility of these assays for any type of quantitative assessments, whether NOAEL- or BMD-based approaches.

Nonthreshold Approaches As Fig. 4-3 shows, numerous dose–response curves can be proposed in the low-dose region of the dose–response curve if a threshold assumption is not made. Because the risk assessor generally needs to extrapolate beyond the region of the dose–response curve for which experimentally observed data are available, the choice of models to generate curves in this region has received lots of attention. For nonthreshold responses, methods for dose–response assessments have models for extrapolation to de minimus (10^{-4} to 10^{-6}) risk levels at very low doses, far below the biologically observed response range and far below the effect levels evaluated for threshold responses.

EPA cancer guidelines define the dose–response methods as requiring two steps: (1) defining the “POD” or the lowest dose associated with adverse effects within the range of the experimental data and (2) the extrapolation from the POD to low environmentally

relevant exposure levels based on experimental data. The extrapolation can be done with a linear model or a nonlinear model with this choice dependent on the amount and type of experimental data available. Risk estimates using the linear model (biological response increases proportionally with level of exposure) are generally higher than those using nonlinear models. For example, in 2003, the EPA released a Dioxin Reassessment and used the BMD dose–response method. The reassessment used a POD based on a 1% response with a linear extrapolation model based on the position that the scientific data were inadequate to rule out the EPA’s standard default linear assumption. The EPA Dioxin Reassessment was evaluated in a National Academies Report in 2006 (National Academy of Science, 2006) and this review discussed remaining extrapolation issues. In EPA’s recent draft of dioxin risk assessment (US EPA, 2010b) revised TCDD cancer risk assessment is presented using the upper bound on the regression slope for estimating cancer mortality risk from the epidemiology evaluation by Cheng *et al.* (2006). The top 5% of exposure estimates from this epidemiologic study were excluded as the dose-related changes in cancer mortality plateaued at high doses. EPA lagged exposures by 15 years and adjusted cancer risk based on cumulative TCDD fat concentrations. Their analysis included an estimate of TCDD cancer risks above the TCDD background levels found in the NIOSH worker cohort analyzed by Chang *et al.* Below the POD, the EPA assumed a default linear slope value. (For more information, please go to US EPA as this draft document is undergoing final comments and discussion.) This document represents one of the most recent interpretations of cancer risk assessment by EPA for data-rich compounds with multiple cancer risk estimates for animal and human studies as well as how extensive mechanistic and kinetic information is considered. This draft report provides insight into recent interpretations of US EPA cancer guidelines (US EPA, 2005).

Statistical or Probability Distribution Models Two general types of dose–response models exist for extrapolation: statistical (or probability distribution models) and mechanistic models (Krewski and Van Ryzin, 1981). The distribution models are based on the assumption that each individual has a tolerance level for a test chemical and that this response level is a variable following a specific probability distribution function. These responses can be modeled using a cumulative dose–response function. Chap. 2 discusses the common normal distribution pattern (see Fig. 2-3). A log probit model estimates the probability of response at a specified dose (d); thus, $P(d) = \phi[a + \beta \log d]$, where ϕ is the cumulative function for a standard normal distribution of the log tolerances with standard deviations σ and mean μ , a equals μ/σ , and β equals the slope of the probit line ($-1/\sigma$). The probit curve at low doses usually assumes an S shape. Chap. 2 discusses determination of the LD_{50} value from such a curve. However, extrapolation of the experimental data from 50% response levels to a “safe,” “acceptable,” or “de minimus” level of exposure—for example, one in a million risk above background—illustrates the huge gap between scientific observations and highly protective risk limits (sometimes called virtually safe doses [VSDs] or those corresponding to a 95% upper confidence limit on adverse response rates).

The log-logistic model was derived from chemical kinetic theory. The probability of response at dose d is defined as $P(d) = [1 + \exp(a + \beta \log d)]^{-1}$. Like the probit model, this model defines sigmoidal curves that are symmetrical around the 50% response level; however, the log-logistic curves approach the 0% and 100% response levels with a shallow curve shape. The logit and probit curves are indistinguishable in fitting the data in the region of the response curve where experimentally derived data are present (Brown, 1984; Hartung, 1987; Allen *et al.*, 1994b).

Models Derived from Mechanistic Assumptions This modeling approach designs a mathematical equation to describe dose–response relationships that are consistent with postulated biological mechanisms of response. These models are based on the idea that a response (toxic effect) in a particular biological unit (animal, human, pup, etc) is the result of the random occurrence of one or more biological events (stochastic events).

Radiation research has spawned a series of such “hit models” for cancer modeling, where a hit is defined as a critical cellular event that must occur before a toxic effect is produced. The simplest mechanistic model is the one-hit (one-stage) linear model in which only one hit or critical cellular interaction is required for a cell to be altered. For example, based on somatic mutation theory, a single mutational change would be sufficient for a cell to become cancerous through a transformational event and dose-independent clonal expansion. The probability statement for these models is $P(d) = 1 - \exp(-\lambda d)$, where λd equals the number of hits occurring during a time period. Using this approach, a single molecule of a genotoxic carcinogen would have a minute but finite chance of causing a mutational event.

As theories of cancer have grown in complexity, so too have these hit-based mechanistic models. Multihit models have been developed that can describe hypothesized single-target multihit events, as well as multi-target, multi-hit events in carcinogenesis. The probability statements for these models are $P(d) = \int_0^{\lambda d} x^{k-1} \exp(-x) / \Gamma(k) dx$, where $\Gamma(k)$ denotes the gamma function with k being the critical number of hits for the adverse response. The Weibull model has a dose–response function with characteristics similar to those of the multihit models, where the response equation is $P(d) = 1 - \exp[-\lambda d^k]$. Here again, k is the critical number of hits for the toxic cellular response.

Armitage and Doll (1957) developed a multistage model for carcinogenesis that was based on these equations and on the hypothesis that a series of ordered stages was required before a cell could undergo mutation, initiation, transformation, and progression to form a tumor. This relationship was generalized by Crump (1984) by maximizing the likelihood function over polynomials, so that the probability statement is:

$$P(d) = 1 - \exp[-(\lambda_0 + \lambda_1 d + \lambda_2 d^2 + \dots + \lambda_k d^k)].$$

If the true value of λ_1 is replaced with λ_1^* (the upper confidence limit of λ_1), then a linearized-multistage model can be derived where the expression is dominated by $\lambda_1^* d$ at low doses. The slope on this confidence interval, q_1^* , has been used by EPA for quantitative cancer assessment. To obtain an upper 95% confidence interval on risk, the q_1^* value (risk/ Δ dose in mg/kg per day) is multiplied by the amount of exposure (mg/kg per day). Thus, the upper bound estimate on risk (R) is calculated as:

$$R = q_1^* [\text{risk (mg/kg per day)}^{-1}] \times \text{exposure (mg/kg per day)}.$$

This relationship has been used to calculate a “VSD,” which represents the lower 95% confidence limit on a dose that gives an “acceptable level” of risk (eg, upper confidence limit for 10^{-6} excess risk). The Integrated Risk Information System (IRIS) (US EPA, 2011e) developed by EPA gives q_1^* values for many environmental carcinogens (US EPA, 2000b). Because both the q_1^* and VSD values are calculated using 95% confidence intervals, the values are believed to represent conservative, protective estimates.

The EPA has utilized the LMS model to calculate “unit risk estimates” in which the upper confidence limit on increased individual lifetime risk of cancer for a 70-kg human breathing $1 \mu\text{g}/\text{m}^3$ of contaminated air or drinking 2 L per day of water

containing 1 ppm (1 mg/L) is estimated over a 70-year life span. The example given in Fig. 4-6 shows the calculation of incremental lifetime cancer risk (ILCR) of skin cancer using soil exposure and q_1^* values for inorganic arsenic. If a POD-based approach is used for low-dose extrapolation, the model would be used to extrapolate from the POD or upper confidence limit and these slopes would be considered for the q_1^* values.

Toxicological Enhancements of the Models Three exemplary areas of research that have improved the models used in risk extrapolation are time to tumor information, physiologically based TK modeling, and BBDR modeling (Albert, 1994). Chap. 7 discusses in detail improvements in our estimation of exposure and offers approaches on how to model “target internal effective dose” in risk assessment rather than just using single-value “external exposure doses.” In this chapter we discuss the BBDR modeling.

BBDR modeling aims to make the generalized mechanistic models discussed in the previous section more clearly reflect specific biological processes. Measured rates are incorporated into the mechanistic equations to replace default or computer-generated values. For example, the Moolgavkar–Venson–Knudson (MVK) model is based on a two-stage model for carcinogenesis, where two mutations are required for carcinogenesis and birth and death rates of cells are modeled through clonal expansion and tumor formation. This model has been applied effectively to human epidemiologic data on retinoblastoma. In animal studies, kidney and liver tumors in the 2-acetylaminofluorene (2-AAF) “mega mouse” study, rat lung tumors following radiation exposure, rat liver tumors following *N*-nitrosomorpholine exposure, respiratory tract tumors following benzo[*a*]pyrene exposure, and mouse liver tumors following chlordane exposure have been modeled (Cohen and Ellwein, 1990; Moolgavkar and Luebeck, 1990).

There have been concerted research efforts to improve our mechanistic understanding of response at lower and lower exposures. Two excellent examples of the use of biomarkers to supplement our exploration of these dose–response relationships are seen in Bailey *et al.* (2009) and Vlaanderen *et al.* (2011). Hormetic responses are U-shaped dose–response relationships where small doses of a chemical can be beneficial but high doses are toxic. These are discussed in Chap. 2. These responses pose challenges to risk assessors. In general, science-based mechanistic conditions of low-dose response are always critical. See approaches used by the Institute of Medicine for vitamins and essential elements as these compounds consistently exhibit hormesis (Institute of Medicine (US), 2008).

Development of BBDR models for end points other than cancer is limited; however, several approaches have been explored in developmental toxicity, utilizing MOA information on cell cycle kinetics, enzyme activity, and cytotoxicity as critical end points (Faustman *et al.*, 1989, 2005a; Shuey *et al.*, 1994; Leroux *et al.*, 1996; Gohlke *et al.*, 2002, 2004, 2005, 2007; Daston *et al.*, 2004). Approaches have been proposed that link pregnancy-specific TK models with temporally sensitive TD models for developmental impacts (Faustman *et al.*, 1999; Faustman and Omenn, 2006). Unfortunately, there is a lack of specific, quantitative biological information on both kinetics and dynamics for most toxicants and end points (NRC, 2000; Faustman *et al.*, 2005a).

EXPOSURE ASSESSMENT

The primary objectives of exposure assessment are to determine source, type, magnitude, and duration of contact with the chemical(s) of interest. This is a critical element of the risk assessment process, as hazard does not occur in the absence of exposure. However, it is

A. Ingestion of arsenic from soil—point estimation method

$$\frac{\text{Soil concentration} \times \text{Ingestion rate} \times \text{Exposure duration} \times \text{Exposure frequency}}{\text{Body weight} \times \text{Averaging time}} \times \text{Bioavailability} \times q^* = \text{Lifetime cancer risk (ILCR)} \\ \text{from skin cancer}$$

$$\frac{2300 \text{ mg/kg} \times 100 \text{ mg per day} \times 30 \text{ years} \times 350 \text{ days per year}}{70 \text{ kg} \times 25,550 \text{ days}} \times 0.09 \times 1.50 \text{ (mg/kg per day)}^{-1} = 1.8 \times 10^{-4}$$

B. Ingestion of arsenic from soil—probabilistic methods

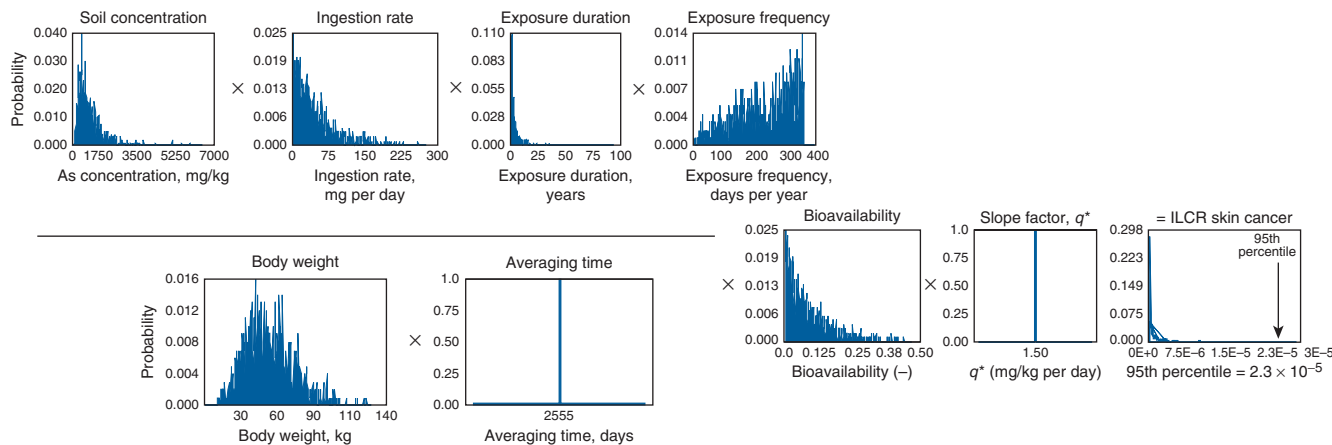

Figure 4-6. Example of risk calculations for incremental lifetime cancer risk (ILCR) of skin cancer due to ingestion of arsenic in soil. (A) Point exposure estimation method for calculation of ILCR. Point estimates for arsenic exposure input parameters are used in this example to calculate the ILCR. This exposure estimate is multiplied by the bioavailability of arsenic in soil to calculate the absorbed dose. Multiplication of the dose by the slope factor (q^*) yields the lifetime risk. (B) Probabilistic exposure methods for calculating the ILCR from arsenic ingestion. In this example, the soil concentration, ingestion rate, exposure duration and frequency, body weight, and bioavailability are modeled as distributions. Note that q^* and averaging time (years) are given as single-point estimations. This method yields a distribution of ILCR, with a 95th percentile upper confidence interval of 2.3×10^{-5} . Data from Calabrese *et al.* (1989), US EPA (1989, 1992, 1999a), Davis *et al.* (1990), Israeli and Nelson (1992), Brorby and Finley (1993), and Agency for Toxic Substances and Disease Registry (2007).

also frequently identified as the key area of uncertainty in the overall risk determination. Here, the primary focus is on uses of exposure information in quantitative risk assessment.

The primary goal of exposure calculations is not only to determine the type and amount of total exposure but also to find out specifically who may be exposed and how large a dose may be reaching target tissues. A key step in making an exposure assessment is determining what exposure pathways are relevant for the risk scenario under development. Fig. 4-7 shows an example exposure diagram used to illustrate possible exposure pathways from a hazardous chemical release. The subsequent steps entail quantitation of each pathway identified as a relevant exposure and then summarizing these pathway-specific exposures for calculation of overall exposure. Such calculations can include an estimation of total exposures for a specified population as well as calculation of exposure for highly exposed individuals. The EPA has published numerous documents that provide detailed definitions and guidelines for determining such exposures (US EPA, 1992, 2008, 2011a), with the recognition that special considerations need to be adopted when assessing childhood exposures (US EPA, 2008).

Conceptually, calculations are designed to represent “a plausible estimate” of exposure of individuals in the upper 90-95th percentile of the exposure distribution. Upper bound estimations would be “bounding calculations” designed to represent exposures at levels that exceed the exposures experienced by all individuals in the exposure distribution and are calculated by assuming upper limits for all exposure variables. A calculation for individuals exposed at concentrations near the middle of the exposure distribution is a central estimate. Fig. 4-7 gives example risk calculations using

two types of exposure estimation procedures (US EPA, 1989, 1992, 2011a). Part A shows an example point estimation method for the calculation of arsenic (As) exposure via a soil ingestion route. In this hypothetical scenario, As exposure is calculated using point estimates for the upper 95th percent confidence limit of the arithmetic mean for each value in the lifetime average daily dose (LADD) equation. The LADD is calculated as follows:

$$\text{LADD} = \frac{\text{concentration of the toxicant in soil} \times \text{contact rate} \times \text{exposure duration}}{\text{bodyweight} \times \text{lifetime}}$$

In this scenario, the average time (AT) is lifetime (25,550 days) and the contact or ingestion rate (CR) is equal to 100 mg soil per day. The exposure frequency and duration (EDF) is equal to the exposure frequency (daily exposure = 365 days per year) times the exposure duration (30 years). To obtain the ILCR, the LADD must be multiplied by the bioavailability to obtain an absorbed dose and q^* where the upper 95% CLM slope (q^*) is $1.5 \times$ change in risk per mg/kg body weight per day in this example.

Many exposures are now estimated using probability distributions for exposures rather than single-point estimates for the factors within the LADD equation (Finley *et al.*, 1994; Cullen and Frey, 1999). Such approaches can provide a reality check and can be useful for generating more realistic exposure profiles reflective of population exposures. Good sources for US exposures can be obtained from the EPA *Exposure Factors Handbook* (US EPA, 2011a). Fig. 4-7B shows how this is done using an example arsenic risk scenario with soil As concentration, ingestion rate, exposure duration, frequency, body weight, and bioavailability modeled as

Figure 4-7. Exposure pathway schematic. Within the risk assessment process, a critical early step is the identification of the exposure pathway(s). To fully characterize exposure, the site- and chemical-specific exposure pathways must be identified. This hypothetical exposure pathway schematic illustrated the various ways in which contaminants can move from the source through media to points of exposure. (Adapted from Sexton *et al.* (1992); reproduced with permission from Taylor & Francis Group, LLC, <http://www.taylorandfrancis.com>.)

distributed variables. Using Monte Carlo simulation techniques, an overall ILCR distribution can be generated and a 95th percentile for population risk obtained.

The FQPA of 1996 has highlighted the need for considerations of potential special risks for children and the need to evaluate child-specific exposures as well as cumulative exposures and risks (US EPA, 1996b). In 2006, the EPA released a supplemental document with child-specific exposure factors to address the special considerations necessary when evaluating childhood exposures (US EPA, 2008). Table 4-6 shows example exposure factors for drinking water intake for children and adults. The EPA *Child-Specific Exposure Factors Handbook*, which is online, provides useful information about such exposure distributions. The FQPA also identified the need to evaluate total exposures by determining aggregate exposure measures for all exposures to a single substance. Cross-media exposure analyses, such as those conducted for lead and mercury, are good examples of the value of looking at such total exposures in evaluating human risks, and complex models are available for some compounds (see EPA's integrated exposure uptake biokinetic [IEUBK] model for lead in children; US EPA, 2010c). Cumulative exposures and cumulative risk refer to the total exposure and risks from a group of compounds. In FQPA chemicals with similar modes of toxicity are evaluated using cumulative exposure and risk estimates. For example, EPA is identifying and categorizing pesticides

that act by a common MOA, and cumulative exposures to classes of organophosphates with similar MOAs (cholinesterase inhibition) have been used as examples of classes of pesticides for which cumulative exposure and cumulative risk estimates are needed (US EPA, 1996c; ILSI, 1999; Ryan, 2010). WHO has recently published a framework for combined exposures (Meek *et al.*, 2011).

Additional considerations for exposure assessments include how time and duration of exposure are evaluated in risk assessments. In general, estimates for cancer risk use average exposure over a lifetime (see LADD example above). In a few cases, short-term exposure limits (STELs) are required (eg, ethylene oxide) and characterization of brief but high levels of exposure is significant. In these cases exposures are not averaged over the lifetime and the effects of high, short-term doses are estimated. With developmental toxicity, a single exposure can be sufficient to produce an adverse developmental effect if exposures occur during a window of developmental susceptibility; thus, daily doses are used, rather than lifetime weighted averages (US EPA, 1991; Weller *et al.*, 1999).

RISK CHARACTERIZATION

Risk characterization is a summary of the risk assessment components and serves to outline the key findings and inform the risk manager in public health decisions. It is an analysis and integration

Table 4-6

Example Exposure Factor Handbook Information: Drinking Water Intake for Children

AGE GROUP	INTAKE (mL PER DAY),		INTAKE (mL/kg PER DAY),	
	MEAN	95TH PERCENTILE	MEAN	95TH PERCENTILE
Newborn (<1 month)	184	839	52	232
Infants (1 to <3 months)	227	896	48	205
Infants (3 to <6 months)	362	1056	52	159
Infants (6 to <12 months)	360	1055	41	126
Child (1 to <2 years)	271	837	23	71
Child (2 to <3 years)	317	877	23	60
Child (3 to <6 years)	380	1078	22	61
Child (6 to <11 years)	447	1235	16	43

of the conclusions from the hazard assessment, the dose–response, and the exposure assessment. EPA outlines the science policy and elements for completing a risk characterization in their *Risk Characterization Handbook* (US EPA, 2000c). As shown in Fig. 4-1, risk characterization considers the nature, estimated incidence, and reversibility of adverse effects in a given population; how robust the evidence is; how certain the evaluation is; if susceptible populations are characterized; and if there is a relevant mode of action.

For many years there has been an information sharing process aimed at harmonization of chemical testing regimes and clinical trials methodologies, so that data might be accepted in multiple countries. Efforts by WHO and IPCS have included the Harmonization of Approaches to the Assessment of Risk from Exposure to Chemicals Project (WHO, 2011a). This project has the goal of globally harmonizing but not standardizing the approaches to risk assessment by increasing understanding and developing basic principles and guidance on specific chemical risk assessment issues. The WHO has worked to harmonize dose–response methodologies (DRM) and released a report providing descriptive guidance for risk assessors in using DRM in hazard characterization (International Programme on Chemical Safety, 2006). Examples of other reports include those on terminology (International Programme on Chemical Safety, 2004) and exposure assessment (World Health Organization, 2006) and *Uncertainty and Data Quality in Exposure Assessment* (International Programme on Chemical Safety, 2008).

Uncertainty analysis is an essential component in our final risk characterization and includes factors such as variability and lack of knowledge (NRC, 1994). Variability refers to true differences such as is reflected in temporal, spatial, or interindividual differences. It usually cannot be reduced with further study. Lack of knowledge can also be discussed as a source of uncertainty and these factors may be reduced with further study. For example, if only a few environmental samples are taken from a contaminated site for analysis, then uncertainty can be reduced by taking further samples. Formal methods for dealing with uncertainty analysis are described in several references including IPCS (2008) and Bogen *et al.* (2009). Using probabilistic-based approaches (PRA) for exposure assessment and assuming distributional versus

dichotomous data for exposure factors is one way of addressing uncertainty that is commonly applied.

Variation in Susceptibility

Risk assessment methodologies incorporating human variability have been slow to develop. Generally, assay results utilize means and standard deviations to measure variation, or even standard errors of the mean. This ignores variability in response due to specific differences in age, sex, health status, and genetics. Default factors of 10× are overutilized to describe cross- and between-species differences and TK and dynamic data are rare. Nevertheless, EPA and OSHA are expected under the Clean Air Act and the Occupational Safety and Health Act to promulgate standards that protect the most susceptible subgroups or individuals in the population (Omenn *et al.*, 1990; Cullen and Frey, 1999; Faustman and Omenn, 2006; Kramer *et al.*, 2006; Cullen *et al.*, 2008). Sensitive or susceptible populations have been defined and interpreted for the Clean Air Act and in this context “particularly sensitive citizens, such as bronchial asthmatics and emphysematics”, are to be protected by the standards. This illustrates not only the importance but also the challenge to risk assessors to ensure protection for human populations.

Ecogenetics has been defined as the study of critical genetic determinants that define susceptibility to environmentally influenced adverse health effects (Costa and Eaton, 2006). Ecogenetic variation can affect biotransformation systems that activate and detoxify chemicals or alter the response in target tissues. With the completion of the Human Genome Project in April 2003, the identification of human polymorphisms has greatly expanded our potential for understanding how genetic variability can impact biological response and susceptibility. There have been numerous activities initiated with the goal of understanding the linkage between genes and the environment. The following databases and initiatives are designed to identify polymorphisms, including single-nucleotide polymorphisms (SNP), insertions, deletions, amplifications, and alternative splicing. These include the International HapMap Project (HapMap, 2009), the DNA Polymorphism Discovery Resource (National Human Genome Research Institute, 2010), the National Center for Biotechnology Information (NCBI) SNP databases (NCBI, 2011a,b), and the NIH

GAIN program (National Human Genome Research Institute, 2010). Using the information from such databases, researchers hope to identify genetic similarities and differences in human beings with the goal of identifying genes that affect health, disease, and individual responses to medications and environmental factors (Omen, 2012). Recent observations now demonstrate that not only genetics is significant, but also epigenetics (Sartor *et al.*, 2012). SNP arrays are now available that can identify and characterize approximately 1×10^6 SNPs in the human population. Arrays also exist that evaluate SNPs in pathways significant for drug metabolism enzymes and transporters. These are in FDA-approved pathways and have been used for evaluation of appropriate drug therapies. However, they are just starting to be used for environmental risk assessment (Guerrette *et al.*, 2011). Next-generation sequencing, where coverage of the genome can be extended to 40 \times , has revealed rare copy number variants that can be linked to disease and provide another level of understanding concerning human variation (Sudmant *et al.*, 2010). It should be noted that this genetic information on individuals can raise ethical, social, and legal concerns regarding protections of individuals and their rights (Hsieh, 2004). Recent legislation that protects individuals from discrimination on the basis of genetic variation helps to ensure protection and not exclusion for all workers (Human Genome Program, 2008; United States Act, 2008).

One of the key challenges for toxicologists doing risk assessments will be the interpretation and linking of observations from highly sensitive molecular and genome-based methods with the overall process of toxicity (Eisen *et al.*, 1998; Limbird and Taylor, 1998; Andersen and Barton, 1999; NRC, 2000). The basic need for linkage of observations was highlighted in early biomarker work. NRC reports on biomarkers (NRC, 1989a,b, 1992a,b) drew distinctions for biomarkers of effect, exposure, and susceptibility across a continuum of exposure, effect, and disease/toxicity. Biomarkers of early effects, such as frank clinical pathology, arise as a function of exposure, response, and time. Early, subtle, and possibly reversible effects can generally be distinguished from irreversible disease states. Chemical-specific biomarkers have the potential to provide critical information, but there is an inherent complexity in pulling the information together. If biomarkers are considered a reflection of exposure or disease state, then considerations have to be made regarding the interactions between genes and the environment and the difference between a population-based assessment and individual assessment (Groopman and Kensler, 1999).

Nowhere is the challenge for interpretation of early and highly sensitive response biomarkers clearer than in the complicated data from gene expression arrays (toxicogenomics). Our continued ability to monitor changes in response in thousands of genes has proven challenging for toxicologists. Emphasis on toxicity-based risk assessment methods and analysis has been strongly encouraged by several significant NAS reports (NRC, 2000, 2007a,b; NRC, 2010) as well as development and application of pathway-based methods (Yu *et al.*, 2006). Toxicogenomics projects have confirmed the repeatability and cross-platform concordance of microarray data (Bammler *et al.*, 2005; Guo *et al.*, 2006; Nature Biotechnology Editorial, 2006; Patterson *et al.*, 2006) and standards for data interpretation (minimum information about a microarray experiment [MIAME]) accepted (Brazma *et al.*, 2001).

Microarray analysis for risk assessment requires sophisticated analyses beyond basic cluster analysis (Eisen *et al.*, 1998) to arrive at a functional interpretation and linkage to conventional toxicological (apical) end points. Because of the vast number of measured responses with gene expression arrays, pattern analysis techniques are being used through pathway mapping platforms such as MAPPFinder and GenMAPP (Moggs *et al.*, 2004; Currie *et al.*,

2005). The Gene Ontology Consortium has developed a controlled vocabulary (ontology) for sharing biological information across species. Database users can then annotate their gene products with gene ontology (GO) terms, establishing a consistent description and definition across databases and studies, and this facilitates risk assessment. Through the power of GO terms, analysis methods are being developed to allow for a quantitative time- and dose-dependent interpretation of genomic response using systems-based approaches to integrate responses at the biological and cellular level (Yu *et al.*, 2006). A very good approach to integrated analysis of multiple omics datasets is Conceptgen (Sartor *et al.*, 2010).

Both the EPA and FDA have formally recognized the power of genomic information as well as its potential limitations. Both agencies have issued interim policies guiding how to include genomic information into risk assessments and they have agreed to use genomic information in conjunction with (but not in isolation of) standard risk assessment data (FDA, 2011; US EPA, 2011f). Extensive research efforts by the US EPA Computational Toxicology program will facilitate future risk assessment uses (US EPA, 2012b).

INFORMATION RESOURCES

There are numerous information resources available for risk assessment and a few are listed below to provide the reader with examples but not a comprehensive list of risk assessment resources and databases. Such resources include the Toxicology Data Network (<http://toxnet.nlm.nih.gov/>) from the US National Library of Medicine, the US NTP (National Toxicology Program, 2011a) including the *Report on Carcinogens* and the *Office of Health Assessment and Translation*, the WHO IPCS (WHO, 2011a), and the IARC (WHO, 2011b). The WHO Toolkit for Risk Assessment is especially user friendly for new risk assessors (WHO, 2010). WHO, through its IPCS, produces useful risk documents entitled *Concise International Chemical Assessment Documents* that cover a variety of chemical substances (WHO, 2011c). The Codex Alimentarius Commission created by FAO and WHO produces guidelines and reports relevant for food safety and standards (FAO and WHO, 2011). The IRIS is US EPA's human health assessment program that evaluates health risks for over 500 chemical substances (US EPA, 2011e). IRIS lists specific risk values used by the US EPA. It is anticipated that additional databases will be available from REACH.

There is a need for a note of caution for users of these risk-relevant databases as with most databases there is a need to consider multiple contributions to differences between recommended values. These differences can be due to variations in how and when new scientific information is incorporated in the evaluations. Also, different regulatory drivers for national values or issues related to legal priorities or delays in implementing draft to final recommended values can occur. Such factors have contributed to differences in arsenic and dioxin risk estimates in the United States.

Recently, new toxicogenomic databases that identify and, in some cases, provide characterization of chemicals have become available. The NCBI (2011a,b) provides access to an enormous set of biomedical and genomic information. Its portfolio of comprehensive data and tools can be valuable for risk assessment and the aim to integrate with toxicologically relevant end points and disease is laudable. It has Chemicals and Bioassays, Data and Software, DNA and RNA, Protein Domains and Structures, Genes and Expression, genetic information databases linked with decision outcomes, Genomes and Gene Maps, and Cross-Species Homology. Resources covering databases and tools help in the study of SARs. A publicly available functional genomics data repository (Gene Expression Omnibus [GEO] database) supports MIAME-compliant

data submission, and allows for easily accessible microarray- and sequence-based data, which are searchable for specific profiles of interest based on gene annotation or precomputed profile characteristics. Also variations such as data on genomic variation, interaction of genotypes and phenotypes, and the single-nucleotide polymorphisms (dbSNP) can be obtained through the NCBI. ACToR (<http://actor.epa.gov/actor/faces/ACToRHome.jsp>), EPA's online database on chemical toxicity data and potential chemical risks to human health and the environment, is another useful resource for risk assessments. It allows users to search and query data including Toxicity Reference Database (ToxRefDB) (30 years and \$2 billion worth of animal toxicity studies), ToxCastDB (data from screening 1000 chemicals in over 500 high-throughput assays), ExpoCastDB, and DSSTox (provides high-quality chemical structures and annotations). The ToxRefDB captures thousands of *in vivo* animal toxicity studies on hundreds of chemicals. Another curated Comparative Toxicogenomics Database (CTD, <http://ctd.mdibl.org/>) includes data describing cross-species chemical–gene/protein interactions and chemical– and gene–disease relationships to illuminate molecular mechanisms underlying variable susceptibility and environmentally influenced diseases. These data provide insight into complex chemical–gene and protein interaction networks. These databases can be especially useful for hazard identification and mechanistic information; few emphasize exposure information.

RISK PERCEPTION AND COMPARATIVE ANALYSES OF RISK

It is well known that individuals respond differently to information about hazardous situations and products (Fischhoff, 1981; Fischhoff *et al.*, 1993, 1996; Sandman, 1993; NRC, 1996; Risk Commission, 1997; Institute of Medicine, 1999; Slovic, 2010). Understanding these behavioral responses at the individual, community, and population levels is critical in stimulating constructive risk communication and evaluating potential risk management options for risk assessment issues. In a classic study, students, League of Women Voters members, active club members, and scientific experts were asked to rank 30 activities or agents in order of their annual contribution to deaths (Slovic *et al.*, 1979, 2005). Club members ranked pesticides, spray cans, and nuclear power as safer than did other laypersons. Students ranked contraceptives and food preservatives as riskier and mountain climbing as safer than did others. Experts ranked electric power, surgery, swimming, and x-rays as more risky, but nuclear power and police work as less risky than did laypersons. From studies like these, we now know that there are cultural and gender differences in perception of risks. There are also group differences in perceptions of risk from chemicals among toxicologists, correlated with their employment in industry, academia, or government (Neal *et al.*, 1994). Recent risk perception research has emphasized the importance of knowing the balance between analytical thinking and “affect.” Our immediate emotional reaction can shape our initial risk perceptions (“affect”), while our thoughtful, deliberate “analytical” thinking also impacts our risk understanding but the latter is a slower response. Understanding this balance can help us explain why there is a complex relationship between perceived risk and benefits (Slovic, 2010).

Psychological factors such as dread, perceived uncontrollability, and involuntary exposure interact with factors that represent the extent to which a hazard is familiar, observable, and “essential” for daily living (Lowrance, 1976; Morgan, 1993). Fig. 4-8 presents a grid on the parameters controllable/uncontrollable and observable/not observable for a large number of risky activities;

for each of the two-paired main factors, highly correlated factors are described in the boxes.

Public demand for government regulations often focuses on involuntary exposures (especially in the food supply, drinking water, and air) and unfamiliar hazards, such as radioactive waste, electromagnetic fields, asbestos insulation, and genetically modified crops and foods. The public can respond negatively when they perceive that information about hazards or new technologies has been withheld or under-rated. This can explain some of the very strong responses to genetically modified foods, HIV-contaminated blood transfusions in the 1980s, or hazardous chemical and radioactive wastes. Loss of trust is exemplified by Japanese reactions following the Fukushima Daiichi nuclear reactor meltdown (March 2011), where initial perceived benefits of nuclear power were transformed to distrust during follow-up actions and responses to the earthquake and tsunami.

Perceptions of risk led to the addition of an extra safety factor (default value 10) for children in the FQPA of 1996. Engineering-based “as low as reasonably achievable” (ALARA) approaches also reflect the general “precautionary principle,” which is strongly favored by those who, justifiably, believe we are far from knowing all risks given frequently limited toxicity testing data (Roe *et al.*, 1997).

EMERGING CONCEPTS

In order for risk assessment to inform environmental risk management, there is a need to ensure that the initial “problem formulation” of the risk question(s) is succinctly framed to answer questions in the real world. Environmental health is very dynamic and many divergent emerging environmental challenges such as climate change, energy shortages, and engineered nanoparticles will require an expansion of our context well beyond single-chemical, single-exposure scenarios. In order to accomplish this goal, several factors need to be considered. These factors include defining not only health but also well-being and sustainability and will require a context of global and international scale.

Well-being is increasingly being used to describe human health and the goal of sustainable environmental risk management. The WHO has championed the use of well-being rather than health to describe the Millennium Development Goals (WHO, 2011d). Well-being goes beyond “disease-free” existence to freedom from want (including food and water security) and fear (personal safety) and sustainable futures. Concepts such as food security (abundance and quality of foods), water security (plentiful supplies and high quality of water), and sustainability form internationally recognized environmental and developmental goals. Sustainability embraces the risk management concept that “development that meets the needs of the present, without compromising the ability of future generations” to thrive and hence well-being is one of the goals of environmental actions and decisions. Recognition that environmental problems are global is essential to our understanding of how we manage risks and how we address sustainability (Leiserowitz *et al.*, 2006; Gohlke *et al.*, 2008; Kite-Powell *et al.*, 2008). Ocean health and air pollution are excellent examples of the need for understanding the global context where pollutants do not honor country and national borders. World Trade Organization (WTO) agreements have also placed risk assessment approaches in the forefront as tools for managers working to meet the global goals for sustainable trade and economic health. At the most basic level new risk assessments are being done with a new global emphasis (Carruth and Goldstein, 2004; US EPA Office of Research and Development, 2011). Recent reorganization of EPA along management lines of sustainability now provides an integrative framework for working toward sustainability goals. As a response for this broader framing of health impacts, the EPA

Figure 4-8. Perceptions of risk illustrated using a “risk space” axis diagram. Risk space has axes that correspond roughly to a hazard’s perceived “dreadedness” and to the degree to which it is familiar or observable. Risks in the upper right quadrant of this space are most likely to provoke calls for government regulation.

Office of Research and Development realigned their research within a new structure of Chemical Safety for Sustainability; Sustainable and Healthy Communities; Safe and Sustainable Water Resources; and Air, Climate and Energy. Risk assessment is viewed as one of the critical approaches for integrating these goals and toxicology is one of the tools used within that approach (Teichman and US EPA, 2011).

PUBLIC HEALTH RISK MANAGEMENT

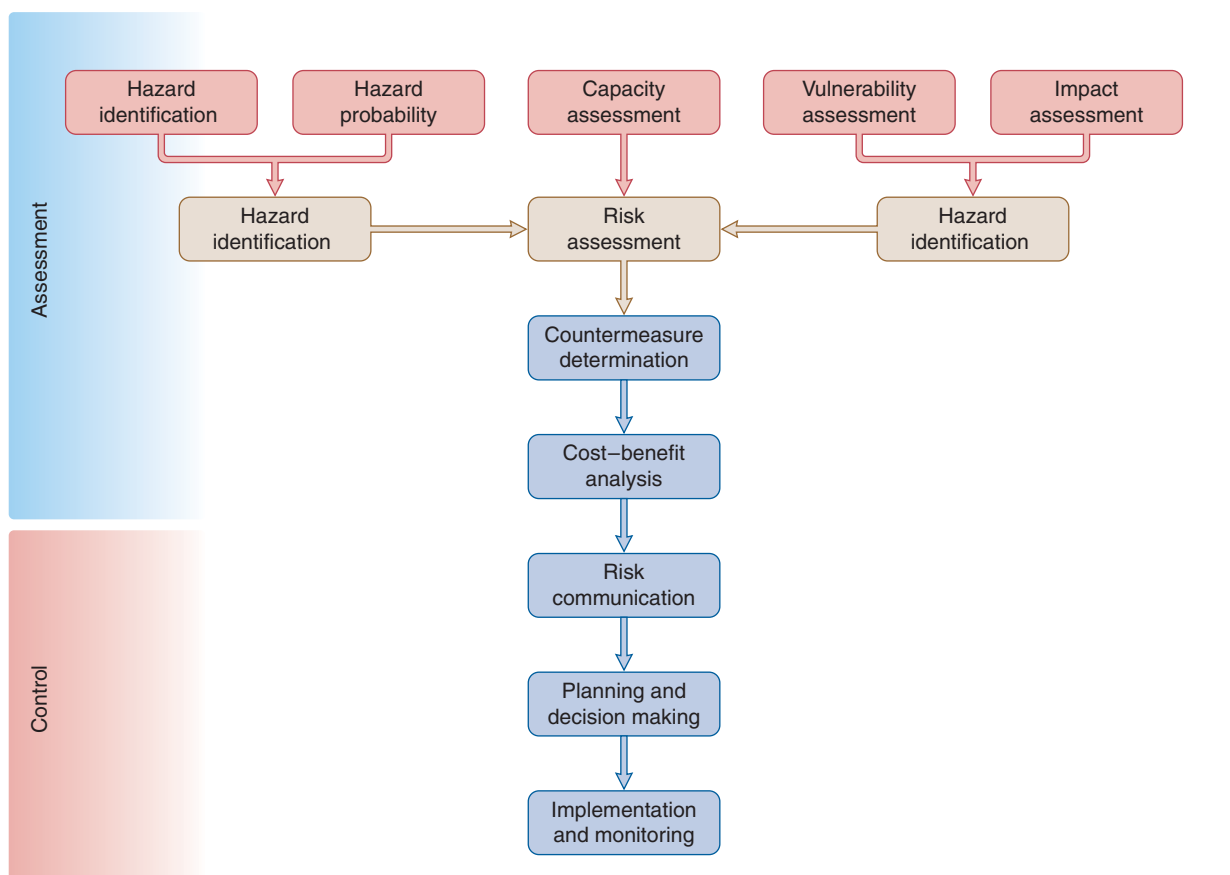

Associated with concepts of well-being and sustainability is a public health orientation to risk assessment and risk management. Public health as a discipline is very compatible with toxicology, where toxicological tests are performed to identify and characterize potential health risks and to prevent the unsafe use of such agents. Public health also has an emphasis on approaches for identifying, characterizing, and preventing risks.

Within public health risk management, there are three stages of prevention: *primary*, whose goal is prevention and risk or hazard avoidance; *secondary*, whose goal is mitigation or preparedness including risk or vulnerability reduction and risk transfer; and *tertiary*, where prompt response or recovery is an approach for decreasing residual risk or risk reduction (Frumkin, 2010). Fig. 4-9 shows an overview of risk assessment and management for public health where concepts of capacity assessment, vulnerability, and impact assessment are included. In this context, vulnerability assessment would include consideration of exposure and susceptibility as

part of the vulnerability assessment. Hazard analysis refers to both hazard identification and probability-based frequency of anticipated events. Capacity assessment has been used for identifying strengths and resiliency of a system to impact. Recent disasters such as Hurricane Katrina, the Gulf Oil Spill, and the Fukushima Daiichi nuclear reactor meltdown all point to the need for environmental risk assessment to be considered as a part of an even larger context in order to understand critical infrastructure for determining human and environmental risks. Life-cycle analysis, green chemistry, and built environment all require such a broad context for evaluation (Keim, 2002; NRC, 2009). Fig. 4-4 also suggests that understanding population variability and vulnerability in a context of “built environment” is important. The “built environment” encompasses all man-made resources and infrastructure, including buildings, spaces, and transportation systems, which support human activity and have a strong influence on public health (Perdue *et al.*, 2003). These types of frameworks can allow for easier consideration of public health concepts for sustainability, environmental disaster response, and life-cycle systems analysis than many of our traditional frameworks for environmental chemical risk assessment, which can be done in relative isolation.

SUMMARY

The NRC and Risk Commission frameworks for risk assessment and risk management provide a consistent framework-based approach for evaluating risks and taking action to reduce

Component	Activities
Hazard analysis Hazard identification Hazard probability	Identifying hazards with the potential to cause loss or damage of an asset Determining frequency of past hazard events
Impact assessment Asset assessment Loss assessment	Determining critical assets (ie, population, medical facilities, and so forth) Identifying expected loss or damage of each asset for each hazard Prioritizing assets based on consequence of loss
Capacity assessment	Identifying strengths, attributes, and resources available for responding to and recovering from a disaster
Vulnerability assessment Exposure Susceptibility	Estimating degree of vulnerability of each asset for each hazard Identifying preexisting countermeasures and their level of effectiveness
Countermeasure determination Avoidance or reduction Transfer or retention	Identifying new countermeasures that may be taken to eliminate or lessen hazards and vulnerabilities Identifying countermeasure costs and benefits
Cost-benefit analysis	Prioritizing options
Risk communication	Preparing a range of recommendations for decision makers and the public
Risk management plan	Developing a plan for disaster risk treatment for each phase of the emergency cycle
Implementation and monitoring	Implementing the risk management program and monitoring it, according to plan

Figure 4-9. Overview and process for environmental risk management. This scheme shows a broad context for thinking about risk management that includes considerations of vulnerabilities and impact analysis frequently discussed in environmental engineering and public health. (Adapted from Frumkin *et al.* (2010); reproduced with permission from John Wiley & Sons, Inc.)

risks. The objectives of risk assessments vary with the issues, risk management needs, and statutory requirements. Hence, setting the context and problem formation for risk evaluation is essential (NRC, 2009). The frameworks are sufficiently flexible to address various objectives and to accommodate new knowledge while also providing guidance for priority setting in industry, environmental organizations, and government regulatory and public health agencies. Risk assessment analyzes the science and, if incomplete, identifies uncertainty and provides approaches for moving forward with decisions (NRC, 2009). Toxicology, epidemiology, exposure assessment, and clinical observations can be linked with biomarkers, cross-species investigations of mechanisms of effects, and systematic approaches to risk assessment, risk communication, and risk management. Advances in toxicology are certain to improve the quality of risk assessments for a broad array of health end points as scientific findings substitute data for assumptions and help to describe and model uncertainty more credibly.

Conclusion

INTRODUCTION

The disposition of a chemical or xenobiotic is defined as the composite actions of its absorption, distribution, biotransformation, and elimination. This chapter will focus on the contribution of absorption, distribution, and elimination to xenobiotic toxicity, whereas Chap. 6 is dedicated to biotransformation. The quantitative characterization of xenobiotic disposition is termed pharmacokinetics or toxicokinetics and is reviewed in Chap. 7.

The various factors and organs involved in affecting disposition of a toxicant are depicted in Fig. 5-1. The diagram is a pictorial overview of the processes of absorption, distribution, and excretion, and its complexity is intended to illustrate that, although they will be discussed separately, the processes that determine disposition are likely to occur simultaneously. Moreover, the disposition of any compound is a fundamental factor that contributes to its potential for toxicity. Specifically, the toxicity of a substance is directly dependent on the dose, where “dose” is defined as the amount that ultimately reaches the site or sites of action (tissue, cell, or molecular target). Therefore, the disposition of a chemical determines its concentration at the site of action such that the concerted actions of absorption, distribution, and elimination also determine the potential for adverse events to occur.

The skin, lungs, and alimentary canal are the main barriers that separate higher organisms from an environment containing a large number of chemicals (Fig. 5-1). Toxicants must cross one or

several of these incomplete barriers to exert deleterious effects, and only chemicals that are caustic and corrosive (acids, bases, salts, oxidizers), which act directly at the point of contact, are exceptions to this generalization. A chemical absorbed into the bloodstream or lymphatics through any of the major barriers is distributed, at least to some extent, throughout the body, including the site where it produces damage. This site is called the target organ or target tissue. A chemical may have one or several target organs, and, in turn, several chemicals may have the same target organ or organs. However, target organ concentration is not the only factor that can influence the susceptibility of organs to toxicants, and the organ or tissue with the highest concentration of a toxicant is not necessarily the site where toxicity is observed. A classic example of this distinction is dichlorodiphenyltrichloroethane (DDT), a chlorinated hydrocarbon insecticide that achieves high concentrations in fat depots but is not toxic to that tissue.

Poor absorption of a toxicant resulting from a low amount absorbed or from a low rate of absorption will limit or prevent toxicity because a chemical may never attain a sufficiently high concentration at a potential site of action to cause toxicity. Similarly, a chemical that is well absorbed but rapidly biotransformed or eliminated from an organism is less likely to be toxic because rapid excretion prevents it from reaching a sufficiently high concentration at a potential site of action to cause toxicity. These are examples of how the disposition of toxicants contributes to the fundamental concept that the “dose makes the poison.”

Figure 5-1. Summary of the disposition of toxicants as determined by absorption, distribution, and excretion in the body. Black lines represent major pathways of absorption into the body, blue designates distribution, and green lines identify pathways of final excretion (elimination) from the body, with the exception of enterohepatic circulation, which is designated in red.

The processes comprising xenobiotic disposition are interrelated and influence each other. The integrated relationship of these processes is illustrated in Fig. 5-1. In this chapter, the qualitative aspects of absorption, distribution, and excretion are presented with emphasis on the functional features and molecular determinants of these processes. As all these processes involve passage across biological membranes, we begin with a discussion of this important and ubiquitous barrier.

CELL MEMBRANES

Toxicants usually pass through a number of cells, such as the stratified epithelium of the skin, the thin cell layers of the lungs or the gastrointestinal (GI) tract, capillary endothelium, and ultimately the cells of the target organ. The plasma membranes surrounding all these cells are remarkably similar. The basic unit of the cell membrane is a lipid bilayer composed primarily of phospholipids, glycolipids, and cholesterol. The phospholipids, primarily phosphatidylcholine and phosphatidylethanolamine are most abundant. Phospholipids are amphiphilic, consisting of a hydrophilic polar head and a hydrophobic lipid tail. In membranes, the polar head groups are oriented toward the outer and inner surfaces of the membrane, whereas the hydrophobic tails are oriented inward and face each other to form a continuous hydrophobic inner space. The thickness of the cell membrane is about 7 to 9 nm. Numerous proteins are inserted or embedded in the bilayer, and some transmembrane proteins traverse the entire lipid bilayer, functioning as important biological receptors or allowing the formation of aqueous pores, ion channels, and transporters (Fig. 5-2). The fatty acids of the membrane do not have a rigid crystalline structure but are semifluid at physiological temperatures. Overall, hydrophobic interactions are the major driving force in the formation of membrane lipid bilayers, and the fluid character of membranes is determined largely by the structure and relative abundance of unsaturated fatty acids. The more unsaturated fatty acids the membranes contain, the more fluid-like they are, facilitating more rapid active or passive transport.

The membrane barrier is differentially permeable and regulates what enters into or exits from cells. Toxicants cross membranes

either by passive processes in which the cell expends no energy or by mechanisms in which the cell provides energy to translocate the toxicant across its membrane.

Passive Transport

Simple Diffusion Most toxicants cross membranes by simple diffusion, following the principles of Fick's law, which establishes that chemicals move from regions of higher concentration to regions of lower concentration without any energy expenditure. Small hydrophilic molecules (up to about 600 Da) permeate membranes through aqueous pores (Benz *et al.*, 1980), in a process termed paracellular diffusion, whereas hydrophobic molecules diffuse across the lipid domain of membranes (transcellular diffusion). The smaller a hydrophilic molecule is, the more readily it traverses membranes by simple diffusion through aqueous pores. Consequently, a small, water-soluble compound such as ethanol is rapidly absorbed into the blood from the GI tract and is distributed just as rapidly throughout the body by simple diffusion from blood into all tissues.

Figure 5-2. Schematic model of a biological membrane.

Table 5-1

Octanol/Water Partition Coefficients (*P*) of Different Molecules Expressed as log *P*

COMPOUND	LOG <i>P</i>
Paraquat	Charged molecule
Cephalosporin C	-4.72
Glycine	-3.21
Glutathione	-3.05
Cysteine	-2.35
Glucose	-2.21
Ethylene glycol	-1.37
Lead acetate	-0.63
<i>p</i> -Aminohippuric acid	-0.25
Dimercaprol	0.18
Scopolamine	0.30
Aspirin (acetyl salicylic acid)	1.02
Colchicine	1.19
Atropine	1.32
Benzoic acid	1.88
Benzene	2.14
Salicylic acid	2.19
Methyl salicylate	2.34
2,4-D	2.73
Warfarin	2.89
Digitoxin	3.05
Parathion	3.47
DDT	6.76
TCDD	7.05

2,4-D, 2,4-dichlorophenoxyacetic acid; DDT, dichlorodiphenyltrichloroethane; TCDD, 2,3,7,8-tetrachlorodibenzo-p-dioxin.

For larger organic molecules with differing degrees of lipid solubility, the rate of transport across membranes correlates with lipophilicity. Lipid solubility is generally determined by the octanol/water partition coefficient, *P*, which is defined as the ratio of the concentration of neutral compound in organic and aqueous phases under equilibrium conditions. It is usually expressed in logarithmic form as log *P*, and numerous examples are listed in Table 5-1. The log *P* is an extremely informative physicochemical parameter relative to assessing potential membrane permeability, with positive values associated with high lipid solubility. In contrast, charged molecules such as paraquat do not have a measurable log *P*. As illustrated by the compounds in Table 5-1, amino acids such as glycine are highly water soluble and have a negative log *P*, whereas the environmental contaminants DDT and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) are very lipid soluble and have a high, positive log *P*. There are a variety of experimental methods for empirical determination of log *P*, along with computational tools that can be used to predict log *P* for any chemical (Mannhold *et al.*, 2009).

Many chemicals are weak organic acids or bases, which in solution are ionized according to Arrhenius' theory. The ionized form usually has low lipid solubility and thus does not permeate readily through the lipid domain of a membrane. There may be some transport of organic anions and cations (depending on their molecular weight) through the aqueous pores, but this is a slow and inefficient process. In contrast, the nonionized form of weak organic acids and bases is lipid soluble to some extent, resulting in diffusion across the lipid domain of a membrane. The rate of movement of the nonionized form is proportional to its lipid solubility such that the extent to which a compound is nonionized determines its diffusion.

The molar ratio of ionized to nonionized molecules of a weak organic acid or base in solution depends on the ionization constant, which is defined as the pH at which a weak organic acid or base is 50% ionized (denoted as pK_a or pK_b for acids and bases, respectively). Like pH, pK_a and pK_b are defined as the negative logarithm of the ionization constant of a weak organic acid or base. An organic acid with a low pK_a is relatively a strong acid, and one with a high pK_a is a weak acid. The opposite is true for bases. The numerical value of pK_a does not indicate whether a chemical is an organic acid or a base. Knowledge of the chemical structure is required to distinguish between organic acids and bases.

The Henderson-Hasselbalch equation describes the derivation of pH as a function of the pK_a in a biological system. Two equivalent forms of this equation are

$$pH = pK_a + \log \frac{[\text{ionized}]}{[\text{nonionized}]}$$

$$pH = pK_a - \log \frac{[\text{nonionized}]}{[\text{ionized}]}$$

Rearranging these equations enables determination of the extent to which a weak acid or base is ionized or nonionized at any pH as follows:

$$\text{For acids: } pK_a - pH = \log \frac{[\text{nonionized}]}{[\text{ionized}]}$$

$$\text{For bases: } pK_a - pH = \log \frac{[\text{nonionized}]}{[\text{ionized}]}$$

The effect of pH on the degree of ionization of an organic acid (benzoic acid) and an organic base (aniline) is illustrated in Fig. 5-3. According to the Brønsted-Lowry acid-base theory, an acid is a proton (H^+) donor and a base is a proton acceptor. Thus, the ionized and nonionized forms of an organic acid represent an acid-base pair, with the nonionized moiety being the acid and the ionized moiety being the base. At a low pH, a weak organic acid such as benzoic acid is largely nonionized. At pH 4, exactly 50% of benzoic acid is ionized and 50% is nonionized because this is the pK_a of the compound. As the pH increases, more and more protons are neutralized by hydroxyl groups, and benzoic acid continues to dissociate until almost all of it is in the ionized form. For an organic base such as aniline, the inverse is true. At a low pH, when protons are abundant, almost all of aniline is ionized. This form of aniline is an acid because it can donate protons. As the pH increases, ions from aniline continue to dissociate until almost all the aniline is in the nonionized form, which is the aniline base. As transmembrane passage is largely restricted to the nonionized form, benzoic acid is more readily translocated through a membrane from an acidic environment, whereas more aniline is transferred from an alkaline environment.

Filtration When water flows in bulk across a porous membrane, any solute small enough to pass through the pores flows with it. Passage through these channels is called filtration, as it involves

Acidic pH	pH	1	2	3	4	5	6	7	Neutral pH
	[Nonionized] [Ionized]								
<chem>OC(=O)c1ccccc1</chem> $pK_a \approx 4$		$\frac{1000}{1}$	$\frac{100}{1}$	$\frac{10}{1}$	$\frac{1}{1}$	$\frac{1}{10}$	$\frac{1}{100}$	$\frac{1}{1000}$	<chem>[O-]C(=O)c1ccccc1</chem>
<chem>Nc1ccccc1</chem> $pK_a \approx 5$		$\frac{1}{10000}$	$\frac{1}{1000}$	$\frac{1}{100}$	$\frac{1}{10}$	$\frac{1}{1}$	$\frac{10}{1}$	$\frac{100}{1}$	<chem>Nc1ccccc1</chem>

Figure 5-3. Effect of pH on the ionization of benzoic acid ($pK_a = 4$) and aniline ($pK_a = 5$).

bulk flow of water caused by hydrostatic or osmotic force. One of the main differences between various membranes is the size of these channels. In renal glomeruli, a primary site of filtration, these pores are relatively large (about 70 nm) allowing molecules smaller than albumin (approximately 60 kDa) to pass through. In contrast, there are no aqueous pores at cellular tight junctions, and channels in most cells are much smaller (3–6 Å), thereby only permitting substantial passage of molecules with molecular weights of no more than a few hundred daltons (Schanker, 1962; Lin, 2006).

Special Transport

There are numerous compounds whose movement across membranes cannot be explained by simple diffusion or filtration. Some compounds are too large to pass through aqueous pores or too insoluble in lipids to diffuse across the lipid domains of membranes. Nevertheless, they are often transported very rapidly across membranes, even against concentration gradients. To explain these phenomena, specialized transport systems have been identified. These systems are responsible for the transport (both influx and efflux) across cell membranes of many nutrients, such as sugars and amino and nucleic acids, along with numerous foreign compounds. Based on the sequencing of the human genome, there are at least 500 genes whose putative function involves membrane transport (Venter *et al.*, 2001). However, not all of these genes contribute to the disposition of toxicants. Throughout this chapter, membrane-associated transporters known to contribute to the disposition and subsequent effects of xenobiotics will be emphasized. Importantly, the role of xenobiotic transporters in chemical disposition is an expanding research field, and new information regarding their function, molecular regulation, and genetic polymorphisms continues to inform and modify traditional concepts in toxicology.

Active Transport Active transport is characterized by (1) movement of chemicals against electrochemical or concentration gradients, (2) saturability at high substrate concentrations, (3) selectivity for certain structural features of chemicals, (4) competitive inhibition by chemical congeners or compounds that are carried by the same transporter, and (5) requirement for expenditure of energy, so that metabolic inhibitors block the transport process.

Substances actively transported across cell membranes presumably form a complex with a membrane-bound macromolecular

carrier on one side of the membrane. The complex subsequently traverses to the other side of the membrane, where the substance is released. Afterward, the carrier returns to the original surface to repeat the transport cycle.

Facilitated Diffusion Facilitated diffusion applies to carrier-mediated transport that exhibits the properties of active transport except that the substrate is not moved against an electrochemical or concentration gradient, and the transport process does not require the input of energy; that is, metabolic poisons do not interfere with this transport. The transport of glucose from the GI tract across the basolateral membrane of the intestinal epithelium, from plasma into red blood cells, and from blood into the central nervous system (CNS) occurs by facilitated diffusion.

Xenobiotic Transporters Significant advances in identifying and understanding the carrier-mediated transport systems for xenobiotics have been made in the recent years. In total, it is estimated that at least 5% of all human genes are transporter related, indicative of the importance of the transport function in normal biological and toxicological outcomes (Hediger *et al.*, 2004). Transporters mediate the influx (uptake) or efflux of xenobiotics and can be divided into 2 categories, determined by whether they mediate active or facilitated transfer of compounds. The first active, energy-dependent xenobiotic transporter identified was a phosphoglycoprotein overexpressed in tumor cells that showed resistance to anticancer drugs. The gene conferred multidrug resistance (MDR) to the cells, and was also called P-glycoprotein (P-gp or MDR1; gene name *MDR1*). This transporter functions as an efflux pump, which in cancerous cells, exudes cytotoxic drugs out of the tumor cells, and thus contributes to their resistance (Ambudkar *et al.*, 1999). MDR1 was the first member of a large superfamily of transport proteins known as ATP-binding cassette (ABC) transporters, with 7 subfamilies of ABC transporters now identified (Box 5-1). These are classified as subfamilies A to G with 49 genes in humans (Ueda, 2011). Many of these transporters play key roles in the homeostasis of numerous endogenous substrates. For example, ABCA1 is a major regulator of cholesterol in cells, mediating its efflux from liver, and ABCB4 specifically transports phospholipid substrates. In this chapter, transporters that play important roles in xenobiotic disposition and toxicity are described, with emphasis on the human genes and proteins. For example, in humans, the major

Box 5-1

Human ABC Transporters: Gene Family Overview and Major Transporters Involved in Xenobiotic Disposition

ABC SUBFAMILY	GENES IN FAMILY	GENE SYMBOLS
A	12	<i>ABCA1-10, 12, 13</i>
B	11	<i>ABCB1-11</i>
C	13	<i>ABCC1-13*</i>
D	4	<i>ABCD1-4</i>
E	1	<i>ABCE1</i>
F	3	<i>ABCF1-3</i>
G	5	<i>ABCG1, 2, 4, 5, 8</i>

Bolded subfamily designations are those with a major role in xenobiotic disposition.

**ABCC13 is reported to be a pseudogene.*

GENE SYMBOL	COMMON NAME	GENERAL FUNCTION
<i>ABCB1</i>	Multidrug resistant protein/P-glycoprotein (MDR)	Efflux from gut, brain, placenta; biliary excretion
<i>ABCB11</i>	Bile salt export pump (BSEP)	Bile salt transport
<i>ABCC1</i>	Multidrug resistance–associated protein 1 (MRP1)	Multidrug resistance in many tissues; export pump
<i>ABCC2</i>	Multidrug resistance–associated protein 2 (MRP2)	Organic anion efflux, glucuronide and glutathione conjugates, biliary excretion
<i>ABCC3</i>	Multidrug resistance–associated protein 3 (MRP3)	Organic anion efflux, glucuronide and glutathione conjugates
<i>ABCC4</i>	Multidrug resistance–associated protein 4 (MRP4)	Nucleoside transport and organic anion efflux
<i>ABCC5</i>	Multidrug resistance–associated protein 5 (MRP6)	Mainly nucleoside transport
<i>ABCC6</i>	Multidrug resistance–associated protein 6 (MRP6)	Some glutathione conjugates
<i>ABCC10</i>	Multidrug resistance–associated protein 7 (MRP7)*	Organic anions, vinca alkaloids
<i>ABCC11</i>	Multidrug resistance–associated protein 8 (MRP8)*	Cyclic nucleotides and organic anions
<i>ABCC12</i>	Multidrug resistance–associated protein 9 (MRP9)*	Not defined
<i>ABCG2</i>	Breast cancer resistance protein (BCRP)	Organic anion efflux, many sulfate conjugates, biliary excretion

**There is little functional information available for MRP7, MRP8, and MRP9. A single nucleotide polymorphism in MRP8 is known to determine wet or dry earwax.*

SOURCE: Compiled from Kruh et al. (2007), Klaassen and Aleksunes (2010), and Ueda et al. (2011).

form of MDR1 involved in xenobiotic transport is a single protein (ABCB1; MDR1), whereas in rodents there are 2 drug-transporting MDR1 homologs identified as Mdr1a and Mdr1b.

The second important ABC transport subfamily is the ABCC subfamily, which is also known as the multiresistant drug protein (MRP) family (see Box 5-1). ABCC1 (MRP1) was also originally isolated from multidrug resistant cells. Members of this family excrete chemicals from cells, with MRP2 and MRP3 particularly important in the efflux of xenobiotic metabolites, especially those conjugated with UDP-glucuronic acid or glutathione. The breast cancer resistance protein (BCRP) is a member of the ABCG subfamily (ABCG2) and was originally isolated from a breast cancer cell line. It is expressed in a variety of normal tissues and contributes to the disposition of the efflux transport of numerous endogenous and xenobiotic sulfate conjugates. It is also highly expressed in numerous stem cells, particularly the side population of human

bone marrow and other organs where it is purported to provide protection from xenobiotics (Ni *et al.*, 2010).

ABC transporters exhibit the characteristics of active transport outlined above, and most notably, they require expenditure of energy to function. For most ABC transporters, the binding and hydrolysis of ATP provides the energy required to move their substrates across membranes. The typical structure of most ABC transporters consists of two types of structural domains including hydrophobic membrane spanning domain (MSD) and the hydrophilic, intracellular nucleotide binding domain (NBD) where ATP binds and is hydrolyzed (Fig. 5-4). The typical structural organization of the ABC transporter, as exemplified by MDR1, is a tandem repeat of two domains (1 MSD followed by 1 NBD). The two repeated halves are joined by a polypeptide linker sequence. MRPs are distinguished from MDR1 in that they comprise 5 domains, with an extra MSD that comprises 5 transmembrane segments and

Figure 5-4. Diagrammatic representation of the structure of MRD1, illustrating the membrane spanning domain and ATP-binding domains (NBD).

an extracytosolic amino terminus, whereas BCRP is a “half-transporter” with a single MSD of 6 transmembrane segments preceded by a single NBD. Recent evidence suggests that BCRP forms a homodimer or a homotetramer to function as an efflux pump (Leslie *et al.*, 2005, Ni *et al.*, 2010). These differences in structure account for differences in molecular weight (approximately 170, 190, and 70 kDa for MDR1, MRP1, and BCRP, respectively), but there is considerable overlap in many of the xenobiotics that are transported by these proteins.

Members of the ABC transporter family are expressed constitutively in many cells, and collectively they play important roles in absorption from the GI tract and elimination into bile or into urine for a wide range of xenobiotics. They are also critical to maintaining

the barrier function of numerous tissues sites including the blood–brain barrier (BBB), the blood–testis barrier, and the maternal–fetal barrier or placenta. Hence, they play a central role in the disposition and toxicity of xenobiotics. Their function in absorption, distribution, and excretion will be discussed throughout the remaining sections of this chapter.

The second major family of xenobiotic transporters is the solute carriers (SLCs), which function predominantly as facilitative transporters. There are 43 SLC gene families identified, and many of the nearly 300 genes comprising the 43 distinct SLC families play important roles in the disposition of endogenous compounds, including glucose, neurotransmitters, nucleotides, essential metals, and peptides. Additionally, there are several families that are vital to xenobiotic disposition, regulating the movement of many diverse organic anions and cations across cell membranes (Hediger *et al.*, 2004; Klaassen and Aleksunes, 2010).

The major human solute carriers involved in xenobiotic disposition are summarized in Box 5-2. The organic-anion transporting peptides (OATPs, SLCO family) are important membrane transport proteins that mediate the sodium-independent transport of a wide range of compounds, including organic acids, bases, and neutral compounds. Although they are largely regarded as influx pumps, solutes can move bidirectionally, and these proteins appear to be especially important in the hepatic uptake of xenobiotics. In human liver, OATP1B1, OATP1B3, OATP1A2, and OATP2B1 have

Box 5-2

Major Members of the Human Solute Carrier Transporter Families Involved in Xenobiotic Disposition

TRANSPORTER	GENE FAMILY	HUMAN PROTEINS	GENE NAME	FUNCTION
Organic anion transporting polypeptide (OATP)	SLCO	OATP1A2	SLCO1A2	Transport of organic anions, cations, and neutral compounds
		OATP1B1	SLCO1B1	
		OATP1B3	SLCO1B3	
		OATP1C1	SLCO1C1	
		OATP2A1	SLCO2A1	
		OATP2B1	SLCO2B1	
		OATP3A1	SLCO3A1	
		OATP4A1	SLCO4A1	
		OATP4C1	SLCO4C1	
		OATP5A1	SLCO5A1	
OATP6A1	SLCO6A1			
Organic cation transporter (OCT)	SLC22	OCT1	SLC22A1	Transport of organic cations
		OCT2	SLC22A2	
		OCT3	SLC22A3	
Organic cation/carnitine transporter (OCTN)	SLC22	OCTN1	SLC22A4	Organic cations; OCTN2 specific for carnitine
		OCTN2	SLC22A5	
Organic anion transporter (OAT)	SLC22	OAT1	SLC22A6	Transport of organic anions
		OAT2	SLC22A7	
		OAT3	SLC22A8	
		OAT4	SLC22A11	
		OAT5	SLC22A10	
Peptide transporter (PEPT)	SLC15	PEPT1	SLC15A1	Transport of di- and tripeptides, some xenobiotics
		PEPT2	SLC15A2	
Multidrug and toxin extrusion transporter (MATE)	SLC47	MATE1	SLC47A1	Efflux of organic cations; MATE2K localized to kidney
		MATE2K	SLC47A2	

Gene and protein members of the solute carrier families are compiled from Mizuno *et al.* (2003), Hagenbuch and Meier (2004), Sahi (2005), Lin (2006), Hagenbuch and Guo (2008), Kusuhashi and Sugiyama (2009), and Klaassen and Aleksunes (2010).

been identified, whereas the major Oatps in rat liver are Oatp1a1, Oatp1a4, and Oatp1b2. For OATPs, the mechanism of transport is anion exchange such that the cellular influx of an organic compound is thought to be coupled to the efflux of bicarbonate, glutathione, or glutathione conjugates.

The organic-anion transporter (OAT; SLC22) family is particularly important in the renal uptake of anions, and human proteins (OAT1-5) have been identified in the kidney, whereas Oat1 and Oat3 are the major transporters identified in rodent kidneys. The organic-cation transporter (OCT; also SLC22) family is important in both the renal and hepatic uptake of xenobiotics. In this family, OCT1 is expressed in human liver, whereas only OCT2 has been detected in human kidney. In rats, Oct1 is found in liver, whereas both Oct1 and Oct2 are expressed in rat kidney. Novel organic-cation transporters (OCTNs; also SLC22) have also been identified which transport exogenous cations along with important endogenous compounds such as carnitine. OATs transport substrates against an electrochemical gradient in exchange for intracellular dicarboxylates, such as α -ketoglutarate, whereas the driving force for OCT-mediated transport is the electrochemical gradient of the transported cation, typical of facilitated diffusion (described above). Peptide transporters (PEPT1 and PEPT2; SLC15) are responsible for the transport of di- and tri-peptides as well as drugs and toxicants such as the β -lactam antibiotics. Finally, the multidrug and toxin extrusion transporters (MATEs; SLC47) are a unique gene family of solute carriers expressed predominantly in liver and kidney that function specifically as cation efflux pumps.

Additional Transport Processes Other forms of specialized transport have been proposed, but their overall importance is not as well established as that of active transport and facilitated diffusion. Phagocytosis and pinocytosis are proposed mechanisms for cell membranes flowing around and engulfing particles. This type of transfer has been shown to be important for the removal of particulate matter from the alveoli by phagocytes and from blood by the reticuloendothelial system of the liver and spleen.

ABSORPTION

The process by which toxicants cross body membranes to enter the bloodstream is referred to as absorption. There are no specific systems or pathways for the sole purpose of absorbing toxicants. Xenobiotics penetrate membranes during absorption by the same processes as do biologically essential substances such as oxygen, foodstuffs, and other nutrients. The main sites of absorption are the GI tract, lungs, and skin. However, absorption may also occur from other sites, such as the subcutis, peritoneum, or muscle, if a chemical is administered by special routes. Experimentalists and medical professionals often distinguish between parenteral and enteral administration of drugs and other xenobiotics. Enteral administration includes all routes pertaining to the alimentary canal (sublingual, oral, and rectal), whereas parenteral administration involves all other routes (intravenous, intraperitoneal, intramuscular, subcutaneous, etc).

Absorption of Toxicants by the Gastrointestinal Tract

The GI tract is one of the most important sites where toxicants are absorbed. Many environmental toxicants enter the food chain and are absorbed together with food from the GI tract. This site of absorption is also particularly relevant to toxicologists because accidental ingestion is the most common route of unintentional

exposure to a toxicant (especially for children) and intentional overdoses most frequently occur via the oral route.

The GI tract may be viewed as a tube traversing the body. Although it is within the body, its contents remain outside of the body. Therefore, unless a noxious agent has direct caustic or irritating properties, toxicants remaining in the GI tract may damage the cells that make up the organ, but usually do not produce systemic injury until they are absorbed.

Absorption of toxicants can take place along the entire GI tract, even in the mouth and the rectum. Therefore, although the majority of drugs are given orally, drugs such as nitroglycerin are administered sublingually whereas others are administered as rectal suppositories. If a toxicant is an organic acid or base, it tends to be absorbed by simple diffusion in the part of the GI tract where it exists in its most lipid-soluble (nonionized) form. Because gastric juice is acidic (pH about 2) and the intestinal contents are nearly neutral, the lipid solubility of weak organic acids or bases can differ markedly in these 2 areas of the GI tract. The Henderson–Hasselbalch equations (discussed above) determine the fraction of a toxicant that is in the nonionized (lipid-soluble) form and estimate the rate of absorption from the stomach or intestine. As illustrated in Fig. 5-3, a weak organic acid such as benzoic acid is present mainly in the nonionized (lipid-soluble) form in the stomach and predominantly in the ionized form in the intestine. Therefore, weak organic acids are absorbed more readily from the stomach than from the intestine. In contrast, organic bases (except very weak organic bases) are likely to be ionized and not lipid soluble in the stomach, but are more likely to be in the nonionized form in the intestine, suggesting that the absorption of such compounds occurs predominantly in the intestine rather than in the stomach. However, the Henderson–Hasselbalch calculations are not an absolute determination of absorption because other factors—including the mass action law, surface area, and blood flow rate—have to be taken into consideration in examining the absorption of weak organic acids or bases. For example, only 1% of benzoic acid is present in the lipid-soluble form in the neutral pH of the intestine. Therefore, one might conclude that the intestine has little capacity to absorb this organic acid. However, absorption is a dynamic process. The blood keeps removing benzoic acid from the lamina propria of the intestine, and according to the mass action law, the equilibrium will always be maintained at 1% in the nonionized form, providing continuous availability of benzoic acid for absorption. Moreover, absorption by simple diffusion is also proportional to the surface area. The small intestine has a very large surface because the villi and microvilli increase the surface area approximately 600-fold, such that the overall capacity of the intestine for absorption of benzoic acid is quite large. Similar considerations are also valid for the absorption of all weak organic acids from the intestine.

The mammalian GI tract has numerous specialized transport systems (carrier-mediated) for the absorption of nutrients and electrolytes (Table 5-2). The absorption of some of these substances is complex and depends on several additional factors. For example, iron absorption is determined by the need for iron and takes place in 2 steps: Iron first enters the mucosal cells of the GI tract and then moves into the blood. The first step is relatively rapid, whereas the second is slow. Consequently, iron accumulates within the mucosal cells as a protein–iron complex termed ferritin. When the concentration of iron in blood drops below normal values, some iron is liberated from the mucosal stores of ferritin and transported into the blood. As a consequence, the absorption of more iron from the intestine is triggered to replenish these stores. Calcium is also absorbed by a 2-step process: absorption from the lumen followed by exudation into the interstitial fluid. The first step is faster than the

second, and therefore intracellular calcium rises in mucosal cells during absorption. Vitamin D is required for both steps of calcium transport.

Some xenobiotics are absorbed by the same specialized transport systems for nutrients, thereby leading to potential competition or interaction. For example, 5-fluorouracil is absorbed by the pyrimidine transport system (Yuasa *et al.*, 1996), thallium utilizes the system that normally absorbs iron (Leopold *et al.*, 1969), lead can be absorbed by the calcium transporter (Fullmer, 1992), and cobalt and manganese compete for the iron transport system (Flanagan *et al.*, 1980).

Numerous xenobiotic transporters are expressed in the GI tract where they function to increase or decrease absorption of xenobiotics (Fig. 5-5). Several proteins in the SLC families are expressed in the intestine where they are predominantly localized on the apical brush-border membranes of the enterocytes and increase uptake from the lumen into the enterocytes. In humans, OATP1A2 and OATP2B1 are the most abundant and important members of this family that are expressed in the intestine, although OATP3A1 and OATP4A1 have also been identified. In contrast, in rodents Oatp1a5 is the predominant uptake transporter. OCTN1 and OCTN2 are also present in the intestine, with OCTN2 specifically involved in the uptake of carnitine. The peptide transporter, PEPT1 is highly expressed in the GI tract and mediates the transport of peptide-like drugs such as antibiotics, particularly those containing a β -lactam structure. The OCTs, particularly OCT1 and OCT2, also contribute to xenobiotic uptake into enterocytes, but are expressed on the basolateral membrane (Klaassen and Aleksunes, 2010; Tamai, 2012). The primary active efflux transporters such as MDR1, MRP2, and BCRP are also expressed on enterocyte brush-border membranes where they function to excrete their substrates into the lumen, thereby decreasing the net absorption of xenobiotics. MRP3 is also found in the intestine, but is localized to the basolateral membrane. The expression of the intestinal transporters varies across the GI tract. For example, MDR1 expression increases from the duodenum

to colon, whereas MRP2 and most of the uptake transporters are expressed most highly in the duodenum and decrease to in the terminal ileum and colon. BCRP is found throughout the small intestine and colon.

The efflux transporters are particularly relevant to the disposition of toxicants, as there will be a net reduction in the absorption of chemicals that are substrates for these transporters, and this is a desirable outcome for toxic chemicals. For example, the dietary

Figure 5-5. Schematic model showing the important xenobiotic transport systems present in the human gastrointestinal tract.

carcinogen, 2-amino-1-methyl-6-phenylimidazo (4,5-b)pyridine (PhIP), a heterocyclic amine produced during the cooking of meat, is a substrate for MRP2. Studies comparing the disposition of PhIP in wild-type and Mrp2-deficient rats showed that MRP is very important in limiting the oral absorption of this harmful compound (Dietrich *et al.*, 2001). However, although limiting absorption of toxicants and carcinogens is beneficial, these transporters can also function to limit the oral absorption of drugs. For example, the immunosuppressive drug cyclosporine and the chemotherapeutic anticancer drugs paclitaxel (taxol), colchicine, and vincristine are not readily absorbed from the GI tract because they are good substrates for MDR1.

The number of toxicants actively absorbed by the GI tract is low; most enter the body by simple diffusion. Although lipid-soluble substances are absorbed by this process more rapidly and extensively than are water-soluble substances, the latter may also be absorbed to some degree. After oral ingestion, about 10% of lead, 4% of manganese, 1.5% of cadmium, and 1% of chromium salts are absorbed. If a compound is very toxic, even small amounts of absorbed material produce serious systemic effects. An organic compound that would not be expected to be absorbed on the basis of the pH-partition hypothesis is the fully ionized quaternary ammonium compound pralidoxime chloride (2-PAM; molecular weight 137), yet it is absorbed almost entirely from the GI tract. The mechanism by which some lipid-insoluble compounds are absorbed is not entirely clear. It appears that organic ions of low molecular weight (<200) can be transported across the mucosal barrier by paracellular transport, that is, passive penetration through aqueous pores at the tight junctions or by active transport as discussed above.

Particles and particulate matter can also be absorbed by the GI epithelium. In this case, particle size is a major determinant of absorption, whereas factors such as the lipid solubility or ionization characteristics are less important. For particles, size is inversely related to absorption such that absorption increases with decreasing particle diameter (Florence *et al.*, 1995). This explains why metallic mercury is relatively nontoxic when ingested orally and why powdered arsenic was found to be significantly more toxic than its coarse granular form (Schwartz, 1923). Large particles (greater than about 20 μm in diameter) enter intestinal cells by pinocytosis, a process that is much more prominent in newborns than in adults, after which they are carried through the intestinal epithelium in intact vesicles and discharged into the interstices of the lamina propria. Absorption into gut-associated lymphoid tissue (such as Peyer's patches) and the mesenteric lymph supply also plays a key role in systemic absorption of particles (Jani *et al.*, 1990; Florence *et al.*, 1995).

There is increasing interest in particles of very small diameter that may be used in a variety of chemical and biological processes. Nanoparticles or nanomaterials are typically less than 100 nm in size, and numerous issues have been raised regarding the toxic potential of these entities (Chap. 28). Although the absorption of large particles is typically limited, absorption of nanoparticles by the GI tract in rats is as high as 30% for particles that are less than 50 nm in diameter (Jani *et al.*, 1990). Additionally, surface characteristics of nanoparticles contribute to their absorption, with hydrophobic, nonionized particles being more extensively absorbed than those modified to possess an ionized surface as is the case with larger particles, the gut-associated lymphoid tissue appears to be the predominant absorption pathway for nanoparticles from the GI tract (Stern and McNeil, 2008). Overall, the absorption of a toxicant from the GI tract depends on its physical properties, including lipid solubility and its dissolution rate. Although it is often generalized that an increase in lipid solubility increases the absorption

of chemicals, an extremely lipid-soluble chemical is unlikely to dissolve in the aqueous fluids within the GI tract, which limits its absorption from the GI tract. Similarly, if the toxicant is a solid and is relatively insoluble in GI fluids, it will also have limited contact with the GI mucosa and its rate of absorption will be low (Lipinski *et al.*, 2001).

In addition to the characteristics of the compounds themselves, there are numerous additional factors relating to the GI tract itself that influence the absorption of xenobiotics. These factors include pH, the presence of food, digestive enzymes, bile acids, and bacterial microflora in the GI tract, along with the motility and permeability of the GI tract. Chemical resistance or lack of resistance to alteration by the acidic pH of the stomach, enzymes of the stomach or intestine, or the intestinal microflora are extremely important. A toxicant may be hydrolyzed by stomach acid, biotransformed by enzymes in the GI tract or modified by the resident microflora to new compounds with a toxicity different from that of the parent compound. For example, snake venoms, which are proteinaceous moieties, are much less toxic by the oral route relative to intravenous exposure because they are degraded by digestive enzymes of the GI tract.

Intestinal microflora can also influence absorption and toxicity of compounds. For example, a variety of nitroaromatic compounds are reduced by intestinal bacteria to potentially toxic and carcinogenic aromatic amines. Nitroreduction of 2,6-dinitrotoluene to the mutagenic 2,6-diaminotoluene in the GI tract produces long-term adverse effects, including mutagenicity and carcinogenicity, which are not observed in germ-free animals (Rickert *et al.*, 1984). Similarly, the nitroaromatic perfume, musk xylene, can inhibit the activity of cytochrome P450 enzymes in the liver only after it is reduced to an amine derivative by resident microflora in the GI tract and subsequently absorbed (Lehman-McKeeman *et al.*, 1997). It has also been shown that ingestion of well water with a high nitrate content produces methemoglobinemia much more frequently in infants than in adults. In this case, bacteria in the GI tract convert nitrate to nitrite, increasing the likelihood of methemoglobinemia (Mensinga *et al.*, 2003). Infants are more susceptible to methemoglobinemia because the higher pH of the neonatal GI tract is permissive for the growth of bacteria (such as *Escherichia coli*) that convert nitrate to nitrite. One example wherein intestinal microflora reduce the potential toxicity is that of the mycotoxin, deoxynivalenol, which is found in numerous grains and foodstuffs. Strict anaerobes detoxify this compound leading to the absorption of a less toxic reductive metabolite (Awad *et al.*, 2010). The contribution of bacteria in the GI tract to other aspects of xenobiotic disposition, particularly enterohepatic circulation, is discussed in greater detail later in this chapter.

Agents such as the chelator, ethylenediaminetetraacetic acid (EDTA), increase absorption of some toxicants by increasing intestinal permeability. An increase in permeability is thought to result from the chelation of calcium that is involved in the formation and maintenance of tight intercellular junctions (Ballard *et al.*, 1995) such that binding of calcium reduces the integrity of the cell junctions, allowing more paracellular absorption. Furthermore, simple diffusion is proportional not only to the surface area and the permeability but also to the residency time within various segments of the GI tract. Therefore, the rate of absorption of a toxicant remaining for longer periods in the intestine increases, whereas that with a shorter residency time decreases. Experiments have shown that the oral toxicity of some chemicals is increased by diluting the dose (Borowitz *et al.*, 1971). This phenomenon may be explained by more rapid stomach emptying induced by increased dosage volume, which in turn leads to greater absorption in the duodenum because of the larger surface area there. Furthermore, some agents

used as laxatives alter absorption of xenobiotics by increasing intestinal motility, whereas agents used as antidiarrheals may increase absorption by slowing intestinal motility.

The amount of a chemical that enters the systemic circulation after oral administration depends on several factors. The amount absorbed into the cells of the GI tract is important, and transporters can influence this amount by affecting the uptake or efflux from the cells. Further, before a chemical enters the systemic circulation, it can be biotransformed by the cells in the GI tract or extracted by the liver and excreted into bile with or without prior biotransformation. This phenomenon of the removal of chemicals before entrance into the systemic circulation is referred to as presystemic elimination or first-pass effect. The lung can also contribute to the biotransformation or elimination of chemicals before their entrance into the systemic circulation, although its role is less well defined than that of the intestine and the liver. Chemicals that have a high first-pass effect will appear to have a lower absorption because they are eliminated as quickly as they are absorbed. For toxicants, a high first-pass effect will serve to limit exposure and typically minimizes toxic potential.

A number of other factors have been shown to alter absorption. For example, although lead and many other heavy metal ions are not absorbed readily from the GI tract, EDTA and other chelators increase the lipid solubility and thus the absorption of complexed ions. Thus, it is important not to administer a chelator orally when excess metal is still present in the GI tract after oral ingestion. Furthermore, metal ions can affect absorption of other ions. For example, cadmium decreases the absorption of zinc and copper, calcium decreases cadmium absorption, and magnesium decreases absorption of fluoride (Pfeiffer, 1977). Consumption of grapefruit juice can also influence GI absorption through the actions of naringin, a flavonoid that inhibits the function of several transporters including MDR1 and OATP1A2 (Bailey, 2010). By reducing MDR1-dependent efflux, grapefruit juice increases GI absorption of numerous pharmaceutical agents (such as calcium-channel blockers and cholesterol-lowering agents), and, in some cases, this effect leads to toxic or adverse reactions resulting from increased exposure to the drugs. Alternatively, inhibition of OATPs reduces absorption and could limit toxicity.

Species differences in absorption across the GI tract are widely recognized. As one example, absorption of nadolol after intraperitoneal and oral dosing was compared across species by calculating the exposure as plasma area-under-the-curve (AUC) and was found to be essentially complete in dogs, substantially less in humans, and limited in rats. Urinary and fecal excretion of nadolol support the bioavailability data, as the low oral absorption of nadolol in rats is consistent with the large amount of drug recovered in feces (Table 5-3). However, excretory data further indicate that in addition to the nonabsorbed portion of this compound, biliary and possibly nonbiliary sources also contribute to the fecal excretion of this compound. Similar comparisons across species provide further evidence for species differences in the absorption of numerous compounds, indicating that nadolol is not an exceptional case (Calabrese, 1984).

The factors that contribute to species differences in absorption are not fully understood. Anatomical considerations are likely to contribute to species differences in intestinal absorption, and substantial functional differences exist between species. Because most xenobiotics are transported across the GI mucosa by passive diffusion, and because this transport is surface area- and site-dependent, it is likely that these factors will also contribute to species differences. Furthermore, species differences in the pH along the GI tract exist (Table 5-4), varying by as much as 2 pH units. The magnitude of this diversity can translate into differences up to 2 orders of magnitude in the concentration of the nonionized versus ionized moiety of a weak

organic acid or base available for absorption. In addition, the GI absorption is often higher in dogs compared to other species because paracellular absorption is thought to occur to a greater extent in dogs.

Another factor that may result in species-dependent absorption of xenobiotics is the presence and function of the GI microflora. Bacteria in the GI tract are highly abundant, with strict anaerobes (oxygen intolerant) being the most prevalent. More than 400 species of bacteria have been found in the GI tract. In general, the intestinal microflora in animals is remarkably similar, although qualitative and quantitative differences have been reported (Rowland et al., 1985). For example, rabbit and humans are distinguished from other species in that the number of microbes found in the upper regions of the GI tract is relatively low (Table 5-5). The more acidic pH of the stomach in rabbits and humans contributes to the lower number of microbes found in this region. Importantly, bacterial metabolism is a prerequisite for absorption of some xenobiotics, and species differences in absorption may result from differences in the type and number of microbes in the GI tract.

Absorption of Toxicants by the Lungs

Toxic responses to chemicals can occur from absorption following inhalation exposure. Relevant examples include carbon monoxide poisoning and silicosis, an important occupational disease. These toxicities result from absorption or deposition of airborne poisons in the lungs.

A major group of toxicants that are absorbed by the lungs are gases (eg, carbon monoxide, nitrogen dioxide, and sulfur dioxide), vapors of volatile or volatilizable liquids (eg, benzene and carbon tetrachloride), and aerosols. Because the absorption of inhaled gases and vapor differs from that of aerosols, aerosols are discussed separately below. However, the absorption of gases and vapors is governed by the same principles, and therefore the word gas is used to represent both in this section.

Gases and Vapors A vapor is the gas form of substance that can also exist as a liquid or solid at atmospheric pressure and normal temperature. Most organic solvents evaporate and produce vapors, and some solids can also sublime into a gaseous form. Vapor pressure is that exerted by a vapor above its own liquid in a closed system, such that liquids that have a high vapor pressure have a higher tendency to evaporate. A toxicant with a high vapor pressure at room temperature is considered to be volatile. Examples of the vapor pressure of several toxicants are presented in Table 5-6.

The absorption of inhaled gases takes place mainly in the lungs. However, when inhaled, gases first pass through the nose, filtering through delicately scrolled, simple epithelial-lined turbinates, which serve to increase the surface area of exposure. Because the mucosa of the nose is covered by a film of fluid, gas molecules can be retained by the nose and do not reach the lungs if they are very water soluble or react with cell surface components. Therefore, the nose acts as a “scrubber” for water-soluble

Table 5-6

Vapor Pressures of Common Solvents or Toxicants

SUBSTANCE	VAPOR PRESSURE (SI UNITS; kPa)	VAPOR PRESSURE (mm Hg)

and highly reactive gases, partially protecting the lungs from potentially injurious insults. Although these actions may serve to reduce systemic exposure or to protect the lungs, they also increase the risk that the nose could be adversely affected. Such is the case with formaldehyde (Kerns et al., 1983) and vinyl acetate (Bogdanffy et al., 1999), which cause tumors of the nasal turbinates in rats.

Absorption of gases in the lungs differs from intestinal and percutaneous absorption of compounds in that the dissociation of acids and bases and the lipid solubility of molecules are less important factors in pulmonary absorption because diffusion through cell membranes is not rate-limiting in the pulmonary absorption of gases. There are at least 3 reasons for this. First, ionized molecules are of very low volatility, so that they do not achieve significant concentrations in normal ambient air. Second, type I pneumocytes (epithelial cells lining the alveoli; Chap. 15) are very thin and the capillaries are in close contact with the pneumocytes, so that the distance for a chemical to diffuse is very short. Third, chemicals absorbed by the lungs are removed rapidly by the blood, and blood moves very quickly through the extensive capillary network in the lungs.

When a gas is inhaled into the lungs, gas molecules diffuse from the alveolar space into the blood and then dissolve. Except for some gases with a special affinity for certain body components (eg, the binding of carbon monoxide to hemoglobin), the uptake of a gas by a tissue usually involves the simple physical process of dissolving. The end result is that gas molecules partition between two media, namely air and blood during the absorptive phase and blood and other tissues during the distributive phase. As the inspired gas remains in contact with blood in the alveoli, more molecules dissolve in blood until gas molecules in blood are in equilibrium with gas molecules in the alveolar space. At this equilibrium, the ratio of the concentration of chemical in the blood and chemical in the gas phase is constant. This solubility ratio is called the blood-to-gas partition coefficient, and it is unique for each gas. Note that although the ratio is constant, the concentrations achieved vary in accordance with Henry's law, which dictates that the amount of gas dissolved in a liquid is proportional to the partial vapor pressure of the gas in the gas phase at any given concentration before or at saturation. Thus, the higher the inhaled concentration of a gas (ie, the higher the partial pressure), the higher the gas concentration in blood, but the blood:gas ratio does not change unless saturation has occurred. When equilibrium is reached, the rate of transfer of gas molecules from the alveolar space to blood equals the rate of removal by blood from the alveolar space. For example, chloroform has a relatively high blood-to-gas partition coefficient (approximately 20), whereas ethylene has a low coefficient (0.14). By comparison, a smaller percentage of the total ethylene in the lungs is removed into the blood during each circulation because the low blood-to-gas partition coefficient dictates that blood is quickly saturated with this gas. Therefore, an increase in the respiratory rate or minute volume does not change the transfer of such a gas to blood. In contrast, an increase in the rate of blood flow increases the rate of uptake of a compound with a low solubility ratio because of more rapid removal from the site of equilibrium, that is, the alveolar membranes. It has been calculated that the time to equilibrate between the blood and the gas phase for a relatively insoluble gas is about 10 to 20 minutes.

A gas with a high blood-to-gas partition coefficient, such as chloroform, is readily transferred to blood during each respiratory cycle so that little if any remains in the alveoli just before the next inhalation. The more soluble a toxic chemical is in blood,

the more of it will be dissolved in blood by the time equilibrium is reached. Consequently, the time required to equilibrate with blood is much longer for a gas with a high blood-to-gas partition coefficient than for a gas with a low ratio. This has been calculated to take a minimum of one hour for compounds with a high solubility ratio, although it may take even longer if the gas also has high tissue affinity (ie, high fat solubility). With highly soluble gases, the principal factor limiting the rate of absorption is respiration. Because the blood is already removing virtually all gases with a high solubility ratio from the lungs, increasing the blood flow rate does not substantially increase the rate of absorption. However, the rate can be accelerated greatly by increasing the rate of respiration.

The blood carries the dissolved gas molecules to the rest of the body. In each tissue, the gas molecules are transferred from the blood to the tissue until equilibrium is reached at a tissue concentration dictated by the tissue-to-blood partition coefficient. After releasing part of the gas to tissues, blood returns to the lungs to take up more of the gas. The process continues until a gas reaches equilibrium between blood and each tissue according to the tissue-to-blood partition coefficients characteristic of each tissue. This equilibrium is referred to as steady state, and at this time, no net absorption of gas takes place as long as the exposure concentration remains constant.

AEROSOLS AND PARTICLES

Absorption of aerosol and particles is distinguished from gases and vapors by the factors that determine absorption from the inhalation route of exposure. The absorption of gases and vapors by inhalation is determined by the partitioning of the compound between the blood and the gas phase along with its solubility and tissue reactivity. In contrast, the important characteristics that affect absorption after exposure to aerosols are the aerosol size and water solubility of any chemical present in the aerosol.

The site of deposition of aerosols and particulates depends largely on the size of the particles. This relationship is discussed in detail in Chap. 15. In general, the smaller the particle, the further into the respiratory tree the particle will deposit (Fig. 5-6). Particles ranging from 5 μm or larger, described as “course particles” usually are deposited in the nasopharyngeal region. Those deposited on the unciliated anterior or rostral portion of the nose tend to remain at the site of deposition until they are removed by nose wiping, blowing, or sneezing. The mucous blanket of the ciliated nasal surface propels insoluble particles by the movement of the cilia. These particles and particles inhaled through the mouth are swallowed within minutes. Soluble particles may dissolve in the mucus and be carried to the pharynx or may be absorbed through the nasal epithelium into the blood.

Figure 5-6. Representation of particle distribution in the lungs relative to size. (Oberdorster *et al.*, 2005, with permission.)

Particulate matter with diameters of approximately 2.5 μm , referred to as “fine particles” are deposited mainly in the tracheo-bronchiolar regions of the lungs, from which they may be cleared by retrograde movement of the mucus layer in the ciliated portions of the respiratory tract (also known as the mucociliary escalator). The rate of cilia-propelled movement of mucus varies in different parts of the respiratory tract, although in general it is a rapid and efficient transport mechanism. Toxicants or viral infections that damage cilia may impair the efficiency of this process. Measurements have shown transport rates between 0.1 and 1 mm/min, resulting in removal half-lives between 30 and 300 minutes. Coughing and sneezing greatly increase the movement of mucus and particulate matter toward the mouth. Particles eventually may be swallowed and absorbed from the GI tract or expectorated.

Particles 1 μm and smaller penetrate to the alveolar sacs of the lungs. Ultrafine- or nanoparticles, particularly those that are approximately 10 to 20 nm in size, have the greatest likelihood of depositing in the alveolar region. These extremely small particles may be absorbed into blood or cleared through the lymphatics after being scavenged by alveolar macrophages (Oberdorster *et al.*, 2005).

In addition to being a major determinant of lung deposition, as particle size decreases, the number of particles in a unit of space increases along with the total surface area of the particles. This relationship, illustrated in Table 5-7, indicates that nanoparticles have the propensity to deliver high amounts of particulates to the lung. However, it appears that the surface properties of nanoparticles may be more important determinants of toxic potential than their size or surface area. The contribution of nanoparticles to toxic responses, with special emphasis on their disposition (and factors that influence disposition including size, composition, surface structure, surface group modification, solubility, and aggregation) are major areas of toxicological and human health effects research (Nel *et al.*, 2006; Stern and McNeil, 2008).

The mechanisms responsible for the removal or absorption of particulate matter from the alveoli are less clear than those responsible for the removal of particles deposited in the tracheobronchial tree. Removal appears to occur by three major mechanisms. First, particles may be removed from the alveoli by a physical process. As described earlier, it is thought that particles deposited on the fluid layer of the alveoli are aspirated onto the mucociliary escalator of the tracheobronchial region. From there, they are transported to the mouth and may be swallowed. The origin of the thin fluid layer in the alveoli is probably a transudation of lymph and secretions of lipids and other components by the alveolar epithelium. The alveolar fluid flows by an unknown mechanism to the terminal

bronchioles. This flow seems to depend on lymph flow, capillary action, the respiratory motion of the alveolar walls, the cohesive nature of the respiratory tract’s fluid blanket, the propelling power of the ciliated bronchioles, and the surface tension within the fluid layer. Second, particles from the alveoli may be removed by phagocytosis. The principal cells responsible for engulfing alveolar debris are the resident alveolar macrophages. These phagocytic cells are found in large numbers in normal lungs and contain many phagocytized particles of both exogenous and endogenous origin. They apparently migrate to the distal end of the mucociliary escalator and are cleared and eventually swallowed. Third, removal may occur via the lymphatics. The endothelial cells lining lymphatic capillaries are permeable to very large molecules and particles (molecular weight >1000 kDa), although the rate of penetration is low when molecular weight exceeds 10 kDa. Nevertheless, the lymphatic system plays a prominent role in collecting high-molecular-weight proteins leaked from cells or blood capillaries and particulate matter from the interstitium and the alveolar spaces. Particulate matter may remain in lymphatic tissue for long periods, and this explains the phenomenon of “dust store of the lungs.”

In general, the overall removal of particles from the alveoli is relatively inefficient. The rate of clearance by the lungs can be predicted by a compound’s solubility in lung fluids. The lower the solubility, the lower the removal rate. Thus, it appears that removal of particles that enter the alveoli is largely due to dissolution and vascular transport. Some particles may remain in the alveoli indefinitely. This may occur when long-lived alveolar macrophages phagocytose indigestible dust particles and secrete cytokines that stimulate the development of a local network of type I and III collagen fibers to form an alveolar dust plaque or nodule.

Absorption of Toxicants Through the Skin

Skin is the largest body organ and provides a relatively good barrier for separating organisms from their environment. Overall, human skin comes into contact with many toxic chemicals, but exposure is usually limited by its relatively impermeable nature. However, some chemicals can be absorbed by the skin in sufficient quantities to produce systemic effects. For example, there are several insecticides for which fatal exposures have occurred in agricultural workers after absorption through intact skin (see Chap. 19). In addition, there are numerous chemicals that increase tumor development in other organs after dermal application.

The skin comprises 2 major layers, the epidermis and dermis (Fig. 5-7). The epidermis is the outermost layer and contains keratinocytes that are metabolically competent and able to divide. Proliferating keratinocytes in the stratum germinativum displace maturing keratinocyte layers upward until they reach the outermost layer, the stratum corneum. The stratum corneum contains densely packed keratinized cells that have lost their nuclei and are biologically inactive. The stratum corneum is replaced approximately every 3 to 4 weeks in adult humans. This complex process involves dehydration and polymerization of intracellular matrix forming keratin-filled dried cell layers. During the process, the cell walls apparently double in thickness and transform into a dry, keratinous semisolid state with much lower permeability for diffusion of toxicants. The stratum corneum is unique anatomically and represents the single most important barrier to preventing fluid loss from the body while also serving as the major barrier to prevent the absorption of xenobiotics into the body.

The dermis is situated beneath the epidermis and consists primarily of fibroblasts. This region also contains the vascular network that provides the dermis and epidermis with blood supply and

serves to carry absorbed compounds into the body. Although the major anatomical area that controls absorption across the skin is the stratum corneum, compounds may also be absorbed through dermal appendages, including sweat and sebaceous glands and hair follicles found in the dermis. Sweat glands and hair follicles are scattered in varying densities on skin. These appendages account for no more than 1% of the total cross-sectional area of the total skin surface, and, in general, passage through these areas is much more rapid than passage through the stratum corneum. Ultimately, to be absorbed a chemical must pass the barrier of the stratum corneum and then traverse the other six layers of the skin (Dugard, 1983; Poet and McDougal, 2002).

In contrast to the complexity of the GI tract, the skin is a simpler penetration barrier for chemicals because passage through the stratum corneum is the rate-determining step. All toxicants move across the stratum corneum by passive diffusion. In general, lipophilic (fat-soluble) compounds are absorbed more readily across the stratum corneum, whereas the penetration of hydrophilic (water-soluble) compounds is more limited. Nonpolar toxicants diffuse through the skin in a manner that is proportional to their lipid solubility and inversely related to molecular weight. However, although lipophilic compounds may pass more readily through the stratum corneum, their passage through the dermis may become rate-limiting. Hydrophilic compounds are more likely to penetrate the skin through appendages such as hair follicles.

Human stratum corneum is significantly different in structure and chemistry in various regions of the body, and these differences affect the permeability of the skin to chemicals. Skin from the palmar and plantar regions is much different from skin from other areas of the body in that the stratum corneum of the palms and soles is adapted for weight bearing and friction and there are no hair follicles present. The stratum corneum of the rest of the body surface is adapted for flexibility and fine sensory discrimination. The

permeability of the skin also depends on both the diffusivity and the thickness of the stratum corneum. Although the stratum corneum is much thicker on the palms and soles (400–600 μm in callous areas) than on the arms, back, legs, and abdomen (8–15 μm), it has much higher diffusivity per unit thickness. In contrast, the skin of the scrotum is characterized by a thin stratum corneum and a high diffusivity. Consequently, as illustrated by the comparative absorption of malathion across different human skin sites (Table 5-8), toxicants are likely to readily cross scrotal skin, whereas absorption across forehead skin is less extensive, and penetration across the palm is lowest because of the thickness of the stratum corneum and the lack of dermal appendages.

The second phase of percutaneous absorption consists of diffusion of the toxicant through the lower layers of the epidermis (stratum germinativum, spinosum, and granulosum) and the dermis. Despite possessing tight intercellular junctions, these cell layers are

Table 5-8

far inferior to the stratum corneum as diffusion barriers. In contrast to the stratum corneum, they contain a porous, nonselective, aqueous diffusion medium. Toxicants pass through this area by diffusion and enter the systemic circulation through the numerous venous and lymphatic capillaries in the dermis. The rate of diffusion depends on blood flow, interstitial fluid movement, and perhaps other factors, including interactions with dermal constituents.

There are several factors that can influence the absorption of toxicants through the skin, including (1) the integrity of the stratum corneum, (2) the hydration state of the stratum corneum, (3) temperature, (4) solvents as carriers, and (5) molecular size. Because the stratum corneum plays a critical role in determining cutaneous permeability, removal of this layer causes a dramatic increase in permeability of the epidermis for a variety of large or small molecules, both lipid-soluble and water-soluble (Poet and McDougal, 2002). Caustic agents, such as acids and alkalis, that damage the stratum corneum increase its permeability. The most frequently encountered penetration-enhancing damage to the skin results from burns and various skin diseases. Water also plays an extremely important role in skin permeability. Under normal conditions, the stratum corneum is partially hydrated, containing about 7% water by weight. This amount of water increases the permeability of the stratum corneum approximately 10-fold over the permeability that exists when it is completely dry. On contact with water, the stratum corneum can increase its weight of tightly bound water up to 5-fold, which increases permeability an additional 2- to 3-fold. In many studies, the site of application will be covered with plastic wrap (occlusive application), originally described by Draize *et al.* (1944), to hydrate the stratum corneum and enhance the absorption of some toxicants. Similarly, an increase in temperature will increase dermal penetration by increasing dermal blood flow. This is particularly important for occupational exposures to chemicals such as insecticides in which agricultural workers are likely to be working strenuously at relatively high temperatures. Such environmental conditions increase dermal penetration and may increase the risk of systemic toxicity.

Solvents used to dissolve compounds of interest can also influence dermal penetration. In general, lower absorption will be observed if a toxicant is highly soluble in the vehicle, whereas low solubility of the toxicant in the vehicle will tend to increase dermal penetration. In addition, solvents such as dimethyl sulfoxide (DMSO) facilitate the penetration of toxicants through the skin by increasing the permeability of the stratum corneum. Although the mechanism by which DMSO enhances skin permeability is not fully understood, it has been suggested that it (1) removes much of the lipid matrix of the stratum corneum, making holes or artificial shunts in the penetration barrier; (2) alters keratin configuration to change protein structure; and (3) functions as a swelling agent (Williams and Berry, 2004).

With respect to molecular size, it is generally recognized that compounds above 400 Da exhibit poor dermal penetration. As such, nanoparticles may exhibit higher dermal absorption and systemic exposures in light of their small size. However, although nanoparticles appear to penetrate the skin as a function of their size, their overall absorption is relatively low. For nanomaterials, hair follicles can contribute to dermal penetration, and as a general rule, particles that are approximately 300 to 600 nm penetrate deeply into hair follicles, where the extensive capillary network around the follicles facilitates uptake (Lademann *et al.*, 2011). Based on these features, nanoparticle formulations may facilitate absorption from the skin. In contrast, nanosized particles of titanium dioxide and zinc oxide, which are widely used in sunscreens, do not appear to penetrate beyond the stratum corneum, a feature that is consistent with their skin protective effects (Newman *et al.*, 2009).

Dermal absorption has been studied in most laboratory animals including rats, mice, rabbits, guinea pigs, primates, and pig, and dermal absorption varies widely across these species. As a general rule, dermal absorption across rodent skin is greater than human skin, whereas the cutaneous permeability characteristics of guinea pigs, pigs, and monkeys are more similar to those observed in humans (Wester and Maibach, 1993). Species differences in percutaneous absorption account for the differential toxicity of insecticides in insects and humans. For example, the LD₅₀ of injected DDT is approximately equal in insects and mammals, but DDT is much less toxic to mammals than to insects when it is applied to the skin. This appears to be due to the fact that DDT is poorly absorbed through the skin of mammals but passes readily through the chitinous exoskeleton of insects. Furthermore, insects have a much greater body surface area relative to weight than mammals.

Species differences in dermal absorption of xenobiotics result from several anatomic, physiological, and biochemical factors (Dugard, 1983; Poet and McDougal, 2002). First, the composition and thickness of the stratum corneum along with the nature of the dermal appendages are highly variable across species. The stratum corneum is much thicker in humans than in most laboratory animals, making human skin typically less permeable than animal skin. However, the thinner stratum corneum in animals is often compensated for by a relatively thick hair cover, diminishing direct contact of the skin with a xenobiotic. Sweat and pilosebaceous ducts also vary across species. For example, eccrine sweat glands are located in the pads of the extremities of all mammals. However, the general body surface of humans contains 100 to 600/m² of coiled tubular sweat glands, whereas rodents, rabbits, cats, and dogs have none. The number of pilosebaceous ducts in humans and pigs is similar (about 40/cm²), but rodents may have up to 100 times more. Another important potential rate-limiting step in the dermal absorption of chemicals is the cutaneous blood flow. In humans, the skin plays an important thermoregulatory function as opposed to furred animals. Consequently, there is a much more extensive vasculature in humans than in most mammals (Calabrese, 1984). Biotransformation reactions in skin can also facilitate absorption, and the presence of metabolizing enzymes is highly variable across species. Xenobiotic transporters, including members of the ABC family and the SLCO and SLC families have been identified in skin with expression predominantly in keratinocytes. Differences in levels or patterns of expression of these transporters may also contribute to species differences in dermal absorption of toxicants (Kao *et al.*, 1985; Baron *et al.*, 2001).

Overall, commonly used laboratory animals are typically not good models of human absorption of toxicants. An example of the species differences and lack of concordance with human data for dermal absorption of the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) is illustrated in Table 5-9. As illustrated by these data, absorption through rat skin was higher than in other species. In general, absorption through primate or pig skin is considered to most closely predict human dermal absorption (Wester and Maibach, 1993). Additionally, *in vitro* methods using human skin may provide reasonable alternatives to the use of laboratory animals for evaluating dermal absorption of toxicants (Bronaugh *et al.*, 1982).

Absorption of Toxicants After Special Routes of Administration

Toxicants usually enter the bloodstream after absorption through the skin, lungs, or GI tract. However, in studying the effects of chemicals in laboratory animals, other routes of administration may also be used. The most common routes are (1) intravenous,

Table 5-9

Comparison of Dermal Absorption of 2,4-D Across Species

SPECIES	WASH TIME (HOUR)	COLLECTION TIME (HOUR)	% ABSORBED
Rat	24	336	20
Rabbit	24	336	12
Monkey	24	336	6
Human	4	120	3.7

NOTE: Data from Ross et al. (2005) and represent application of the dimethylamine salt of 2,4-dichlorophenoxyacetic acid (2,4-D). In all cases, the dose applied was 4 $\mu\text{g}/\text{cm}^2$. For rats, rabbits, and monkeys, the application site was washed after 24 hours, whereas human skin was washed after 4 hours. The collection time denotes the interval over which data were collected to determine absorption.

(2) intraperitoneal, (3) subcutaneous, and (4) intramuscular. The intravenous route introduces the toxicant directly into the bloodstream, eliminating the process of absorption. Intraperitoneal injection results in rapid absorption of xenobiotics because of the rich peritoneal and mesenteric blood supply and the relatively large surface area of the peritoneal cavity. In addition, this route of administration circumvents the delay and variability of gastric emptying. Intraperitoneally administered compounds are absorbed primarily through the portal circulation and therefore pass through the liver before reaching other organs. Subcutaneous and intramuscular injections usually result in slower absorption rates, but toxicants enter directly into the general circulation. The rate of absorption by these two routes can be altered by changing the blood flow to the injection site. For example, epinephrine causes vasoconstriction and will decrease the rate of absorption if it is coinjected intramuscularly with a toxicant. The formulation of a xenobiotic may also affect the rate of absorption, as toxicants are typically absorbed more slowly from suspensions than from solutions.

The toxicity of a chemical may or may not depend on the route of administration. If a toxicant is injected intraperitoneally, most of the chemical enters the liver via the portal circulation before reaching the general circulation. Therefore, with intraperitoneal administration, a compound may be completely extracted and biotransformed by the liver with subsequent excretion into bile without gaining access to the systemic circulation. Propranolol (Shand and Rangno, 1972) and lidocaine (Boyes *et al.*, 1970) are classical examples of drugs with efficient extraction during the first pass through the liver. A chemical with a high first-pass effect that is toxic in an organ other than the liver and GI tract is likely to be less toxic when administered

intraperitoneally than when administered by other routes (intravenously, intramuscularly, or subcutaneously) because the intraperitoneal route favors extraction in the liver to reduce what is available systemically. In contrast, compounds with no appreciable biotransformation in the liver are likely to show similar toxicity independent of the route of administration if the rates of absorption are equal. Therefore, preliminary information on the contribution of biotransformation and excretion of xenobiotics to toxic outcome can be derived by comparing toxic responses after administration by different routes.

DISTRIBUTION

After gaining entry into the bloodstream, regardless of route of exposure, a toxicant distributes to tissues throughout the body. The rate of distribution to organs or tissues is determined primarily by blood flow and the rate of diffusion out of the capillary bed into the cells of a particular organ or tissue, and usually occurs rapidly. The final distribution depends largely on the affinity of a xenobiotic for various tissues. In general, the initial phase of distribution is dominated by blood flow, whereas the eventual distribution is determined largely by affinity. The penetration of toxicants into cells occurs by passive diffusion or special transport processes, as discussed previously. Small water-soluble molecules and ions apparently diffuse through aqueous channels or pores in the cell membrane. Lipid-soluble molecules readily permeate the membrane itself. Very polar molecules and ions of even moderate size (molecular weight of 50 or more) cannot enter cells easily except by special transport mechanisms because they are surrounded by a hydration shell, making their actual size much larger.

Volume of Distribution

A key concept in understanding the disposition of a toxicant is its volume of distribution (Vd), a primary determinant of the concentration of a toxicant in blood that is used to quantify distribution throughout the body. It is defined as the volume in which the amount of drug would need to be uniformly dissolved in order to produce the observed blood concentration. Total body water is derived from that which is either extracellular or intracellular and represents three distinct compartments: plasma water and interstitial water comprise the extracellular compartment and are distinguished from intracellular water (Box 5-3). If a chemical distributes only to the plasma compartment (no tissue distribution), it has a high plasma concentration and hence, a low Vd. In contrast, if a chemical distributes throughout the body (total body water), the effective plasma concentration is low and hence, a high Vd. However, the distribution of toxicants is complex and under most circumstances cannot be simply equated with distribution into one of the water compartments of the body. Binding to and/

Box 5-3

Estimates of the Size of the Major Compartments That Contribute to Volume of Distribution

COMPARTMENT	PERCENTAGE OF TOTAL	LITER IN 70-kg HUMAN	PLASMA CONCENTRATION AFTER 1 g OF CHEMICAL (mg/L)
Plasma water	4.5	3	333
Total extracellular water	20	14	71
Total body water	55	38	26
Tissue binding	—	—	0–25

or dissolution in various storage sites of the body, such as fat, liver, and bone, are usually more important factors in determining the distribution of chemicals.

Some toxicants do not readily cross cell membranes and therefore have restricted distribution, whereas other toxicants rapidly pass through cell membranes and are distributed throughout the body. Some toxicants selectively accumulate in certain parts of the body as a result of protein binding, active transport, or high solubility in fat. The target organ for toxicity may be the site of accumulation, but this is not always the case. If a toxicant accumulates at a site other than the target organ or tissue, the accumulation is likely to be protective because plasma levels and consequently its concentration at the site of action is reduced. In this case, it is assumed that the chemical in the storage depot is toxicologically inactive. However, a chemical in a storage depot is also in equilibrium with the free fraction of the toxicant in plasma, so that it is released into the circulation as the unbound fraction of toxicant is eliminated. Examples illustrating a wide range of Vd are noted in Table 5-10, and the factors that contribute to the Vd are discussed below.

Storage of Toxicants in Tissues

Because only the free fraction of a chemical is in equilibrium throughout the body, binding to or dissolving in certain body constituents greatly alters the distribution of a xenobiotic. Some xenobiotics attain their highest concentrations at the site of toxic action, such as carbon monoxide, which has a very high affinity for hemoglobin, and paraquat, which accumulates in the lungs. Other chemicals concentrate at sites other than the target organ. For example, lead is stored in bone, but manifestations of lead poisoning appear in soft tissues. The compartment where a toxicant is concentrated is described as a storage depot. Toxicants in these depots are always in equilibrium with the free fraction in plasma, so that as a chemical is biotransformed or excreted from the body, more is released

Table 5-10

Examples of Factors that Contribute to Volume of Distribution (Vd)

COMPOUND	Vd (L/kg)	FACTORS INFLUENCING DISTRIBUTION
Warfarin	0.1	High plasma protein binding with little distribution into tissues
Ethanol	0.5	Distribution in total body water
Propranolol	4.3	Distributed to peripheral tissues
Tamoxifen	50	Extensive distribution to peripheral tissues and high protein binding
Chloroquine	100	High tissue uptake and trapping in lysosomes

from the storage site. As a result, the biological half-life of stored compounds can be very long.

Plasma Proteins as Storage Depot Binding to plasma proteins is the major site of protein binding, and several different plasma proteins bind xenobiotics and some endogenous constituents of the body. As depicted in Fig. 5-8, albumin is the major protein in plasma and it binds many different compounds. α_1 -Acid glycoprotein, although present at a much lower concentration than albumin, is also an important protein in plasma, and compounds with basic characteristics tend to bind to it. Transferrin, a β -globulin, is important for the transport of iron in the body. The other major metal-binding protein in plasma is ceruloplasmin, which carries copper. The α - and β -lipoproteins are very important in the transport of

Figure 5-8. Schematic representation of the electrophoretic separation of plasma proteins and xenobiotics that interact with these proteins.

lipid-soluble compounds such as vitamins, cholesterol, and steroid hormones as well as xenobiotics. Plasma γ -globulins are antibodies that function specifically in immunological reactions. Overall, plasma proteins bind acidic compounds such as phenylbutazone, basic compounds such as imipramine, and neutral compounds such as digitoxin.

Albumin, present in the plasma at a concentration of 500 to 600 μM , is the most abundant protein in plasma and serves as both a depot and multivalent transport protein for many endogenous and exogenous compounds. Protein–ligand interactions occur primarily as a result of hydrophobic forces, hydrogen bonding, and Van der Waals forces. Because of their high molecular weight, plasma proteins and the toxicants bound to them cannot cross capillary walls. Consequently, the fraction of a toxicant bound to plasma proteins is not immediately available for distribution into the extravascular space or filtration by the kidneys. However, the interaction of a chemical with plasma proteins is a reversible process, and as unbound chemical diffuses out of capillaries, bound chemical dissociates from the protein until the free fraction reaches equilibrium between the vascular space and the extravascular space. In turn, diffusion in the extravascular space to sites more distant from the capillaries continues, and the resulting concentration gradient provides the thermodynamic force for continued dissociation of the bound fraction in plasma. Active transport processes are not limited by the binding of chemicals to plasma proteins.

The binding of toxicants to plasma proteins is usually determined by equilibrium dialysis or ultrafiltration. The total amount in plasma is determined prior to these separation methods, and the fraction that passes through a dialysis membrane or appears in the ultrafiltrate is the unbound (or free) fraction. The bound fraction is determined as the difference between the total and unbound fractions. The extent of plasma protein binding varies considerably among xenobiotics. Some, such as antipyrine, are not bound; others, such as secobarbital, are bound to about 50%; and some, such as warfarin, are 99% bound. For warfarin, the high protein binding is the single most important determinant of its V_d , which is limited to the plasma compartment (Table 5-10).

The binding of chemicals to plasma proteins is an important concept in toxicology for two reasons. Toxicity is typically manifested by the amount of a xenobiotic that is unbound. Therefore, a compound with a high degree of plasma protein binding may not show toxicity when compared to one that is less extensively bound to plasma proteins. Ironically, a high degree of protein binding also tends to increase the risk of adverse effects resulting from interactions with other highly bound compounds. In particular, severe toxic reactions can occur if a toxicant with a high degree of protein binding is displaced from plasma proteins by another chemical, increasing the free fraction of the toxicant in plasma. This interaction increases the equilibrium concentration of the toxicant in a target organ, thereby increasing the potential for toxicity. For example, if a compound is 99.9% bound to plasma protein (0.1% free), then an interaction that decreases protein binding to 99.5%, which may seem to be a minor change, is effectively a 5-fold increase in the free plasma concentration (0.5% free). Most research on the adverse interactions associated with binding of xenobiotics to plasma proteins has been conducted with drugs. For example, if a strongly bound sulfonamide is given concurrently with an anti-diabetic drug, the sulfonamide may displace the anti-diabetic drug and induce a hypoglycemic coma. Similarly, interactions resulting from displacement of warfarin can lead to inappropriate blood clotting and possible deleterious effects. Xenobiotics can also compete with and displace endogenous compounds that are bound to plasma

proteins. The importance of this phenomenon was demonstrated in a notable clinical trial comparing the efficacy of tetracycline with that of a penicillin–sulfonamide mixture in the management of bacterial infections in premature infants (Silverman *et al.*, 1956). The penicillin–sulfonamide mixture led to much higher mortality than did the tetracycline because the sulfonamide displaced a considerable amount of bilirubin from albumin. Free bilirubin then diffused into the brain of the newborns (because the BBB is not fully developed), causing a severe form of brain damage termed kernicterus. In addition to drugs, some chemicals, such as the insecticide dieldrin, also bind avidly to plasma proteins (99%). Therefore, it is to be expected that chemical–chemical interactions that alter plasma protein binding occur with many different xenobiotics.

Plasma protein binding can also give rise to species differences in the disposition of xenobiotics. For example, plasma protein binding of clofibrac acid is considerably different between mice, rats, and humans and correlates with the half-lives of this compound in these species (Table 5-11). Because clofibrac acid is primarily eliminated in all three species by renal glomerular filtration without tubular reabsorption, differences in the free fraction of this compound in plasma across the species contribute to the observed species differences in drug half-life. Additional factors that influence plasma protein binding across species include differences in the concentration of albumin, in binding affinity, and/or in competitive binding of endogenous substances.

Liver and Kidney as Storage Depots The liver and kidney have a high capacity for binding many chemicals. These two organs probably concentrate more toxicants than do all the other organs combined, and, in most cases, active transport or binding to tissue components are likely to be involved.

Hepatic uptake of lead illustrates how rapidly liver binds foreign compounds: just 30 minutes after a single dose, the concentration of lead in liver is 50 times higher than the concentration in plasma (Klaassen and Shoeman, 1974). In addition, some proteins serve to sequester xenobiotics in the liver or kidney. For example, metallothionein (MT), a specialized metal-binding protein, sequesters both essential and toxic metals including zinc and cadmium (Cd) with high affinities in the kidney and liver. In liver, Cd bound to MT serves to concentrate and sequester the heavy metal while preventing its excretion into bile. In kidney, however, the Cd–MT complex is very toxic and is mechanistically involved in the chronic toxicity of Cd (Klaassen and Liu, 1997). Another protein that sequesters certain toxicants in the kidney is $\alpha_2\text{u}$ -globulin. This protein, which is synthesized in large quantities only in male rats, binds to a diverse array of xenobiotics including metabolites of D-limonene (a major constituent of orange juice) and 2,4,4-trimethylpentane (found in unleaded gasoline). The chemical- $\alpha_2\text{u}$ -globulin complex is taken up by the kidney, where it accumulates within

the lysosomal compartment and damages the proximal tubule cells. Ultimately, the accumulation of this complex in the kidney is responsible for male-rat specific nephrotoxicity and carcinogenicity (Lehman-McKeeman, 2010).

As noted in Table 5-10, chloroquine has a very high Vd, which is determined largely by extensive storage in peripheral tissues. This compound is an example of a wide range of chemicals referred to as cationic amphiphiles. At physiological pH, chloroquine is non-ionized, but once in cells, it is taken up into the acidic milieu of the lysosome where it becomes highly ionized (as per Henderson-Hasselbalch equations) and is subsequently trapped in this compartment. A variety of xenobiotics share these attributes, which ultimately lead to lysosomal dysfunction and the accumulation of phospholipids, referred to as phospholipidosis (Hanumegowda *et al.*, 2010).

Fat as Storage Depot There are many organic compounds that are highly stable and lipophilic, leading to their accumulation in the environment. The lipophilic nature of these compounds also permits rapid penetration of cell membranes and uptake by tissues, and it is not surprising that highly lipophilic toxicants are distributed and concentrated in body fat where they are retained for a very long time. The environmental accumulation and potential toxicological significance of long-term storage of numerous compounds including the pesticides aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, mirex, and toxaphene, along with polychlorinated and polybrominated biphenyls, polybrominated flame retardants, dioxins, and furans is a major issue in toxicology. There is extensive research efforts designed to assess the potential for these compounds to produce carcinogenic, developmental, and endocrine effects, which is directly related to their accumulation and storage in body fat (Jandacek and Tso, 2001).

Toxicants appear to accumulate in fat by dissolution in neutral fats, which constitute about 50% and 20% of the body weight of obese individuals and lean athletic individuals, respectively. Thus, toxicants with a high lipid/water partition coefficient may be stored in body fat, and higher amounts are likely to be retained in obese individuals. Storage lowers the concentration of the toxicant in the target organ such that toxicity is likely to be less severe in an obese person than in a lean individual. However, of more practical toxicological concern is the possibility that a sudden increase in the concentration of a chemical in blood and the target organ of toxicity may occur if rapid mobilization from fat occurs. Several studies have shown that signs of intoxication can be produced by short-term starvation of experimental animals that were previously exposed to persistent organochlorine insecticides.

There have been numerous attempts to alter storage of lipophilic toxins in adipose tissues in animal models and humans. Changes in body fat composition appear to be the most effective in reducing body burdens, and interventions designed to reduce the absorption of these compounds from the GI tract appear to be somewhat helpful in reducing storage depots of persistent organic pollutants in fat (Jandacek and Tso, 2001).

Bone as Storage Depot Compounds such as fluoride, lead, and strontium may be incorporated and stored in the bone matrix. For example, 90% of the lead in the body is eventually found in the skeleton. Skeletal uptake of xenobiotics is essentially a surface chemistry phenomenon, with exchange taking place between the bone surface and the fluid in contact with it. The fluid is the extracellular fluid, and the surface is that of the hydroxyapatite crystals of bone mineral. Many of those crystals are very small, resulting in a large surface area relative to the mass of the bone. The extracellular fluid brings the toxicant into contact with the hydration shell

of the hydroxyapatite, allowing diffusion through it and penetration of the crystal surface. As a result of similarities in size and charge, F⁻ may readily displace OH⁻, whereas lead or strontium may substitute for calcium in the hydroxyapatite lattice matrix through an exchange-adsorption reaction.

Foreign compounds deposited in bone are not sequestered irreversibly by that tissue. Toxicants can be released from the bone by ionic exchange at the crystal surface and dissolution of bone crystals through osteoclastic activity. An increase in osteolytic activity such as that seen after parathyroid hormone administration leads to enhanced mobilization of hydroxyapatite lattice, which can be reflected in an increased plasma concentration of toxicants. Ultimately, deposition and storage of toxicants in bone may or may not be detrimental. Lead is not toxic to bone, but the chronic effects of fluoride deposition (skeletal fluorosis) and radioactive strontium (osteosarcoma and other neoplasms) are well documented.

Blood-Brain Barrier

Access to the brain is restricted by the presence of two barriers: the BBB and the blood-cerebral spinal fluid barrier (BCSFB). Although neither represents an absolute barrier to the passage of toxic chemicals into the CNS, many toxicants do not enter the brain in appreciable quantities because of these barriers.

The BBB is formed primarily by the endothelial cells of blood capillaries in the brain (Fig. 5-9). Each endothelial cell forms a tight junction with adjacent cells, essentially forming a tight seal between the cells and preventing diffusion of polar compounds through paracellular pathways. Diffusion of more lipophilic compounds through endothelial cell membranes is counteracted by xenobiotic efflux transporters present in the endothelial cells. Glial cells, particularly astrocytes, contribute to the BBB by secreting chemical factors that modulate endothelial cell permeability, and astrocytes and perivascular microglial cells extend processes that support the integrity of the BBB. For small- to medium-sized water-soluble molecules, the tighter junctions of the capillary endothelium and the lipid membranes of the glial cell processes represent the major barrier. Although the absorption of lipid-soluble compounds is favored in the brain, such compounds must traverse the membranes of the endothelial cells, not be substrates for xenobiotic transporters, and then traverse the glial cell processes to enter the brain.

Although the BBB is a physical structure that limits distribution to the brain, active transport processes also play a pivotal role in determining the concentration of xenobiotics in the brain. Numerous ATP-dependent transporters have been identified as part of the BBB, comprising various members of the ABC and SLC families (Fig. 5-9) (Kusuhara and Sugiyama, 2005; Deeken and Loscher, 2007; Miller, 2010). Efflux transporters, including MDR1, BCRP, MRP1, 2, 4, and 5 are located on the apical (blood side)

Figure 5-9. Schematic model showing the xenobiotic transporting systems that contribute to the human blood-brain barrier.

Figure 5-10. Schematic model showing the xenobiotic transporting systems that contribute to the human blood–cerebral spinal fluid barrier.

plasma membrane and function to move xenobiotics absorbed into the capillary endothelial cells out into the blood, thereby limiting distribution into the brain. Uptake transporters, including OATP1A2 and OATP1C1 are found on both the basolateral and apical side of the endothelium, and can drive a concentrative efflux if coupled energetically to the electrical potential difference across the endothelial cell membrane. OATP1C1 is suggested to specifically transport thyroid hormone into the brain. Finally, uptake transporters on the apical membranes include OAT3 and CTN2. In combination, these transporters can efficiently efflux a wide range of anionic, cationic, uncharged, and numerous drug conjugates from the brain.

The BCSFB is found between the circulating blood and the circulating cerebral spinal fluid in the brain (Fig. 5-10). It comprises elements of the choroid plexus, the arachnoid membrane, and certain periventricular locations (including the area postrema). The choroid plexus has highly permeable endothelial cells on the blood side but is lined by epithelial cells on the CSF side that form the barrier. Xenobiotic transporters also contribute to removing compounds that may enter the endothelial cells. Blood flow through the choroid plexus is about 10 times higher than in the brain, a feature that provides the high turnover of biological fluids necessary to support the dynamic changes in nutrients required for neuronal function. Furthermore, the protein concentration in CSF is much lower than that in other body fluids. The low protein content of the CSF also limits the movement of water-insoluble compounds by paracellular transport, which is possible in a largely aqueous medium only when such compounds are bound to proteins. In general, toxicants achieve concentrations in the CSF that are no higher than the concentration of the unbound toxicant in the plasma. The BCSFB is more of an anatomical entity than a true barrier, but it does provide some protection against the distribution of toxicants to the CNS, thereby affording some protection against toxicity.

Xenobiotic transporters are also expressed in the epithelial cells of the choroid plexus, but within the BCSFB, MDR1 and Mrp1 are thought to play the most important roles (Fig. 5-10). In this barrier, MDR1 is expressed on the luminal side, with efflux from the choroidal epithelial cells into the CSF. In contrast, MRP1 is expressed on the basolateral side of the choroidal epithelium, catalyzing the transport of xenobiotics out of the cells and into the vascular compartment, and it has been suggested that MDR1 and MRP1 may play an important function to coordinate the absorption and secretion of toxicants into the CNS at the BCSFB (Deeken and Loscher, 2007). Members of the OATP, OAT, OCT, and PEPT families are also expressed in the choroid plexus (Klaassen and Aleksunes, 2010). The function of these proteins is not well

characterized, but studies in rodents suggest that Oatps, particularly Oatp1a4, play an important role in regulating xenobiotic concentrations in the CSF.

The importance of transport processes to the maintenance of the BBB has been demonstrated in genetically modified mouse models. Compounds that are substrates for MDR1 achieve much higher brain levels in P-gp null (*Mdr1a*^{-/-}/*Mdr1b*^{-/-}) mice relative to wild-type mice, and are likely to show increased toxicity as well. Seminal studies demonstrated that MDR1 null mice were far more sensitive to the insecticide, ivermectin, and the anticancer agent, vinblastine. The brain uptake of these compounds was increased 26- and 80-fold, respectively, and the sensitivity to neurotoxicity or lethality was increased up to 100-fold (Schinkel *et al.*, 1994; Lankas *et al.*, 1997). Expression of Mrp1 in the choroid plexus has been shown to modulate the concentrations of toxicants in the cerebral spinal fluid, but no studies have yet shown a correlation to neurotoxic potential relative to Mrp1 function.

In addition to their role in regulating distribution of xenobiotics into the CNS, transporter function is also implicated in neurological diseases. MDR1 and BCRP contribute to the efflux of β -amyloid from the brain. This protein is known to accumulate in Alzheimer's disease, and there is evidence that MDR1 levels are decreased in Alzheimer's patients, with a concomitant increase in BCRP expression. There is also ongoing work to determine the potential for MDR1 to remove toxicants from the brain in a manner that may ultimately be protective against the development of Parkinson's disease (Miller, 2010). These observations require more research, with particular emphasis on how altered transporter function or expression may be affected by toxicant exposures that could contribute to human diseases.

The effectiveness of the BBB varies from one area of the brain to another. For example, the cortex, the lateral nuclei of the hypothalamus, the area postrema, the pineal body, and the posterior lobe of the hypophysis are more permeable than are other areas of the brain. It is not clear whether this is due to the increased blood supply to those areas, or because the BCSFB represents a more permeable barrier, or both. In general, the entrance of toxicants into the brain follows the same principle that applies to transfer across other cells in the body. Only the free fraction of a toxicant (ie, not bound to plasma proteins) equilibrates rapidly with the brain. Lipid solubility plays an important role in determining the rate of entry of a compound into the CNS, as does the degree of ionization, as discussed earlier. Lipid solubility enhances the rate of penetration of toxicants into the CNS, whereas ionization greatly diminishes it. 2-PAM, a quaternary nitrogen derivative, does not readily penetrate the brain and is ineffective in reversing the inhibition of brain cholinesterase caused by organophosphate insecticides. Some very lipophilic compounds may enter the brain but are so efficiently removed by xenobiotic transporters that they do not reach appreciable concentrations. This is particularly true for agents such as cyclosporin. TCDD, which is highly lipophilic, is also not readily distributed into the brain, but it is not known whether transporters influence its distribution to the brain. It is likely that strong binding to plasma proteins or lipoproteins, as well as the composition of the brain (mainly phospholipids), limits the entry of very lipophilic compounds into the brain. Some xenobiotics, although very few, may enter the brain by carrier-mediated processes. For example, methylmercury combines with cysteine, forming a sulfhydryl complex that is similar to methionine, which can be utilized as the large neutral amino acid carrier of the capillary endothelial cells for uptake into the brain (Clarkson, 1987).

The BBB is not fully developed at birth, and this is one reason why some chemicals are more toxic in newborns than adults. The

Table 5-12

Features of the Placental Barrier Based on Separation of Fetal and Maternal Blood

TYPE	SPECIES	MATERNAL TISSUE		
		ENDOTHELIUM	CONNECTIVE TISSUE	EPITHELIUM
Epitheliochorial	Pig, horse, donkey	+	+	+
Synepitheliochorial	Cow, sheep, goat	+	+	–
Endotheliochorial	Cat, dog, elephant	+	–	–
Hemochorial	Human, monkey	–	–	–
Hemoendothelial	Rat, rabbit, guinea pig	–	–	–

Fetal layers that separate maternal and fetal blood also include the endothelial, connective tissue, and epithelial components in all types of placentas.

In the hemoendothelial type, only the fetal epithelium is present.

SOURCE: Modified from Morris *et al.* (1994), Enders and Carter (2004).

example of kernicterus resulting from increased brain levels of bilirubin in infants was noted earlier. In addition, morphine is 3 to 10 times more toxic to newborn than to adult rats because of the higher permeability of the brain of a newborn to morphine. Similarly, lead produces encephalomyelopathy in newborn rats but not in adults, apparently because of differences in the stages of development of the BBB.

Passage of Toxicants Across the Placenta

The term placental barrier has been associated with the concept that the main function of the placenta is to protect the fetus against the passage of noxious substances from the mother. However, the placenta is a multifunctional organ that also provides nutrition for the conceptus, exchanges maternal and fetal blood gases, disposes of fetal excretory material, and maintains pregnancy through complex hormonal regulation. Placental structure and function show more species differences than any other mammalian organ. Anatomically, the placental barrier consists of several cell layers interposed between the fetal and maternal circulations, but the number of cell layers varies across species and with the stage of gestation. The maximum number of cell layers in placentas is 6 (3 maternal and 3 fetal layers), and when all 6 layers are present, the placenta is termed epitheliochorial (Table 5-12). Those in which the maternal epithelium is absent are referred to as syndesmochorial. When only the endothelial layer of the maternal tissue remains, the tissue is termed endotheliochorial; when even the endothelium is gone (as in humans), the chorionic villi bathe in the maternal blood, and the tissue is called hemochorial. In some species, the maternal layers are absent along with the fetal endothelial and connective tissue, and these are called hemoendothelial. Within the same species, the placenta may also change its histological classification during gestation. For example, at the beginning of gestation, the placenta of a rabbit has 6 major layers (epitheliochorial), and at the end it has only one (hemoendothelial). Overall, there are marked species differences in placental structure. The animal models that are most similar to the organization of the human placenta based on its hemochorial histological organization are rodents and primates, but the decidua nature of the rodent placenta still differs markedly from that of humans (Myllynen *et al.*, 2005; Leiser and Kauffman, 1994).

Most of the vital nutrients necessary for the development of the fetus are transported by active transport systems. For example, vitamins, amino acids, essential sugars, and ions such as calcium and iron are transported from mother to fetus against

a concentration gradient (Ganapathy *et al.*, 2000). In contrast, most toxic chemicals pass the placenta by simple diffusion. The only exceptions are a few antimetabolites that are structurally similar to endogenous purines and pyrimidines, which are the physiological substrates for active transport from the maternal to the fetal circulation. The placenta also has biotransformation capabilities that may prevent some toxic substances from reaching the fetus (Syme *et al.*, 2004; Prouillac and Lecoeur, 2010). Among the substances that cross the placenta by passive diffusion, more lipid-soluble substances rapidly attain a maternal-fetal equilibrium. Under steady-state conditions, concentrations of a toxic compound in the plasma of the mother and fetus are usually the same.

Many foreign substances can cross the placenta, and the same factors that dictate the passage of xenobiotics across biological membranes are important determinants of the placental transfer. These include previously discussed attributes including degree of ionization, lipophilicity, protein binding, and molecular weight along with blood flow and the concentration gradient across the barrier. In addition to chemicals, viruses (eg, rubella virus), cellular pathogens (eg, syphilis spirochetes), and globulin antibodies can traverse the placenta. In this regard, the placental barrier is not as precise an anatomical unit like the BBB. The human placenta includes the syncytiotrophoblast and cytotrophoblast layers. The apical membrane of the syncytiotrophoblast, which forms a continuous epithelial layer, is bathed in maternal blood and the basolateral surface is in contact with the discontinuous cytotrophoblast layer, the stromal tissue, or the fetal vasculature. To reach the fetus, toxins must traverse the apical and basolateral membranes of the syncytiotrophoblast as well as the endothelium of the fetal capillaries. Xenobiotic transporters are differentially expressed in these various cells and contribute to the barrier function that restricts distribution of toxicants to the fetus. The transporters are also critical to the movement of nutrients from the maternal circulation to the fetus along with the transfer of toxicants or waste products from the fetus back to the maternal circulation. Of the various cells in the placenta, the syncytiotrophoblasts appear to have the most extensive cohort of xenobiotics transporters (Fig. 5-11). In particular, BCRP is highly expressed in these cells. In fact, BCRP expression is highest in the human placenta relative to any other organ. BCRP, MDR1, and several MRPs are also expressed on the apical border of the syncytiotrophoblast where they play important roles in protecting the fetus from toxicants while regulating the movement of essential nutrients. Several uptake transporters are also expressed on the apical membrane, including OCTNs and OATPs. In contrast,

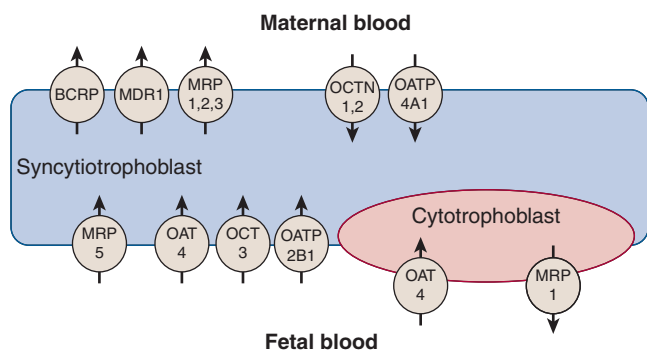

Figure 5-11. Schematic model showing the transport systems that contribute to the barrier function of the human placenta.

the efflux transporter, MRP5 is expressed on the basolateral side of the syncytiotrophoblast along with uptake transporters including OAT4, OCT3, and OATP2B1. Expression of transporters in other cells of the placenta is less characterized, but it appears that the cytotrophoblasts express MRP1 and OAT4 (Prouillac and Lecoeur, 2010; Klaassen and Aleksunes, 2010).

There are several examples illustrating that placental transporters protect the developing fetus from toxicant exposure and possible abnormal development. For example, the fetal concentration of the antibiotic nitrofurantoin is increased 5-fold in Bcrp-null mice, demonstrating that it prevents fetal exposure to this drug (Zhang *et al.*, 2007). Furthermore, homozygous offspring of female MDR1 null mice (*Mdr1a*^{-/-}/*Mdr1b*^{-/-}) develop cleft palate when treated with a photoisomer of avermectin, whereas heterozygous littermates showed intermediate susceptibility and wild-type mice were resistant to this adverse effect (Lankas *et al.*, 1998). Finally, it has been shown that some anticonvulsants, including known developmental toxicants such as valproic acid and phenytoin (see Chap. 10), inhibit OCTN2 function in human placental membrane vesicles (Wu *et al.*, 2004). This transporter is critical for the uptake of carnitine, leading to the hypothesis that inhibition of carnitine uptake by valproic acid (or other drugs) with subsequent fetal deficiency of carnitine may be involved in the adverse developmental effects associated with a variety of anticonvulsant drugs.

Despite the presence of biotransformation systems and xenobiotic transporters designed to nourish and protect the fetus, the transfer of xenobiotics across the placenta can still occur. One important consequence of placental transfer is that of transplacental carcinogenesis. In this case exposing the mother during gestation increases the likelihood of tumor development in the offspring later in life (see Chap. 8). The most well-known transplacental carcinogen in humans is diethylstilbestrol (Newbold and McLachlan, 1996), but other compounds such as the antiviral drug zidovudine (Diwan *et al.*, 1999) and inorganic arsenic (Waalkes *et al.*, 2003; Tokar *et al.*, 2011) induce tumors in mice when exposed to these chemicals only during gestation.

Redistribution of Toxicants

The most critical factors that affect the distribution of xenobiotics are the organ blood flow and its affinity for a xenobiotic. The initial phase of distribution is determined primarily by blood flow to the various parts of the body. Therefore, a well-perfused organ such as the liver may attain high initial concentrations of a xenobiotic. However, chemicals may have a high affinity for a binding site (eg, intracellular protein or bone matrix) or to a cellular constituent (eg, fat), and with time, will redistribute to these high affinity sites. For example, although 50% of a dose of lead

is found in the liver two hours after administration, one month later, 90% of the lead remaining in the body is associated with the crystal lattice of bone. Similarly, persistent organic pollutants do not distribute rapidly to fat, but accumulate selectively in adipose tissue over time.

EXCRETION

Toxicants are eliminated from the body by several routes. The kidney is perhaps the most important organ for the excretion of xenobiotics because more chemicals are eliminated from the body by this route than by any other (see Chap. 14). Biotransformation to more water-soluble products is usually a prerequisite to the excretion of xenobiotics through urine (see Chap. 6). The second important route of elimination of many xenobiotics is through feces, and the third, primarily for gases, is through the lungs. Biliary excretion of xenobiotics and/or their metabolites is most often the major source of fecal excretion, but a number of other sources can be significant for some compounds. All body secretions appear to have the ability to excrete chemicals; toxicants have been found in sweat, saliva, tears, and milk.

Urinary Excretion

The kidney is a very efficient organ for the elimination of toxicants from the body. The functional unit of the kidney is the nephron, comprising the glomerulus, a capillary tuft that initiates the process of filtration of the blood, and tubular elements within the renal cortex and medulla that function to produce and concentrate urine. Toxic compounds are excreted in urine by the same mechanisms the kidney uses to remove the end products of intermediary metabolism from the body, including glomerular filtration, tubular excretion by passive diffusion, and active tubular secretion. In general, the excretion of small molecular weight (<350 Da), water-soluble compounds is favored in urine.

The kidney receives about 25% of the cardiac output, about 20% of which is filtered at the glomeruli. The glomerular capillaries have large pores (approximately 70 nm), which filter compounds up to a molecular weight of about 60 kDa (smaller than albumin). Thus, the degree of plasma protein binding affects the rate of glomerular filtration because protein–xenobiotic complexes, particularly those bound to albumin, will not be filtered. Glomerular filtration rates vary considerably across species, ranging from a high of approximately 10 mL/min/kg in mice to about 1.8 mL/min/kg in humans. This difference appears to be determined by the relative number of nephrons per kilogram of body weight, with mice being the highest (Lin, 1995; Walton *et al.*, 2004).

A toxicant filtered at the glomerulus may remain in the tubular lumen and be excreted in urine. Depending on the physicochemical properties of a compound, it may be reabsorbed across the tubular cells of the nephron back into the bloodstream. The principles governing the reabsorption of toxicants across the kidney tubules are the same as those discussed earlier in this chapter for passive diffusion across cell membranes. Thus, toxicants with a high lipid/water partition coefficient are reabsorbed efficiently, whereas polar compounds and ions are excreted in urine. The pH of urine may vary but it is usually slightly acidic (approximately 6–6.5). Just as the Henderson–Hasselbach calculations determine the absorption of nonionized compounds from the GI tract, they also determine urinary excretion. In this case, urinary excretion of the ionized moiety is favored, such that bases are excreted to a greater extent at lower pH whereas excretion of acids predominates at higher urinary pH. A practical application of this knowledge is illustrated by the

treatment of phenobarbital poisoning with sodium bicarbonate. The percentage of ionization is increased markedly within physiologically attainable pH ranges for a weak organic acid such as phenobarbital ($pK_a = 7.2$) such that alkalinization of urine increases the fraction of drug in the ionized state, thereby increasing the urinary excretion of phenobarbital. Similarly, excretion of salicylate can be accelerated by administering sodium bicarbonate. In a similar manner, urinary acidification can be used to increase the excretion of a weak base such as phencyclidine (PCP) in drug abusers.

Toxic agents can also be excreted from plasma into urine by passive diffusion through the tubule. This process is probably of minor significance because filtration is much faster than excretion by passive diffusion through the tubules, providing a favorable concentration gradient for reabsorption rather than excretion. Exceptions to this generalization may be some organic acids ($pK_a \approx 3-5$) and bases ($pK_a \approx 7-9$) that would be largely ionized and thus trapped at the pH of urine ($pH \approx 6$). For renal excretion of such compounds, the flow of urine is likely to be important for the maintenance of a concentration gradient, favoring excretion. Thus, diuretics can hasten the elimination of weak organic acids and bases because they increase urine flow.

Xenobiotics can also be excreted into urine by active secretion. This process involves the uptake of toxicants from the blood into the cells of the renal proximal tubule, with subsequent efflux from the cell into the tubular fluid from which urine is formed. Fig. 5-12 illustrates the various families of transporters expressed in the human kidney that are directly involved in xenobiotic disposition. There are numerous other transporters such as specific glucose transporters or nucleotide transporters that play a role predominantly in the flux of endogenous substances, which are not presented here. Transporters may be expressed on the apical cell membrane where efflux pumps contribute to tubular secretion and influx pumps are important for reabsorption. Transporters localized to the basolateral membranes serve to transport xenobiotics to and from the systemic circulation or the renal tubular cells and also contribute to reabsorptive and excretory processes. Renal functional activity, as may be altered by toxicant exposure, can also be evaluated by determining the renal clearance of transporter substrates such as the widely used organic anion, *p*-aminohippurate (PAH).

Transporters expressed on the basolateral side of the renal tubules in humans that contribute mainly to excretion include OATs,

OCTs, and OATP4C1. The OAT family is a major contributor to urinary excretion as these proteins mediate the renal uptake of organic acids such as PAH and the renal exchange of dicarboxylates. In humans, OAT1, 2, 3 are expressed on the basolateral membrane, whereas OAT4 is localized to the brush-border membrane. In contrast, in rodents, Oat1 and 3 are localized to the basolateral membranes. Although the OATs play an important role in the physiological exchange of metabolites in the kidney, they can also contribute to the development of renal toxicity. In particular, the clinical use of antiviral drugs cidofovir and adefovir is limited by nephrotoxicity that is mediated by the accumulation of these drugs in the proximal tubule by OAT1 (Ho *et al.*, 2000). Additionally, OAT1 mediates the uptake of methylmercury and ochratoxin A, and as such, may play a role in the nephrotoxicity associated with these toxicants (Rizwan and Burckhardt, 2007).

The OCT family is responsible for the renal uptake of some cations, particularly those of low molecular weight. Substrates for OCTs include endogenous compounds such as choline, tetraethylammonium (TEA), and certain cationic drugs including cisplatin, cimetidine, metformin, and acyclovir. OCT2 is highly expressed in human kidney, whereas OCT1 and 2 are expressed on the basolateral membranes of the rodent kidney (Shitara *et al.*, 2005). The antineoplastic drug, cisplatin, is a substrate and inhibitor of OCT2, and the dose-limiting nephrotoxicity associated with this drug may be directly related to uptake-mediated concentration of drug in the proximal tubule epithelium (Zolk and Fromm, 2011).

A second cation transporter is OCTN, and 2 isoforms, OCTN1 and OCTN2 are localized to the brush-border membranes in human and rodent kidney. Substrates include cations such as TEA, and OCTN2 is particularly important in the renal reabsorption of carnitine, which is an essential cofactor for fatty acid β -oxidation.

In kidney, peptide transporters, localized to the brush-border membrane of the proximal tubule are important for the reuptake of di- and tripeptides. Two transporters, PEPT1 and PEPT2 have been identified in the human and rodent kidney, with PEPT1 localized in the upper region of the proximal tubule (pars convoluta) and PEPT2 expressed in the lower region (pars recta) of the convoluted tubule.

MDR1, MRP2, and MRP4 are also found on the luminal brush border of the proximal tubule, where they contribute to the efflux of xenobiotics out of the cells and into the tubular fluid, thereby enhancing excretion. In general, these efflux transporters work in

Figure 5-12. Schematic model showing the transport systems in the human proximal tubule of the kidney.

concert with uptake transporters to accomplish the urinary excretion of xenobiotics. For example, following OAT-mediated uptake of adefovir (described above), MRP4 transports the potentially toxic drug out of the cell and into the tubular fluid. Similarly, MATE1 and MATE2K are expressed on the apical membrane of renal tubular cells and contribute to the functional coordination of the urinary excretion of cationic compounds. For example, there is a recognized interplay between OCT2-mediated uptake of organic cations, such as metformin, followed by the secretion into the tubular fluid by MATE1 and MATE2K. This is particularly important in the case of metformin because the drug does not undergo extensive hepatic metabolism and is eliminated from the body almost exclusively by urinary excretion (Zolk and Fromm, 2011).

Mrp1 is also expressed in the rodent kidney, but it is primarily found in the epithelial cells of the loop of Henle and the collecting ducts, whereas in humans, MRP1 has been detected in the glomerulus. In Mrp1^(-/-) null mice, the anticancer drug VP-16 causes polyuria indicative of damage to the collecting duct, suggesting that Mrp1 is likely to be involved in the clearance of the compound from the kidney (Wihnholds *et al.*, 1998).

Finally, in humans, BCRP does not appear to be expressed in appreciable levels in the kidney, whereas it is expressed at high levels in the apical brush border of rat and mouse kidney. This transporter appears to play an important role in the efflux of certain sulfate conjugates of xenobiotics. The contribution of this species difference in renal BCRP expression with respect to toxic responses remains to be fully evaluated.

As in all active transport systems, there is competition for renal secretion of xenobiotics. This fact was taken advantage of during World War II, when penicillin was in short supply. Penicillin is actively secreted by the organic acid systems (OATs) of the kidney. To lengthen its half-life and duration of action, another acid was sought to compete with penicillin for renal secretion, and probenecid was successfully introduced for this purpose. Uric acid is also secreted actively by renal tubules, and a unique member of the OAT family, the urate transporter (URAT1; SLC22A12) is expressed only in the kidney where it functions specifically as a mechanism for reabsorption of urate. Various uricosuric agents, including probenecid and phenylbutazone inhibit URAT1 to facilitate the excretion of uric acid from the body.

Because many functions of the kidney are incompletely developed at birth, some xenobiotics are eliminated more slowly in newborns than in adults, and therefore may be more toxic to newborns. For example, the clearance of penicillin by premature infants is only about 20% of that observed in older children. In contrast, some compounds, such as cephaloridine, are nephrotoxic in adult animals but not in newborns. The reduced toxicity results directly from the lack of active uptake of cephaloridine by the kidneys in newborns, such that the chemical is not concentrated in the tubules.

The renal proximal tubule reabsorbs small plasma proteins that are filtered at the glomerulus. This largely occurs by pinocytosis at the brush-border membrane of the proximal tubule epithelium. If a toxicant binds to those small proteins, it can be carried into the proximal tubule cells and exert toxicity. As discussed previously, cadmium bound to MT is readily taken up by the kidney and is the major cause of Cd-induced nephrotoxicity (Klaassen and Liu, 1997). Similarly, chemicals such as limonene and 2,4,4-trimethyl pentane bind to the male-rat-specific protein, α_{2u} -globulin, and are taken up by the proximal tubule to produce hyaline droplet nephropathy and eventually renal tumors in male rats (Lehman-McKeeman, 2010).

Species differences in regard to the urinary excretion of weak organic acids and bases are observed frequently, as the pH of urine

varies widely among species. Differences in renal clearance also can occur for compounds filtered at the glomeruli because of differences in plasma protein binding. Similarly, differences in xenobiotic transporter expression, regulation, and function can contribute to differences in the renal excretion of toxicants.

Additional factors affecting the excretion of xenobiotics are exemplified by the disposition of griseofulvin in rats and rabbits (Table 5-13). Rabbits metabolize griseofulvin to 6-demethylgriseofulvin (a phase-I metabolite), a low-molecular-weight species that is predominantly excreted in urine. In contrast, rats metabolize griseofulvin to many conjugates (phase-II metabolites) that are higher-molecular-weight species (>350) that are preferentially excreted in bile. In this example, species differences in biotransformation ultimately determine the route of excretion of griseofulvin.

Fecal Excretion

Fecal excretion, the second major pathway for the elimination of xenobiotics, is a complex process that is not as well understood as urinary excretion. Excretion of toxicants via the feces can result from direct elimination of nonabsorbed compounds in the GI tract, from delivery to the GI tract via the bile and from secretion into intestinal luminal contents from the enterocytes.

Nonabsorbed Ingesta In addition to undigested material, varying proportions of nutrients and xenobiotics that are present in food or are ingested voluntarily (drugs) pass through the alimentary canal unabsorbed, contributing to fecal excretion. The physicochemical properties of xenobiotics and the biological characteristics that facilitate absorption were discussed earlier in this chapter. Although most chemicals are lipophilic to some extent and thereby available for absorption, it is rare for 100% of a compound to be absorbed. However, some macromolecules and some high-molecular-weight compounds that are essentially completely ionized are not absorbed at all. For example, the absorption of polymers or quaternary ammonium bases is quite limited in the intestine. Consequently, most of a dose of orally administered sucrose polyester, cholestyramine, or paraquat can be found in feces. The nonabsorbed portion of xenobiotics contributes to the fecal excretion of most chemicals to some extent. One other factor contributing to fecal excretion is intestinal secretion, which likely occurs by passive diffusion out of enterocytes or via exfoliation of intestinal cells during the normal turnover of this epithelium.

Biliary Excretion The biliary route of elimination is a significant source contributing to the fecal excretion of xenobiotics and is even more important for the excretion of metabolites. The liver plays

an important role in removing toxic chemicals from blood after absorption from the GI tract because blood from the GI tract passes via the portal circulation through the liver before reaching the general circulation. A compound can be extracted by the liver, thereby preventing its distribution to other parts of the body. The liver is also the main site for biotransformation of toxicants, and metabolites may be excreted directly into bile. In this manner, the liver can remove xenobiotics and their metabolites before entering the general circulation. Furthermore, xenobiotics and/or their metabolites excreted into bile enter the intestine and may be excreted with feces. However, if the physicochemical properties favor reabsorption, an enterohepatic circulation may ensue (discussed below).

Toxic chemicals bound to plasma proteins are fully available for active biliary excretion. The factors that determine whether a chemical will be excreted into bile or into urine are not fully understood. However, as a general rule, low-molecular-weight compounds (<325) are poorly excreted into bile, whereas compounds or their conjugates with molecular weights exceeding about 325 can be excreted in appreciable quantities. Glutathione and glucuronide conjugates have a high predilection for excretion into bile, but there are marked species differences in the biliary excretion of foreign compounds with consequences for the biological half-life of a compound and its toxicity. Table 5-14 provides examples of species differences in biliary excretion, and demonstrates that species variation in biliary excretion is also compound specific. It is therefore difficult to categorize species into “good” or “poor” biliary excretors, but, in general, rats and mice tend to be better biliary excretors than are other species (Klaassen and Watkins, 1984).

Foreign compounds excreted into bile are often divided into 3 classes on the basis of the ratio of their concentration in bile versus that in plasma. Class A substances have a ratio of nearly 1 and include sodium, potassium, glucose, mercury, thallium, cesium, and cobalt. Class B substances have a ratio of bile to plasma greater than 1 (usually between 10 and 1000). Class C substances include bile acids, bilirubin, lead, arsenic, manganese, and many other xenobiotics. Class C substances have a ratio below 1 (eg, inulin, albumin, zinc, iron, gold, and chromium). Compounds rapidly excreted into bile are usually class B substances. However, a compound does not have to be highly concentrated in bile for biliary excretion to be of quantitative importance. For example, mercury is not concentrated in bile, yet bile is the main route of excretion for this slowly eliminated substance.

Biliary excretion is regulated predominantly by xenobiotic transporters present on the canalicular membrane, which include MRP2, BCRP, MDR1, MATE1, and BSEP (Fig. 5-13). MRP2 is extremely important in biliary excretion because it is largely

Figure 5-13. Schematic model showing the xenobiotic transporting systems present in the human liver.

responsible for the transport of organic anions including glucuronide and glutathione conjugates of many xenobiotics. BCRP has particular affinity for sulfated conjugates of toxicants, whereas MDR1 primarily transports a variety of substrates into bile. MATE1 is specifically involved in biliary excretion of organic cations, and BSEP is critical for the secretion of bile salts and the regulation of bile flow.

The important contribution of MRP2 to biliary excretion of toxicants was established in part by the characterization of 2 naturally occurring mutant strains of rat, the Groningen/Yellow transport deficient (TR^-) and the Eisai hyperbilirubinemic rat (EHBR), both of which lack functional Mrp2 protein. These rats are phenotypically similar to humans suffering from Dubin–Johnson syndrome, a rare inherited disorder associated with mutations in MRP2 and characterized by chronic conjugated hyperbilirubinemia. The mutant rats also present with conjugated hyperbilirubinemia, show reduced biliary excretion of glutathione, and are defective in the normal biliary excretion of glucuronide and glutathione conjugates of many xenobiotics. An $Mrp2^{-/-}$ null mouse has been developed, and like its mutant rat counterparts, shows marked reductions in bile flow, biliary glutathione concentrations, and reduced ability to eliminate xenobiotics. For example, plasma levels of the food-derived carcinogen, PhIp, increased 1.9-fold in $Mrp2^{-/-}$ null mice compared to wild-type controls, demonstrating that functional Mrp2 plays a role in reducing exposure to toxic chemicals (Vlaming *et al.*, 2006). Finally, species differences in Mrp2 function may contribute to the qualitative differences

Table 5-14

observed across species in biliary excretion. In a direct comparison of the transport of 2,4-dinitrophenyl-*S*-glutathione (DNP-SG) across canalicular membrane vesicles from various species, clearance ranged from a high rate of 64.2 $\mu\text{L}/\text{min}/\text{mg}$ protein in rats to a low of 3.8 $\mu\text{L}/\text{min}/\text{mg}$ protein in humans, with intermediate values for other species including mouse, guinea pig, rabbit, and dog (Ishizuka *et al.*, 1999). Such differences in transporter function and expression are likely to contribute to species differences in biliary excretion illustrated in Table 5-14.

Although the highest levels of BCRP are found in the placenta, the transporter is expressed on the bile canalicular membrane of hepatocytes where it preferentially transports sulfate conjugates of xenobiotics. Known substrates for BCRP include estrone 3-sulfate and 4-methylembelliferone sulfate and methotrexate. MDR1 is important in the biliary elimination of compounds such as doxorubicin and vinblastine.

As described earlier, MATE1 and MATE2K are involved in the urinary excretion of organic cations such as metformin. MATE1, but not MATE2K, is also expressed on the bile canaliculus, where it also functions to transport organic cations into bile. In the case of metformin, a drug that works to inhibit gluconeogenesis in the liver, biliary excretion reduces hepatic drug concentrations, and thereby limits pharmacological activity.

The biliary excretion of xenobiotics mediated by MRP2, BCRP, and MDR1 usually results in increased excretion of toxicants out of hepatocytes and into bile. In doing so, these transporters increase excretion of xenobiotics and generally limit the likelihood of toxicity in the liver. However, adverse reactions can occur if the function of these transporters is inhibited, as evidenced by the examples illustrated above for the genetic mutant or knockout models. Furthermore, although BSEP does not appear to play a major role in the excretion of xenobiotics, some compounds can inhibit the function of this transporter, thereby decreasing the biliary excretion of bile acids and leading to cholestasis (defined as a decrease in bile flow with increased serum bilirubin) and cholestatic liver injury (Arrese and Ananthanarayanan, 2004). For example, inhibition of BSEP by the pharmaceutical agent, troglitazone, and to a much greater extent, troglitazone sulfate, competitively inhibits BSEP function, leading to intrahepatic cholestasis, which may contribute to the hepatotoxicity of troglitazone. Furthermore, inhibition of BSEP contributes to the cholestasis observed with steroids such as estradiol. Collectively, the ability of a chemical to interfere with the normal function of BSEP may be involved in hepatotoxicity (Morgan *et al.*, 2010).

Although the transporters located on the canalicular membrane are directly responsible for biliary excretion of xenobiotics, other xenobiotic transporters localized to the sinusoidal membranes are also important in determining hepatic concentrations of toxicants and thereby contribute to hepatic disposition and biliary elimination. Transporters present on sinusoidal membranes include the ABC transport family members, MRP3, MRP4, and MRP6, along with OATPs, OATs, and OCT. The Na⁺/taurocholate cotransporting polypeptide is also found on the sinusoidal membrane where it functions specifically in the uptake of bile acids into the liver.

MRP3 transports many of the same organic anions that are substrates for MRP2 from the liver into the blood circulation. It has recently been shown to be important in the excretion of acetaminophen- and morphine glucuronide conjugates from liver into blood (Borst *et al.*, 2006). In humans, it is upregulated during cholestasis and in patients with Dubin–Johnson syndrome, and in a similar manner, it is increased in TR⁻ and EHBR rats. The increase in MRP3 is recognized as a compensatory response that

helps to protect hepatocytes from toxic chemicals for cells deficient in MRP2. MRP4 is specifically involved in the cellular efflux of purine analogs, nucleoside antiviral drugs, and cyclic nucleotides, including cAMP and cGMP. It has also been shown to be a carrier for some xenobiotics including conjugated and unconjugated compounds (Borst *et al.*, 2006). A major role for MRP6 in xenobiotic disposition has not been established, but mutations in human MRP6 are associated with pseudoxanthoma elasticum, a hereditary disease affecting the elasticity of connective tissues (Bergen *et al.*, 2007).

Transporters present on the sinusoidal membranes of hepatocytes also contribute to hepatic uptake and efflux, and thereby contribute to hepatobiliary clearance of xenobiotics. In humans, OATP1B1 and 1B3 contribute to the uptake of many organic anions. Several plant toxins including phalloidin (from mushrooms) and microcystin-LR (from blue–green algae) are transported by the OATP1B proteins, and Oatp1b2-null mice are resistant to hepatotoxicity induced by both of these toxins (Lu *et al.*, 2008). The Oatps exhibit broad substrate specificity and play an important role in the hepatic uptake of numerous drugs and xenobiotics along with a variety of hormones, including thyroxine, and hormone conjugates. OAT2 is expressed in liver and transports small organic anions such as indomethacin and salicylate along with prostaglandins (Anzai *et al.*, 2006). OCT1 is also expressed in human and rodent liver, and contributes to the uptake of organic cations. This includes numerous endogenous compounds such as choline and dopamine as well as cationic xenobiotics such as metformin. Oct1 null mice are generally resistant to lactic acidosis than is caused by metformin (Wang *et al.*, 2003), suggesting a role for this uptake transporter (along with the biliary transporters highlighted above) in the elimination and toxic potential of this compound. In concert, the OATPs, OAT, and OCT family of transporters are important in the uptake of toxicants into the liver, a step that will also influence the contribution of hepatic metabolism, efflux into the bile, or efflux back into the circulation.

An important concept relating to biliary excretion is the phenomenon of enterohepatic circulation. After a compound is excreted into bile, it enters the intestine where it can be reabsorbed or eliminated with feces (illustrated in Fig. 5-1). Many organic compounds are conjugated with UDP-glucuronic acid, sulfate, or glutathione (see Chap. 6) before excretion into bile, and these polar metabolites are not sufficiently lipid soluble to be reabsorbed. However, enzymes found in the intestinal microflora may hydrolyze glucuronide and sulfate conjugates, liberating a more lipophilic moiety and increasing the likelihood of reabsorption. Reabsorption of the liberated xenobiotic completes a cycle in which the compound can return to the liver, where it can again be metabolized and excreted back into bile. Repeated enterohepatic cycling can lead to very long half-lives of xenobiotics in the body. Therefore, it is often desirable to interrupt this cycle to hasten the elimination of a toxicant from the body (Genius, 2011). This principle has been utilized in the treatment of dimethylmercury poisoning; ingestion of a polythiol resin binds the mercury and thus prevents its reabsorption (Magos and Clarkson, 1976).

An increase in hepatic excretory function also has been observed after pretreatment with some drugs (Klaassen and Watkins, 1984). For example, it has been demonstrated that phenobarbital increases plasma disappearance of bromosulfophthalein (BSP) by enhancing its biliary excretion. The increase in bile flow caused by phenobarbital is an important factor in increasing the biliary excretion of BSP. However, other factors, including induction of phase-II enzymes (see Chap. 6) and xenobiotic

transporters may also enhance biliary elimination. Induction of metabolizing enzymes and transporters work in concert to increase the clearance of a toxicant from the plasma. In particular, induction of these processes increases the capacity for a xenobiotic to be (1) taken up into the liver; (2) metabolized to conjugates that are likely to be excreted into bile; and (3) excreted into bile and removed from the general circulation. However, not all microsomal enzyme inducers increase bile flow and excretion, as agents such as 3-methylcholanthrene and benzo[*a*]pyrene are relatively ineffective in this regard.

The toxicity of some compounds can also be directly related to their biliary excretion. For example, the intestinal toxicity of several xenobiotics and drugs is increased by their excretion into bile. This is the case for nonsteroidal anti-inflammatory drugs that cause intestinal ulcerations that can be abolished by bile-duct ligation (Duggan *et al.*, 1975). More recently, irinotecan, an anticancer drug, was found to induce severe GI toxicity (severe diarrhea) in humans and rats. The mechanism for the effect of this drug involved metabolism to an active metabolite that was a good substrate for MRP2. The excretion into bile mediated by MRP2 results in high concentrations of the toxic metabolite in the intestinal lumen and toxicity ensues. The toxicity of irinotecan can be modulated by inhibiting MRP2 function (Chu *et al.*, 1997).

Many xenobiotic transporters are not expressed early in development, and the hepatic excretory system is not fully developed in newborns. As a result, there are numerous examples of compounds that are more toxic to newborns than to adults (Klaassen and Slitt, 2005). For example, ouabain is about 40 times more toxic in newborn than in adult rats. This is due to an almost complete inability of the newborn rat liver to remove ouabain from plasma. The development of hepatic excretory function can be promoted in newborns by administering microsomal enzyme inducers.

Finally, the plasma clearance or biliary excretion of organic acids, such as BSP or indocyanine green (ICG), has been used to evaluate liver function. In particular, ICG is a valuable diagnostic agent in clinical practice. It is injected intravenously after which its disappearance from plasma is easily monitored. A change in plasma clearance of ICG does not distinguish between changes in hepatic blood flow or cellular function, but is highly suggestive of reduced hepatic function, including reduced biliary excretion, consistent with liver dysfunction or injury (Sakka, 2007).

Exhalation

Substances that exist predominantly in the gas phase at body temperature are eliminated mainly by the lungs. Because volatile liquids are in equilibrium with their gas phase in the alveoli, they may also be excreted via the lungs. The amount of a liquid eliminated via the lungs is proportional to its vapor pressure. A practical application of this principle is seen in the breath analyzer test for determining the amount of ethanol in the body. Highly volatile liquids such as diethyl ether and certain volatile anesthetics (nitrous oxide) are excreted almost exclusively by the lungs.

No specialized transport systems have been described for the excretion of toxic substances by the lungs. Some xenobiotic transporters, including MRP1 and MDR1, have been identified in the lung, but overall, compounds excreted via exhalation in the lung are most likely to be eliminated by simple diffusion. Elimination of gases is roughly inversely proportional to the rate of their absorption. Therefore, gases with low solubility in blood, such as ethylene, are rapidly excreted, whereas chloroform, which has a much higher solubility in blood, is eliminated very slowly by the

lungs. Trace concentrations of highly lipid-soluble anesthetic gases such as halothane and methoxyflurane may be present in expired air for as long as 2 to 3 weeks after a few hours of anesthesia. Undoubtedly, this prolonged retention is due to deposition in and slow mobilization from adipose tissue of these very lipid-soluble agents. The rate of elimination of a gas with low solubility in blood is perfusion-limited, whereas that of a gas with high solubility in blood is ventilation-limited.

Other Routes of Elimination

Cerebrospinal Fluid A specialized route of removal of toxic agents from a specific organ is represented by the cerebrospinal fluid (CSF). All compounds can leave the CNS with the bulk flow of CSF through the arachnoid villi. In addition, lipid-soluble toxicants also can exit at the site of the BBB. As discussed earlier, toxicants also can be removed from the CSF by active transport, using the transport systems present in the BCSFB.

Milk The secretion of toxic compounds into milk is extremely important because (1) a toxic material may be passed with milk from the mother to the nursing offspring and (2) compounds can be passed from cows to people via dairy products. Toxic agents are excreted into milk by simple diffusion. Because milk has an acidic pH (about 6.5), basic compounds may be concentrated in milk, whereas acidic compounds may attain lower concentrations in milk than in plasma (Findlay, 1983; Wilson, 1983). More important, about 3% to 4% of milk consists of lipids, and the lipid content of colostrum after parturition is even higher. Lipid-soluble xenobiotics diffuse along with fats from plasma into the mammary glands and are excreted with milk during lactation. Many of the same compounds that can accumulate in fat such as aldrin, chlordane, DDT, and polychlorinated and polybrominated biphenyls, dibenzo-*p*-dioxins, and furans (Van den Berg *et al.*, 1987; Li *et al.*, 1995) have been found in human breast milk, and milk can be a major route of their excretion. More recently, other persistent compounds such as nitromusk perfume ingredients have been identified in milk, but it is unclear as to whether the presence of these compounds is directly responsible for possible adverse effects (Leibl *et al.*, 2000). Species differences in the excretion of xenobiotics with milk are to be expected, as the proportion of milk fat derived from the circulation versus that synthesized *de novo* in the mammary gland differs widely among species. Metals chemically similar to calcium, such as lead, and chelating agents that form complexes with calcium also can be excreted into milk to a considerable extent.

BCRP is expressed in the alveolar epithelial cells of mammary glands and actively secretes a variety of compounds into milk. Endogenous compounds such as vitamin B₁₂ (riboflavin) are actively transported into breast milk by BCRP, as well as numerous toxicants including heterocyclic amines and aflatoxin. The contribution of BCRP to toxicants in the mammary gland and breast milk is paradoxical in that secretion into the milk is likely to be protective to the mother, while simultaneously increasing the potential for exposure in suckling infants or dairy consumers to a variety of toxic chemicals (Van Herwaarden and Schinkel, 2006; Vlaming *et al.*, 2009).

Sweat and Saliva The excretion of toxic agents in sweat and saliva is quantitatively of minor importance. Again, excretion depends on the diffusion of the nonionized, lipid-soluble form of an agent. Toxic compounds excreted into sweat may produce dermatitis. Substances excreted in saliva enter the mouth, where they are usually swallowed to become available for GI absorption.

COMPUTATIONAL AND EXPERIMENTAL APPROACHES TO ASSESS XENOBIOTIC DISPOSITION

In general, the empiric determination of xenobiotic absorption, distribution, and elimination in experiments involving laboratory animals or studies in human subjects is the most reliable means by which disposition can be studied. However, such studies may require the development of sophisticated analytical methods, the use of radioactive compounds and in the case of human studies, controlled laboratory conditions and constant monitoring. As such, these types of studies are not always practical or feasible, and a variety of computational models, nonanimal tools or in vitro cellular systems have been developed to predict dispositional attributes of drugs and toxicants. A brief overview of several of the most widely used tools is presented here, but it is noted that this is a dynamic and rapidly changing field. In general, these models are particularly useful in studying absorption and excretion, particularly biliary excretion. Tissue distribution, with particular emphasis on target organ dosimetry can also be assessed with pharmacokinetic models (Chap. 7).

Absorption A variety of models are used to estimate log P because the lipid solubility is an important, general feature of any toxicant (Mannhold *et al.*, 2009). Additionally, based on the general principles outlined earlier, computational tools to estimate permeability have been developed. One such model predicts poor absorption as a function of the calculated log P (Clog P), the molecular weight and the presence of hydrogen bond donors and acceptors. The concept, based on these 4 elements is referred to as the “rule of 5” because the determinants are based on multiples of 5 and include (1) molecular weight greater than 500; (2) Clog P greater than 5; (3) more than 5 H-bond donors; and (4) 10 H-bond acceptors (Lipinski *et al.*, 2001).

The human colon adenocarcinoma cell line, Caco-2, is widely used to evaluate xenobiotic permeability. These cells form a confluent epithelial monolayer with well-defined tight junctions and typical microvilli on the apical surface. A variety of xenobiotic transporters are expressed on Caco-2 cells. The uptake transporters, OATP2B1, PEPT1, and OCTN2 are expressed on the apical membrane along with efflux transporters, MDR1, MRP2, and BCRP. On the basolateral membrane, efflux transporters MRP3, 4, and 6 have been identified (Sun *et al.*, 2008).

Caco-2 cells are specifically used to estimate the fraction of xenobiotic that will be absorbed in the GI tract. Movement across the apical (A) and basolateral (B) membranes is also used to determine whether a xenobiotic is substrate or inhibitor of xenobiotic transporters. Transport in the A→B direction is indicative of absorption, whereas movement in the B→A direction suggests that carrier-mediated efflux is favored.

Another model used to predict absorption are artificial membranes such as that exemplified by the parallel artificial membrane permeability assay (PAMPA). As an artificial membrane, this system lacks transporters or paracellular pathways and is most useful for assessing the non-energy-dependent diffusion of toxicants.

Dermal exposure can be evaluated in a variety of in vitro systems, either with skin biopsy samples or with models developed to represent human skin. Mathematical models, with emphasis on the lipid matrix as the principal pathway of permeation, have also been developed and used with increasing frequency. Such methods emphasize log P and molecular size in model development (Lian *et al.*, 2008).

Hepatobiliary Excretion The development of sandwich-cultured hepatocytes has become a valuable tool for studying how

xenobiotics move in and out of the liver, with emphasis on transport function, including transporter regulation and species differences in transporter function that may contribute to organ toxicity. Briefly, when hepatocytes are cultured between 2 layers of gelled collagen (hence the sandwich configuration), they retain molecular and biochemical characteristics more consistent with their properties in the whole organ than monolayer cultures of cells. These features include the formation of canalicular networks necessary for biliary excretion. This system has been optimized to assess toxicant accumulation, estimate biliary excretion, and investigate the interplay between metabolism and transport, and has proven to be useful in vitro system to aid in the evaluation of hepatobiliary disposition (Swift *et al.*, 2010).

Xenobiotic transporter function can also be evaluated with membrane vesicles isolated from specific organs or with expressed cell systems. The development of a variety of transporter-deficient models, particularly in mice, have also proven to be very useful for assessing transporter activity and contribution to toxicity as have been described throughout this chapter (Klaassen and Lu, 2008).

CONCLUSION

Humans are in continuous contact with toxic chemicals. Toxicants are in the food we eat, the water we drink, and the air we breathe. Depending on their physical and chemical properties, toxic chemicals may be absorbed by the GI tract, the lungs, and/or the skin. Fortunately, the body has the ability to biotransform and excrete these compounds into urine, feces, and air. However, when the rate of absorption exceeds the rate of elimination, toxic compounds may accumulate and reach a critical concentration at a certain target site, and toxicity may ensue. Whether a chemical elicits toxicity depends not only on its inherent potency and site specificity but also on whether, and if so how, it is absorbed, distributed, and eliminated. Therefore, knowledge of the disposition of chemicals is of great importance in judging the toxicity of xenobiotics. For example, for a potent CNS suppressant that displays a strong hepatic first-pass effect, oral exposure is of less concern than is exposure by inhalation. Also, 2 equipotent gases, with the absorption of one being perfusion rate-limited and that of the other being ventilation rate-limited, will exhibit completely different toxicity profiles at a distant site because of differences in the concentrations attained in the target organ.

Many chemicals have very low inherent toxicity but can be metabolically activated into toxic metabolites, and toxicity may be determined by the rate of formation of toxic metabolites. Alternatively, a very potent toxicant may be detoxified rapidly by biotransformation. The fundamental and overarching concept is that adverse effects are related to the unbound concentration of the “toxic chemical” at the site of action (in the target organ), whether a chemical is administered or generated by biotransformation in the target tissue or at a distant site. Accordingly, the toxic response exerted by chemicals is critically influenced by the rates of absorption, distribution, biotransformation, and excretion.

Biotransformation of Xenobiotics

Andrew Parkinson, Brian W. Ogilvie, David B. Buckley,
Faraz Kazmi, Maciej Czerwinski, and Oliver Parkinson

Introduction

Principles of Xenobiotic Biotransformation

Hydrolysis, Reduction, and Oxidation

Hydrolysis

Carboxylesterases
Cholinesterases (AChE and BChE)
Paraoxonases (Lactonases)
Prodrugs and Alkaline Phosphatase
Peptidases
 β -Glucuronidase
Epoxide Hydrolases

Reduction

Azo- and Nitro-Reduction
Carbonyl Reduction—AKRs and SDRs
Disulfide Reduction
Sulfoxide and N-Oxide Reduction
Quinone Reduction—NQO1 and NQO2

Dihydropyrimidine Dehydrogenase
Dehalogenation
Dehydroxylation—mARC, Cytochrome b_5 , b_5 Reductase, and Aldehyde Oxidase
Aldehyde Oxidase—Reductive Reactions

Oxidation

Alcohol, Aldehyde, Ketone
Oxidation–Reduction Systems
Alcohol Dehydrogenase
Aldehyde Dehydrogenase
Dimeric Dihydrodiol Dehydrogenase
Molybdenum Hydroxylases (Molybdoenzymes)
Xanthine Oxidoreductase
Aldehyde Oxidase
Amine Oxidases
Aromatization
Peroxidase-Dependent Cooxidation
Flavin Monooxygenases

Cytochrome P450
Activation of Xenobiotics by Cytochrome P450
Inhibition of Cytochrome P450
Induction of Cytochrome P450—Xenosensors

Conjugation

Glucuronidation and Formation of Acyl-CoA Thioesters
Sulfonation
Methylation
Acetylation
Amino Acid Conjugation
Glutathione Conjugation
Thiosulfate Sulfurtransferase (Rhodanese)
Unusual Conjugation Reactions
Phosphorylation

INTRODUCTION

In 2003, my father (and Oliver's grandfather), Edward William Parkinson, died of Lou Gehrig disease, otherwise known as amyotrophic lateral sclerosis (ALS) in America and as motor neuron disease (MND) in Britain. He died beeping. The beeping came from a portable, electronic syringe that periodically injected my father with glycopyrrolate, an anticholinergic drug that blocks the production of saliva that many ALS patients have difficulty swallowing. Glycopyrrolate is a quaternary ammonium salt; hence, it is positively charged at physiological pH. As such, glycopyrrolate does not readily cross lipid bilayers, which is why it is injected intravenously or intramuscularly; it has few CNS effects (it does not readily cross the blood–brain barrier), and a relatively small volume of distribution at steady state ($V_{ss} = 0.42$ L/kg). Unchanged glycopyrrolate is rapidly eliminated in urine. The mean elimination half-life increases from 19 minutes in patients with normal kidney function to 47 minutes in patients with severe kidney impairment, indicating that renal disease impairs the elimination of glycopyrrolate. Although it is excreted in urine largely as unchanged drug, glycopyrrolate reinforces a number of principles about xenobiotic biotransformation, the most important of which is: xenobiotic biotransformation is the process—actually a series of enzyme-catalyzed processes—that alters the physicochemical properties of foreign chemicals (xenobiotics) from those that favor

absorption across biological membranes (namely, lipophilicity) to those favoring elimination in urine or bile (namely, hydrophilicity). Without xenobiotic biotransformation, the numerous foreign chemicals to which we are exposed (which includes both man-made and natural chemicals such as drugs, industrial chemicals, pesticides, pollutants, pyrolysis products in cooked food, alkaloids, secondary plant metabolites, and toxins produced by molds, plants, etc) either unintentionally or, in the case of drugs, intentionally would—if they are sufficiently lipophilic to be absorbed from the gastrointestinal tract and other sites of exposure—eventually accumulate to toxic levels. Furthermore, absent xenobiotic biotransformation, many of the drugs in use today would have an unacceptably long duration of action. In contrast, drugs that are not lipophilic, such as glycopyrrolate, are not absorbed from the gastrointestinal tract unless their uptake is mediated by a transporter protein (hence, they are not orally active), and if they are administered parenterally, they are not obligated to undergo biotransformation (because they are already hydrophilic) to facilitate their elimination from the body.

The enzymes that catalyze xenobiotic biotransformation are often called drug-metabolizing enzymes. The acronym ADME stands for *absorption, distribution, metabolism, and elimination*. This acronym is widely used in the pharmaceutical industry to describe the 4 main processes governing drug disposition. The acronym is sometimes extended to include drug transport (AMDET)

or drug toxicity (ADME-Tox). This chapter describes some fundamental principles of xenobiotic biotransformation, and describes the major enzyme systems involved in the biotransformation (or metabolism) of drugs and other xenobiotics. The examples given are biased toward drugs and human enzyme systems for 2 reasons. First, many of the fundamental principles of xenobiotic biotransformation stem from such studies. This is especially true of drugs with a narrow therapeutic index (where the toxic dose is not much greater than the therapeutic dose), which have revealed a large number of genetic and environmental factors that affect xenobiotic biotransformation and, hence, drug toxicity. Second, adverse drug events (ADEs) are one of the leading causes of death in the United States. Lazarou *et al.* (1998) estimated that in 1994 over 2 million hospitalized patients had serious ADEs (also known as adverse drug reactions or ADRs) and 106,000 had fatal outcomes, placing ADEs only behind heart disease, cancer, stroke, and pulmonary disease as a leading cause of death. Of the 548 new chemical entities approved by the Food and Drug Administration (FDA) between 1974 and 1999, ~10% (56 drugs) required black box warnings or were withdrawn from the market because of ADEs that included hepatotoxicity, cardiotoxicity (several as a result of drug–drug interactions), myelotoxicity, immunotoxicity, and warnings to pregnant women (Lasser *et al.*, 2002; Thomas, 2002). Between 1998 and 2005 the number of serious ADEs reported voluntarily to the FDA through the Adverse Events Reporting System (AERS), known as MedWatch reports, increased 2.6-fold (from 34,966 in 1998 to 89,842 in 2005) and the number of ADE-related fatalities increased 2.7-fold (from 5519 in 1998 to 15,107 in 2005) (Moore *et al.*, 2007). These increases in ADE incidence were 4 times greater than the increase in the total number of outpatient prescriptions written during the same period. In many cases, xenobiotic biotransformation is central to understanding these ADEs.

PRINCIPLES OF XENOBIOTIC BIOTRANSFORMATION

It is difficult to make categorical statements about xenobiotic biotransformation because there is an exception to every rule. Nevertheless, the following points, which might be considered principles or rules, apply in the majority of cases:

Point 1 Xenobiotic biotransformation or drug metabolism is the process of converting lipophilic (fat-soluble) chemicals, which are readily absorbed from the gastrointestinal tract and other sites, into hydrophilic (water-soluble) chemicals, which are readily excreted in urine or bile. There are exceptions even to this most basic rule. For example, acetylation and methylation are biotransformation reactions that can actually decrease the water solubility of certain xenobiotics. As a general rule, xenobiotics with a log $D_{7.4} > 0$ require biotransformation to facilitate their elimination (Williams *et al.*, 2003b).

Point 2 The biotransformation of xenobiotics is catalyzed by various enzyme systems that can be divided into 4 categories based on the reaction they catalyze:

1. Hydrolysis (eg, carboxylesterase)
2. Reduction (eg, carbonyl reductase)
3. Oxidation (eg, cytochrome P450 [CYP])
4. Conjugation (eg, UDP-glucuronosyltransferase [UGT])

The mammalian enzymes involved in the hydrolysis, reduction, oxidation, and conjugation of xenobiotics are listed in Table 6-1, together with their principal subcellular location. The conjugation reactions include glucuronidation, sulfonation (often

called sulfation), acetylation, methylation, conjugation with glutathione (GSH; mercapturic acid synthesis), and conjugation with amino acids (such as glycine, taurine, and glutamine). Examples of the major chemical groups that undergo biotransformation together with the enzymes that commonly mediate their biotransformation are given in Table 6-2 (Williams *et al.*, 2003b; Testa and Krämer, 2008, 2010).

Xenobiotic biotransformation is generally catalyzed by enzymes, but there are exceptions. For example, hydrolysis of certain carboxylic and phosphoric acid esters, reduction of sulfoxides to sulfides (eg, rabeprazole), isomerization involving enol–keto tautomerization (eg, thalidomide), and the conjugation of certain xenobiotics with GSH can occur nonenzymatically at an appreciable rate. Certain reactions are catalyzed by gastric acid, such as the hydrolysis of esters and the conversion of indole-3-carbinol to a dimer that is a potent agonist of the aryl hydrocarbon receptor (AhR) and, consequently, an inducer of various enzymes including certain CYP enzymes (CYP1A1, 1A2, 1B1, and 2S1) (Grose and Bjeldanes, 1992).

Point 3 In general, individual xenobiotic-biotransforming enzymes are located in a single organelle. In Table 6-1, some enzymes are listed with 2 or more subcellular locations. However, in such cases, the enzyme name generally refers to 2 or more enzymes, each with its own distinct subcellular location. For example, the epoxide hydrolase located in microsomes is the same enzyme located in the plasma membrane but is a different enzyme from the epoxide hydrolase located in cytosol (ie, they are distinct gene products). From a practical perspective, it is noteworthy that during the homogenization of tissue and the preparation of subcellular fractions, a certain degree of cross-contamination of organelles occurs. For example, microsomes contain detectable levels of monoamine oxidase (MAO) and other outer mitochondrial enzymes, such as the mitochondrial amidoxime-reducing component (mARC) due to their contamination with the outer mitochondrial membrane. On the other hand, some xenobiotic-biotransforming enzymes are present in 2 or more subcellular locations. Some CYP enzymes, such as CYP2E1, are present in microsomes and the inner mitochondrial membrane, which has implications for the site of xenobiotic toxicity, as discussed in the section “CYP2E1.”

Point 4 In general, xenobiotic biotransformation is accomplished by a limited number of enzymes with broad substrate specificities. In humans, for example, 2 CYP enzymes—namely, CYP2D6 and CYP3A4—metabolize over half the orally effective drugs in current use (Gonzalez *et al.*, 2011). The broad and sometimes overlapping substrate specificities of xenobiotic-biotransforming enzymes preclude the possibility of naming the individual enzymes after the reactions they catalyze (which is how most other enzymes are named). Many of the enzymes involved in xenobiotic biotransformation are arranged in families and subfamilies and named according to nomenclature systems based on the primary amino acid sequence of the individual enzymes. CYP2D6, for example, is in CYP family 2, subfamily D, and gene number 6. Some enzymes are given the same name across all mammalian species, whereas others are named in a species-specific manner. For example, some CYP enzymes, such as CYP1A1, CYP1A2, and CYP1B1, are so named in all mammalian species, whereas CYP enzymes in the CYP2, CYP3, and CYP4 families (with certain exceptions such as CYP2E1) are named in a species-specific manner. The convention of using italic and regular letters to distinguish between the gene and gene products (mRNA and protein), respectively, and the convention of using lower case letters to designate mouse genes and gene products will not be followed in this chapter.

Table 6-1

General Pathways of Xenobiotic Biotransformation and Their Major Subcellular Location

REACTION	ENZYME OR SPECIFIC REACTION	LOCALIZATION
Hydrolysis	Carboxylesterase	Microsomes, cytosol, lysosomes, blood
	Butyrylcholinesterase	Plasma and most tissues
	Acetylcholinesterase	Erythrocytes and most tissues
	Paraoxonases	Plasma, microsomes, inner mitochondrial membrane
	Alkaline phosphatase	Plasma membrane
	Peptidase	Blood, lysosomes
	β -Glucuronidase	Microsomes, lysosomes, microflora
	Epoxide hydrolase	Microsomes, plasma membrane, cytosol
Reduction	Azo- and nitro-reduction	Microflora
	Carbonyl (aldo-keto) reduction	Cytosol, microsomes, blood
	Disulfide reduction	Cytosol
	Sulfoxide reduction	Cytosol
	Quinone reduction	Cytosol, microsomes
	Dihydropyrimidine dehydrogenase	Cytosol
	Reductive dehalogenation	Microsomes
	Dehydroxylation (mARC [*])	Mitochondria
Dehydroxylation (aldehyde oxidase)	Cytosol	
Oxidation	Alcohol dehydrogenase	Cytosol
	Aldehyde dehydrogenase	Mitochondria, cytosol
	Aldehyde oxidase	Cytosol
	Xanthine oxidoreductase	Cytosol
	Class I amine oxidases	
	MAO-A and B	Outer mitochondrial membrane, platelets
	PAO	Cytosol, peroxisomes, plasma
	SMOX	Cytosol, nucleus
	Class II amine oxidases (CuAOs)	
	SSAOs (eg, AOC3)	Cytosolic and membrane-associated forms
	DAOs	Microsomes and extracellular matrix
	LOX	Extracellular matrix
Peroxisomes	Microsomes, lysosomes, saliva	
Flavin monooxygenases	Microsomes	
Cytochrome P450	Microsomes, mitochondria	
Conjugation	UDP-glucuronosyltransferase	Microsomes
	Acyl-CoA synthetase	Mitochondria
	Sulfotransferase	Cytosol
	Glutathione transferase	Cytosol, microsomes, mitochondria
	Amino acid transferase	Mitochondria, microsomes
	<i>N</i> -Acetyltransferase	Mitochondria, cytosol
	Methyltransferase	Cytosol, microsomes, blood

*mARC: mitochondrial amidoxime-reducing component.

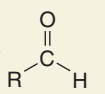

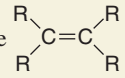

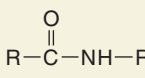

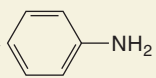

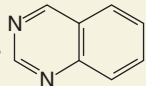

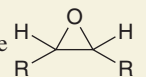

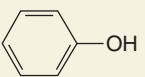

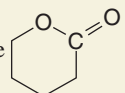

The structure (ie, amino acid sequence) of a given xenobiotic-biotransforming enzyme may differ among individuals, which can give rise to differences in rates of drug metabolism. In general, a variant form of a xenobiotic-biotransforming enzyme (known as an *allelic variant* or *allozyme*) has diminished enzymatic activity or level of expression compared with that of the wild-type enzyme, although this is not always the case (see the sections “Alcohol Dehydrogenase,” “Aldehyde Oxidase,” “Cholinesterases (AChE and BChE),” “Carboxylesterases,” “Epoxide Hydrolase,” “Flavin Monooxygenases,” “Glutathione Conjugation,” “Paraoxonases (Lactonases),” “Sulfonation,” “CYP1A1, 1A2, and 1B1,” “CYP1A1, 1A2, and 1B1,” “CYP2C8,” “CYP2C19,” and “CYP3A5”). The impact of amino acid substitution(s) on the catalytic activity of a

xenobiotic-biotransforming enzyme may be substrate-dependent, such that an allelic variant may interact normally with some substrates (and inhibitors) but interact atypically with others.

The broad substrate specificity of xenobiotic-biotransforming enzymes makes them catalytically versatile but slow compared with most other enzymes (with the exception of hydrolytic reactions). The sequential oxidation, conjugation, and transport of a xenobiotic tend to proceed quicker at each subsequent step, which prevents the accumulation of intracellular metabolites. Were it not for the low catalytic turnover of CYP (one molecule of which may take several seconds or minutes to oxidize a single drug molecule), it would not be possible to achieve the once-a-day dosing characteristic of a large number of drugs.

Table 6-2

Common Chemical Groups and Enzymes Possibly Involved in Their Metabolism

CHEMICAL GROUP	ENZYME(S)	REACTION(S)	CHEMICAL GROUP	ENZYME(S)	REACTION(S)
Alkane $R-CH_2-R$	CYP	Hydroxylation, dehydrogenation	Aldehyde 	CYP, ALDH Aldehyde oxidase	Oxidative deformylation, oxidation to carboxylic acid
Alkene 	CYP, GST	Epoxidation, glutathionylation	Aliphatic amide 	Amidase (esterase)	Hydrolysis
Alkyne $R-C\equiv C-R$	CYP	Oxidation to ketocarbenes and carboxylic acid	Aniline 	CYP, NAT, UGT, peroxidase, SULT	<i>N</i> -Hydroxylation, <i>N</i> -acetylation, <i>N</i> -glucuronidation, <i>N</i> -oxidation, <i>N</i> -sulfonation
Aliphatic alcohol $R-CH_2-OH$	CYP, ADH, catalase, UGT, SULT	Oxidation, glucuronidation, and sulfonation	Aromatic azaheterocycles 	UGT, CYP, aldehyde oxidase	<i>N</i> -Glucuronidation, hydroxylation, <i>N</i> -oxidation, ring cleavage, oxidation
Aliphatic amine $R-NH_2$	CYP, FMO, MAO, UGT, SULT, MT, NAT, peroxidase	<i>N</i> -Dealkylation, <i>N</i> -oxidation, deamination, <i>N</i> -glucuronidation, <i>N</i> -carbamoylglucuronidation, <i>N</i> -sulfonation, <i>N</i> -methylation, <i>N</i> -acetylation	Carbamate $R-NH-C(=O)-O-R$	CYP, esterase	Oxidative cleavage, hydrolysis
Amidine $HN=CR-NH_2$	CYP	<i>N</i> -Oxidation	Ester $R-CH_2-O-C(=O)-R$	CYP, esterase	Oxidative cleavage, hydrolysis
Arene 	CYP	Hydroxylation and epoxidation	Ether $R-CH_2-O-CH_2-R$	CYP	<i>O</i> -Dealkylation
Carboxylic acid $R-COOH$	UGT, amino acid transferases, acyl-CoA synthetase	Gluconidation, amino acylation, coenzyme A thioesterification	Ketone $R-CH_2-C(=O)-R$	CYP, FMO, SDR, AKR	Baeyer-Villiger oxidation, reduction
Epoxide 	Epoxide hydrolase, GST	Hydrolysis, glutathionylation	Phenol 	CYP, UGT, SULT, MT	Ipso-substitution, glucuronidation, sulfonation, methylation
Lactone 	Lactonase (paraoxonase)	Hydrolysis (ring opening)	Thioether $R-CH_2-S-CH_2-R$	CYP, FMO	<i>S</i> -Dealkylation, <i>S</i> -oxidation

ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; AKR, aldo-keto reductases; FMO, flavin monooxygenase; GST, glutathione *S*-transferase; MT, methyltransferase; SDR, short-chain dehydrogenases/reductases; SULT, sulfotransferase; UGT, UDP-glucuronosyltransferase. Data from Williams et al. (2003b).

Point 5 Hydrolysis, reduction, and oxidation expose or introduce a functional group (such as $-\text{OH}$, $-\text{NH}_2$, $-\text{SH}$, or $-\text{COOH}$) that can be converted to a water-soluble conjugate (see Table 6-2). For subsequent conjugation, the functional group introduced or exposed by hydrolysis, reduction, or oxidation must be nucleophilic (in the case of glucuronidation, sulfonation, methylation, acetylation, and conjugation with glycine or taurine) or electrophilic (in the case of glutathionylation).

The first 3 reactions (hydrolysis, reduction, and oxidation) are often called Phase 1 reactions, and the conjugation reactions are often called Phase 2 reactions. The classification of xenobiotic-biotransforming enzymes into Phase 1 and Phase 2 (and the extension of this system to classify xenobiotic transporters as Phase 3) has been criticized by Josephy *et al.* (2005), as being both misleading and contrary to the original principles of Williams (1959), the drug metabolism pioneer who coined the phrases to distinguish reactions that resulted in either a decrease or increase in xenobiotic toxicity (Phase 1) from reactions that resulted in only a decrease in toxicity (Phase 2). Notwithstanding the arguments against the Phase 1–Phase 2 classification, which were summarized in the previous version of this chapter (Parkinson and Ogilvie, 2008), the terms are widely used today not as R. T. Williams's originally intended but to distinguish biotransformation reactions involving oxidation, reduction, or hydrolysis (Phase 1) from those involving conjugation (Phase 2). The original idea that Phase 2 metabolism results in only detoxication is incorrect. Indeed, on a case-by-case basis, all xenobiotic-metabolizing enzymes are capable of increasing the toxicity of one or more xenobiotics, including the conjugating enzymes that R. T. Williams classified as Phase 2 (detoxifying) enzymes. For example, conjugation of carboxylic acid-containing drugs with glucuronic acid or coenzyme A (CoA) to form acyl glucuronides and acyl-CoA thioesters, respectively, is thought to be responsible for the hepatotoxicity observed with numerous nonsteroidal anti-inflammatory drugs (NSAIDs). In fact, in the United States, NSAIDs and other carboxylic acid-containing drugs represent the largest category of drugs whose clinical development was halted or whose regulatory approval was subsequently withdrawn because of liver toxicity in humans (Fung *et al.*, 2001). Although Phase 1 biotransformation often precedes Phase 2 metabolism, some drugs, such as acetaminophen (Tylenol), are conjugated directly (by glucuronidation and sulfonation), whereas other drugs, such as gemfibrozil and diclofenac, undergo Phase 1 metabolism (by CYP [CYP2C8]) after Phase 2 metabolism (glucuronidation) (Ogilvie *et al.*, 2006).

Point 6 Oxidation, reduction, hydrolysis, methylation, and acetylation generally cause a modest increase in the water solubility of a xenobiotic, whereas glucuronidation, sulfonation, glutathionylation, and amino acid conjugation generally cause a marked increase in hydrophilicity. The impact of biotransformation on the physicochemical properties and disposition of xenobiotics and their metabolites can be appreciated from modern approaches to drug development. For a drug to be absorbed by passive diffusion in the gut (so that it can be orally effective and distribute throughout the body) it must generally have a $\log P$ of 0 to 5 and a calculated total polar surface area (TPSA) less than 100 \AA^2 (Smith and Dalvie, 2012). Water-soluble drugs (those with a negative $\log P$) might be orally active if their absorption is mediated by an intestinal drug transporter. Extremely lipophilic drugs ($\log P > 5$) tend to be too insoluble or they dissolve too slowly to be well absorbed from the intestine unless the dose is particularly low. Drugs must undergo desolvation (ie, they must dissociate from water molecules) to penetrate the lipid bilayer of cells. Drugs begin to lose their lipid permeability when their TPSA increases above $\sim 75 \text{ \AA}^2$ and lose it

entirely at a TPSA of around 150 \AA^2 . When drugs meet the aforementioned criteria ($\log P = 0\text{--}5$, $\text{TPSA} < 100 \text{ \AA}^2$), their metabolites formed by oxidation, reduction, hydrolysis, methylation, or acetylation also tend to meet these same criteria; hence, the metabolites formed by these reactions, like the parent drug, readily diffuse across biological membranes down a concentration gradient (unless their diffusion into tissues such as the brain is restricted by efflux transporters). Metabolites formed by conjugation reactions (other than methylation and acetylation) contain a negatively charged glucuronide, sulfate, or amino acid (glycine or taurine) moiety (or a zwitterionic GSH moiety) and consequently have a much lower $\log P$ and a much greater TPSA than the parent drug, so much so that they cannot readily diffuse passively across biological membranes. The elimination of such conjugates from the liver (where they are largely formed) requires active transport across the canalicular (apical) membrane so they can be eliminated in bile or across the sinusoidal (basolateral) membrane, which enables their transport into blood (where they are generally highly bound to albumin given their anionic nature [negative charge]) and then to the kidney for elimination in urine (by either glomerular filtration or possibly active transport [tubular secretion]). Drug conjugates are actively transported into bile primarily by MRP2 (ABCC2) on the canalicular membrane and actively transported into blood primarily by MRP1 (ABCC1; in the case of GSH conjugates) and MRP3 (ABCC3; in the case of glucuronide and sulfate conjugates) on the sinusoidal membrane, although on a case-by-case basis other transporters may be involved (Borst *et al.*, 2006).

Point 7 Not all biotransformation reactions are catalyzed by the mammalian enzymes listed in Table 6-1. Some biotransformation reactions are catalyzed by enzymes in the gut microflora (largely anaerobic bacteria in the colon), whereas the biotransformation of still other xenobiotics is catalyzed by enzymes that participate in intermediary (endobiotic) metabolism. This principle is illustrated in Fig. 6-1 for 3 xenobiotics that are all converted to benzoic acid and then hippuric acid. The conversion of toluene to hippuric acid is catalyzed by some of the xenobiotic-biotransforming enzymes listed in Table 6-1: microsomal CYP converts toluene to benzoic acid in 3 oxidative steps ($\text{R-CH}_3 \rightarrow \text{R-CH}_2\text{OH} \rightarrow \text{RCHO} \rightarrow \text{RCOOH}$), which introduces a functional group (namely, $-\text{COOH}$) that is conjugated with glycine to produce hippuric acid, which is excreted in urine. Cinnamic acid is also converted to benzoic acid but, in this case, the reaction is catalyzed by the mitochondrial enzymes involved in the β -oxidation of fatty acids. Quinic acid is also converted to benzoic acid, but this reductive, multistep reaction is catalyzed by gut microflora. Incidentally, the conversion of benzoic acid to hippuric acid is of historical interest because it is generally recognized as the first xenobiotic biotransformation reaction to be discovered (in dogs by Woehler in 1828, and in humans by Ure in 1841).

Some drugs are intentionally designed to be biotransformed by endobiotic-metabolizing enzymes. For example, the anti-HIV drug zidovudine (AZT) is converted to a triphosphate nucleoside by enzymes in the salvage pathway (nucleoside kinase, nucleoside monophosphate kinase [NMK], and nucleoside diphosphate kinase [NDK]). HIV reverse transcriptase inhibitors, such as zidovudine, are administered as nonphosphorylated analogs to facilitate their absorption and cellular uptake. Conversely, some drugs are administered as a phosphorylated prodrug (eg, fosamprenavir) to promote their water solubility and rate of dissolution. The luminal surface of the small intestine contains high levels of alkaline phosphatase, which hydrolyzes prodrugs such as fosamprenavir and thereby releases the active drug at the surface of the enterocyte, where it is readily absorbed. Generally speaking, kinase and

Figure 6-1. Examples of xenobiotic biotransformation by different enzyme systems: a xenobiotic-biotransforming enzyme (cytochrome P450), an endobiotic-metabolizing enzyme, and gut microflora.

alkaline phosphatase are not usually considered to be xenobiotic-biotransforming enzymes.

Point 8 Just as some xenobiotics are biotransformed by the so-called endobiotic-metabolizing enzymes (Point 7), certain endobiotics are biotransformed by the so-called xenobiotic-metabolizing enzymes. For example, the same CYP enzymes implicated in xenobiotic biotransformation also contribute to the hepatic catabolism of steroid hormones, and the same UGTs that conjugate xenobiotics also glucuronidate bilirubin, thyroid hormones, and steroid hormones. Interestingly, the CYP and UGT enzymes that play a major role in steroid metabolism (namely, CYP3A4 and UGT1A1) display positive homotropic cooperativity (ie, the enzymes have Hill coefficients >1) such that the rate of metabolism of steroid hormones by these enzymes is slow at low substrate concentrations but increases dramatically as the concentration of steroid hormone increases. Benzoic acid, a xenobiotic, is conjugated with glycine (as shown in Fig. 6-1), and so are bile acids (endobiotics). Certain leukotrienes are GSH conjugates. Conjugates of endogenous substrates, such as the glucuronide and sulfate conjugates of steroid and THs, tend to be transported out of the hepatocyte by MRP2, the same canalicular transporter that transports drug conjugates into bile. From the few examples in Points 7 and 8, it is apparent that, on a case-by-case basis, there is often no clear-cut distinction between endobiotic- and xenobiotic-biotransforming enzymes.

The human genome project has helped to establish that what were once thought to be 2 distinct enzymes, one involved in the metabolism of endobiotics and one involved in the metabolism of xenobiotics, are in fact one and the same enzyme. For example, the microsomal enzyme known as 11β -hydroxysteroid dehydrogenase

is identical to the xenobiotic-metabolizing enzyme known as microsomal carbonyl reductase (gene symbol HSD11B1; aka SDR26C1). Likewise, hepoxilin A_3 hydrolase was thought to represent a fifth class of epoxide hydrolases, but was subsequently identified as the same enzyme as soluble epoxide hydrolase (sEH) (Cronin *et al.*, 2011).

Point 9 Several xenobiotic-biotransforming enzymes are inducible, meaning their expression can be increased (upregulated) usually in response to exposure to high concentrations of xenobiotics. Induction is mediated by ligand-activated receptors (so-called xenosensors) that are activated by xenobiotics (ligands) to DNA-binding proteins that upregulate the transcription of various genes encoding xenobiotic-biotransforming enzymes, especially CYP enzymes, which are usually induced to the greatest extent (in terms of fold increase). The major xenosensors are aryl hydrocarbon receptor (AhR), which induces CYP1 enzymes, the constitutive androstane receptor (CAR), which induces CYP2B, 2C, and 3A enzymes, the pregnane X receptor (PXR), which also induces CYP2B, 2C, and 3A enzymes, and the peroxisome proliferator-activated receptor- α (PPAR α), which induces CYP4 enzymes. CAR and PXR are closely related nuclear receptors, and they tend to be activated by the same ligands and bind to the same DNA-response elements (ie, the same discrete regions of DNA that control gene expression), for which reason there is said to be considerable *cross-talk* between these 2 xenosensors. Certain xenosensors are activated by endogenous ligands (eg, bilirubin, bile acids, and fatty acids activate CAR, PXR, and PPAR α , respectively), and certain nuclear receptors, such as the vitamin D receptor (VDR), can mimic PXR and induce CYP3A4, which inactivates the active metabolite of

vitamin D. These examples illustrate how xenosensors are not just involved in xenobiotic disposition but also play a role in endobiotic homeostasis. Two proteins called Kelch-like ECH-related protein (KEAP)-1 and nuclear factor E2 p45-related factor-2 (Nrf2) function as xenosensors inasmuch as they induce enzymes in response to oxidative stress, which is often associated with xenobiotic biotransformation. Binding of the transcription factor Nrf2 to the region of DNA known as the antioxidant response element (also known as the electrophilic response element [EpRE]) induces enzymes that detoxify electrophiles and metabolites that generate reactive oxygen species (ROS), including glutathione transferase (GST; GSTA1), microsomal epoxide hydrolase (mEH), aldo-keto reductase (AKRs; AKR7A, also known as aflatoxin aldehyde reductase), NAD(P)H-quinone oxidoreductase (NQO1, also known as DT-diaphorase), microsomal heme oxygenase, and glutamate–cysteine ligase (GCL), which catalyzes the rate-limiting step in GSH synthesis. Induction of GCL increases the rate of GSH synthesis under conditions of oxidative stress and a decrease in GSH concentration (Lee and Johnson, 2004).

Induction is a reversible, adaptive response to xenobiotic exposure. The induced enzymes (and transporters) usually accelerate the elimination of the xenobiotic that triggered the induction process, in which case the xenobiotic is said to be an autoinducer (one that induces its own metabolism). However, xenobiotics often induce enzymes that are not capable of metabolizing them, in which case the induction is said to be gratuitous. Induction is a pleiotropic response: activation of AhR, CAR, PXR, PPAR α , and Nrf2 all results in alterations in the expression of numerous genes.

Suppression (downregulation) of drug-metabolizing enzymes is often associated with inflammatory diseases (such as arthritis), cancer, infectious diseases (both bacterial and viral), vaccination, and treatment with certain proinflammatory biologics (therapeutic proteins). These disease processes activate nuclear factor kappa-B (NF- κ B) (and other nuclear receptors), which suppresses the expression and induction of CYP and other xenobiotic-metabolizing enzymes because activated NF- κ B suppresses all 4 xenosensors (AhR, CAR, PXR, and PPAR α), as well as several other nuclear receptors. By reversing the disease process—such as lessening the inflammation associated with rheumatoid arthritis—some biologics (large drug molecules such as monoclonal antibodies and other types of therapeutic proteins) can reverse the suppression of drug-metabolizing enzymes and restore their activity to normal (predisease) levels (Morgan, 2009; Huang *et al.*, 2010).

Point 10 The ability of certain xenobiotic-biotransforming enzymes to metabolize hormones and other endobiotics (Point 8) and the ability of certain xenobiotics to induce xenobiotic-biotransforming enzymes (Point 9) have implications for understanding an important mechanism by which certain xenobiotics can alter homeostasis or cause toxicity. Persistent exposure to xenobiotics that are enzyme inducers (especially CAR and PPAR α activators) can increase the rate of steroid hormone oxidation by CYP and increase the rate of thyroid hormone glucuronidation and sulfonation that, in rodents, can lead to the development of Leydig cell tumors (due to elevated levels of LH and FSH) and thyroid follicular tumors (due to elevated levels of thyroid-stimulating hormone [TSH]), respectively (Grasso *et al.*, 1991). Persistent exposure to enzyme inducers can also cause liver tumors, although the mechanism is not fully understood. Activation of certain xenosensors (CAR or PPAR α) is critical to liver tumor development in mice, although upregulation of xenobiotic-biotransforming enzymes is less important than other xenosensor-dependent events, such as, in the case of the CAR activator phenobarbital, altered DNA methylation of numerous genes, upregulation of GADD45B (an antiapoptotic factor) and MDM2

(a negative regulator of the tumor suppressor p53), and the downregulation of gap junctional proteins (connexin 32), which diminishes cell–cell communication (Omiecinski *et al.*, 2011b).

Phenobarbital, Wy-14643, methapyrilene, and Ponceau S are representatives of 4 classes of nongenotoxic rodent tumorigens (epigenetic tumor promoters) that cause hepatocellular hyperplasia and hypertrophy in association with proliferation of the endoplasmic reticulum, peroxisomes, mitochondria, and lysosomes, respectively (Grasso *et al.*, 1991). In the first 2 cases, the hepatocellular changes depend on activation of CAR (in the case of phenobarbital) and PPAR α (in the case of Wy-14643). Prolonged activation of these receptors in rodents results in the development of liver and/or thyroid tumors. However, this is thought to be a rodent-specific phenomenon because, in the case of phenobarbital and other enzyme-inducing antiepileptic drugs (EIAEDs), there is compelling epidemiological evidence that these chemicals do not cause liver tumors in humans even after >30 years of treatment (Parkinson *et al.*, 2006).

The major UGT responsible for conjugating bilirubin is UGT1A1, which is inducible by CAR activators such as phenobarbital and scoparone (6,7-dimethylesculetin). At one time, the management of neonatal jaundice included treatment with phenobarbital to induce bilirubin conjugation, but this practice has been discontinued. However, the Chinese herbal Yin Zhi Huang (active ingredient scoparone) is still used to treat neonatal jaundice. Bilirubin is also a CAR agonist, and high levels of bilirubin induce UGT1A1 and bilirubin/bilirubin glucuronide transporters (MRP2 [ABCC2] and MRP3 [ABCC3]) to increase the rate of bilirubin elimination when bilirubin levels are elevated (eg, during hemolytic anemia).

Although prolonged activation of PXR in rats is associated with thyroid tumor promotion due to induction of triiodothyronine (T3) glucuronidation (Richardson and Klaassen, 2010), this effect is thought not to occur in humans. However, prolonged activation of PXR by rifampin in humans (which induces hepatic and intestinal CYP3A4) is associated with osteomalacia caused by an enhanced rate of conversion of the active metabolite of vitamin D to inactive metabolites by CYP3A4 (Xu *et al.*, 2006; Zhou *et al.*, 2006a).

Point 11 Xenobiotic biotransformation can alter the biological properties of a xenobiotic. It can make the xenobiotic less toxic (detoxication), but in some cases it can make it more toxic (activation). The oxidation of ethanol (alcohol) to acetaldehyde is an example of xenobiotic activation, and the subsequent oxidation of acetaldehyde to acetic acid is an example of detoxication. The biotransformation of drugs can result in (1) a loss of pharmacological activity (eg, the conversion of acetaminophen to acetaminophen glucuronide and the conversion of morphine to morphine-3-glucuronide), (2) no change in pharmacological activity (eg, the conversion of fluoxetine to its *N*-demethylated metabolite norfluoxetine), or (3) an increase in pharmacological activity (eg, the conversion of codeine to morphine, as well as the conversion of morphine to morphine-6-glucuronide). When the parent drug is pharmacologically active, diminished metabolism (due to a genetic deficiency or enzyme inhibition) can result in an exaggerated pharmacological response (Type A toxicity), such as the prolonged or increased hypotension caused by debrisoquine, alprenolol, bufuralol, metropolol, propranolol, and timolol in individuals lacking CYP2D6 (Turner *et al.*, 2001; Ingelman-Sundberg, 2005). When a metabolite is the pharmacologically active component, diminished formation (due to a genetic deficiency or enzyme inhibition) can result in little or no pharmacological response (Type F toxicity), such as the diminished effects of codeine and tamoxifen in individuals lacking CYP2D6 and the diminished effects of clopidogrel in individuals lacking CYP2C19 (discussed in the sections “CYP2D6” and “CYP2C19”).

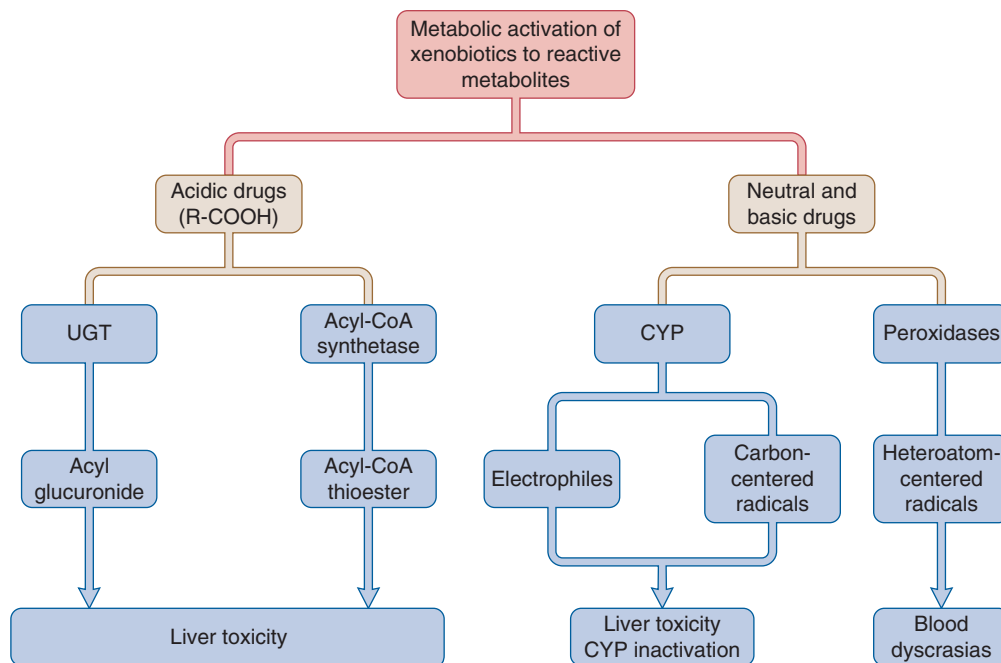

Figure 6-2. Some major pathways of metabolic activation of xenobiotics to reactive metabolites that cause toxicity.

Point 12 In many cases, the toxicity of a xenobiotic is due to the parent compound (the compound that was absorbed), in which case xenobiotic biotransformation serves as a detoxication mechanism. This principle is underscored by the clinical observation that the incidence of ADEs is often higher in individuals with a poor metabolizer (PM) phenotype (discussed later in Point 24). However, xenobiotic-biotransforming enzymes can convert certain xenobiotics to reactive metabolites (eg, electrophiles and radicals), and this activation process plays an important role in chemical toxicity and chemical mutagenicity/carcinogenicity; the former often involves the covalent binding of reactive metabolites to critical cellular nucleophiles such as proteins, whereas the latter involves covalent binding to one or more purine or pyrimidine bases in DNA. Formation of reactive metabolites can also lead to irreversible CYP inhibition (a process known as metabolism-dependent inhibition [MDI] or time-dependent inhibition [TDI]), which is an important cause of drug–drug interactions. As illustrated in Fig. 6-2, carboxylic acid–containing drugs (especially the acetic and propionic acid–containing NSAIDs that cause liver toxicity) can be converted to reactive acyl glucuronides and/or acyl-CoA thioesters, whereas many neutral and basic drugs are converted by CYP to electrophilic metabolites or carbon-centered radicals that may cause liver toxicity (or damage to the cells harboring the activating CYP). Several nitrogen- and sulfur-containing drugs can be activated by peroxidases to heteroatom-centered radicals that can cause blood dyscrasias such as agranulocytosis/neutropenia, aplastic anemia, and thrombocytopenia (Tang and Lu, 2010; Walsh and Miwa, 2011). In Fig. 6-2, the scheme depicting the formation and toxicity of reactive metabolites is an oversimplification. Furthermore, some drugs can be converted to 2 or more reactive metabolites. Tienilic acid, for example, contains a carboxylic acid group, which is converted to a reactive acyl glucuronide and acyl-CoA thioester, and a furan (a neutral group), which is converted by CYP to an epoxide and other reactive metabolites (such as an enedial).

CYP is particularly effective at converting proximate carcinogens to ultimate carcinogens by converting the former to electrophilic metabolites that bind to and mutate DNA, thereby leading to mutations and tumor initiation. The Ames bacterial mutagenicity

assay, which is representative of several mutagenicity tests, is performed in the absence and presence of CYP (ie, liver microsomes) to evaluate the mutagenic potential of both the parent compound and any electrophilic metabolites, respectively. Polycyclic aromatic hydrocarbons (PAHs; combustion pollutants and components of tobacco smoke), aromatic amines (industrial chemicals), aflatoxin (a mycotoxin), cooked food pyrolysis products, and tobacco-specific nitrosamines are all examples of proximate carcinogens that require metabolic activation to form electrophilic, DNA-binding metabolites (ultimate carcinogens).

Certain anticancer drugs require activation by xenobiotic-metabolizing enzymes in order to exert their antineoplastic effects. For example, cyclophosphamide is activated by CYP (CYP2B6 and CYP3A4), and canfosfamide is activated by GST, namely, GSTP1-1, which is often overexpressed in tumors thereby conferring resistance against certain anticancer drugs (see the section “Glutathione Conjugation”) (Gonzalez and Tukey, 2006).

Liver microsomes are widely used in 3 *in vitro* systems to investigate the potential of drugs or drug candidates to be converted to reactive metabolites. First, liver microsomes from Aroclor 1254–treated (induced) rats are used in the Ames bacterial mutagenicity assay. A limitation of this assay is that it is well suited to identify reactive metabolites formed by CYP but not by other xenobiotic-biotransforming enzymes, examples of which are given in the section “Conjugation.” This limitation has been addressed through genetic engineering of *Salmonella typhimurium* so that test bacteria express one or more human xenobiotic-metabolizing enzymes (Iwata *et al.*, 1998; Glatt and Meinel, 2004b). Second, human and rat liver microsomes are widely used to assess the formation of reactive metabolites that bind covalently to microsomal protein or GSH (or a related nucleophile such as *N*-acetylcysteine [NAC]). This system does a poor job of distinguishing hepatotoxic drugs from nonhepatotoxic drugs (Obach *et al.*, 2008), but the distinction is improved when covalent binding is assessed in human hepatocytes and dose is taken into account (Bauman *et al.*, 2009; Nakayama *et al.*, 2009). Third, human liver microsomes are widely used to evaluate a drug candidate’s potential to cause irreversible inhibition of the major drug-metabolizing CYP enzymes.

False-negative results can occasionally occur when metabolism by a non-CYP enzyme is instrumental to CYP inactivation, such as the need to glucuronidate gemfibrozil in order to inactivate CYP2C8. In such cases of so-called system-dependent inhibition the use of human hepatocytes offers advantages over human liver microsomes (Parkinson *et al.*, 2010).

Structural alerts (functional groups) for the bioactivation of xenobiotics to reactive metabolites that cause toxicity and/or CYP inactivation include the following (which is not an exhaustive list): (1) acetic and propionic acids (activated by UGT and/or acyl-CoA synthetase), (2) nitro aromatics (activated by reductases and/or CYP), and (3) a large number of functional groups that are activated by CYP and, in some cases, peroxidases: acetylenes, activated aromatics, 3-alkyl indoles, anilines, cyclopropylamines, formamides, furans, hydrazines, pyrroles, sulfonylureas, thiazolidinones, thioamides, thiophenes, and thioureas (Walsh and Miwa, 2011).

Point 13 The toxicity and potential carcinogenicity of electrophilic metabolites produced by CYP and other xenobiotic-biotransforming enzymes is reduced and often altogether eliminated by their conjugation with GSH, which is often described as a non-critical cellular nucleophile. Conjugation with GSH can occur both enzymatically (by GST) and nonenzymatically. In the majority of cases, conjugation with GSH represents a detoxication reaction, one that protects critical cellular nucleophiles, such as protein and DNA, from covalent modification. However, there are cases (eg, methylbromide and dibromoethane) where conjugation with GSH actually produces a DNA-reactive (mutagenic) metabolite. Activation of haloalkanes and dihaloalkanes (which are used industrially as fumigants) is usually catalyzed by the Theta class of GSTs (Josephy, 2010). Depletion of GSH or genetic deficiency of a particular GST can predispose to certain drug toxicities. For example, the genetic loss of glutathione transferase-Mu (GSTM1) predisposes to the hepatotoxic effects of carbamazepine and valproic acid (Saruwatari *et al.*, 2010), whereas the combined loss of GSTM1 and glutathione transferase-Theta (GSTT1) is a risk factor for troglitazone hepatotoxicity (Ikeda, 2011).

Point 14 The biotransformation of some xenobiotics results in the production of ROS, which can cause cell toxicity (including DNA damage) through oxidative stress and lipid peroxidation. GSH, GSTs, and glutathione peroxidases (GPXs) all limit the toxic effects of ROS just as they limit the toxicity of reactive metabolites formed directly from xenobiotics. Oxidative stress and the formation of electrophilic metabolites reduce GSH levels and thus result in the concurrent oxidation of KEAP-1, which then releases Nrf2, which in turn upregulates the expression of enzymes that detoxify electrophilic metabolites (eg, epoxides) and those metabolites that generate ROS (eg, quinones) (see Point 9). Certain xenobiotics and ischemic reperfusion injury cause an accumulation of unfolded proteins in the endoplasmic reticulum (where proteins are folded and posttranslationally modified), which gives rise to the unfolded protein response (UPR; also known as endoplasmic reticulum stress [ER stress]), which activates Nrf2 and Bax-inhibitor-1 (BI-1). The heme oxygenase induced by Nrf2 as well as BI-1 (which complexes with NADPH-cytochrome P450 reductase) protects cells from oxidative stress by inhibiting the production of ROS by CYP2E1 and other CYP enzymes (discussed in the section “CYP2E1”).

Point 15 The balance between activation and detoxication by xenobiotic-biotransforming enzymes is often a key determinant of chemical toxicity, and is often the basis for organ or species differences in toxicity. For example, aflatoxin is converted by liver microsomal CYP to a reactive epoxide that is thought to be responsible for the hepatotoxic and hepatocarcinogenic effect of this mycotoxin. The fact that this reaction occurs in the liver

explains why aflatoxin causes liver toxicity and liver tumors. On this basis, mice would be expected to be more sensitive than rats to the hepatotoxic effects of aflatoxin because mice catalyze the epoxidation of aflatoxin faster than rats. However, through GSH conjugation, mice also detoxify aflatoxin epoxide faster than rats. Consequently, despite their slower rate of activation, rats are more susceptible than mice to the toxic effects of aflatoxin. Coumarin is hepatotoxic to rats, but not to humans. This species difference is attributable to differences in the metabolites formed by CYP. Rats convert coumarin to a reactive epoxide that rearranges to a reactive aldehyde, whereas humans convert coumarin to the relatively non-toxic metabolite 7-hydroxycoumarin (umbelliferone).

Point 16 Exposure to xenobiotics (especially drugs) is largely through oral ingestion, and the small intestine and liver are highly developed to limit systemic exposure to orally ingested xenobiotics, a process known as *first-pass elimination* (or *presystemic elimination*). The enterocytes at the tips of the small intestinal villi express the efflux transporters P-glycoprotein (ABCB1 or MDR1) and BCRP (ABCG2), which serves to limit xenobiotic absorption. The enterocytes express high levels of certain CYP and UGT enzymes, which biotransform a wide variety of xenobiotics. The liver expresses a number of uptake transporters that actively remove xenobiotics from the blood. They also express a number of efflux transporters that actively discharge xenobiotics or their metabolites (especially conjugates) into the bile canaliculus for biliary excretion, or that actively discharge xenobiotic metabolites (especially conjugates) across the sinusoidal membrane back into the blood for urinary excretion. The liver expresses the largest number and, with few exceptions, the highest concentrations of xenobiotic-biotransforming enzymes.

Although the liver contains higher concentrations of most xenobiotic-biotransforming enzymes, and because the number of hepatocytes in the liver exceeds the number of enterocytes in the small intestine, it might be assumed that, compared with the liver, the small intestine would make only a small contribution to first-pass metabolism, but this is not the case in part because in the small intestine xenobiotics are recycled by P-glycoprotein (ABCB1) and BCRP (ABCG2) on the luminal surface of enterocytes, which delays absorption and increases the opportunity for xenobiotic biotransformation by intestinal enzymes such as CYP (especially CYP3A4), UGT, and sulfotransferase (SULT) (Benet, 2009). Furanocoumarins in grapefruit juice inhibit intestinal but not hepatic CYP3A4 and yet grapefruit juice increases systemic exposure to felodipine and other drugs that undergo first-pass metabolism by CYP3A4 (Paine *et al.*, 2006). The impact of the CYP3A4 inhibitor ketoconazole on the disposition of the CYP3A4 substrate midazolam depends on whether midazolam is given orally or intravenously. When midazolam is given intravenously, such that its clearance is dependent only on hepatic metabolism, ketoconazole causes a 3- to 5-fold increase in the area-under-the-plasma-concentration-time curve (AUC). However, when midazolam is given orally, ketoconazole causes a 10- to 15-fold increase in AUC, the difference reflecting the significant role of intestinal metabolism to the presystemic clearance of midazolam. In rats, administration of the general CYP inhibitor 1-aminobenzotriazole (ABT) by the intravenous route (which inhibits only hepatic CYP enzymes) and the oral route (which inhibits both intestinal and hepatic CYP enzymes) can be used to assess the relative role of the intestine and liver to the first-pass metabolism of a drug or other xenobiotic (Strelevitz *et al.*, 2006).

The small intestine and liver are exposed to high concentrations of xenobiotics, and they possess high levels of the enzymes that potentially convert xenobiotics to reactive or toxic metabolites.

It is perhaps not surprising, therefore, that both tissues possess protective mechanisms to minimize the risk of xenobiotic toxicity and carcinogenicity. As already mentioned, both tissues have enzymes and transporters that facilitate the elimination of xenobiotics and their metabolites. In both tissues, several of the xenobiotic-biotransforming enzymes and transporters are inducible, enabling the liver and the small intestine to respond to high levels of xenobiotics by enhancing the rate of xenobiotic biotransformation and elimination. In the small intestine, the enterocytes at the villus tips undergo extensive turnover, such that the mature cells that are exposed to high levels of xenobiotics and/or reactive metabolites are quickly lost (exfoliated) and replaced in a matter of days. In liver, high levels of GSH (5–10 mM), a large proportion of diploid (binucleated) cells, and a high regenerative capacity all protect the liver from xenobiotic toxicity or help the liver to repair chemical-mediated toxicity. In addition, severely damaged hepatocytes can undergo apoptosis (cell-programmed death) to eliminate precancerous cells (ie, cells with extensive DNA damage).

Point 17 Some of the same mechanisms that protect the small intestine and liver from xenobiotic toxicity also protect certain organs such as the brain and reproductive organs. Xenobiotics that enter the systemic circulation are often excluded from the brain by the blood–brain barrier, which poses a physical barrier to xenobiotic transport (in the form of tight junctions) and a biochemical barrier notably in the form of the efflux transporters *P*-glycoprotein (ABCB1) and BCRP (ABCG2). Germ cells in the testis are protected in part by a blood–testis barrier, by high levels of GSH (and GST and GPX), and by high cell turnover (as in the case of enterocytes). The ovum, with virtually no cell turnover, possesses high levels of GSH (8 mM or more), which protects it from DNA-reactive electrophiles and from the oxidative stress that accompanies both xenobiotic exposure and fertilization. Efflux transporters and GSTs are often overexpressed in tumor cells as a result of chromosomal rearrangements that place the genes encoding these proteins under the control of a strong promoter. The overexpression of a transporter and/or GST can confer resistance to certain cancer chemotherapeutic agents (many of which are intended to be converted to reactive metabolites that damage DNA and kill tumor cells).

Point 18 In view of the important role of CYP in the metabolic activation of proximate carcinogens to ultimate carcinogens, it may seem paradoxical to list CYP induction among the defense mechanisms that protect organisms from the carcinogenic effects of xenobiotics. Activation by CYP is definitely required for certain xenobiotics to exert their carcinogenic effects, and induction of CYP is associated with an increase in the toxicity of certain xenobiotics. However, contrary to expectation, treatment of rodents with a CYP inducer prior to treatment with a known proximate carcinogen (such as aflatoxin, various nitrosamines, or PAHs) is generally associated with a decrease, not an increase, in tumor incidence (Parkinson and Hurwitz, 1991). The route of exposure to the carcinogen can affect the impact of enzyme induction; it protects against orally administered drugs but may increase the tumorigenicity of carcinogens applied directly to their site of action (Nebert *et al.*, 2004), and prolonged treatment of rodents with an enzyme inducer *after* application of the initiating carcinogen can lead to an increase in tumor incidence because many enzyme inducers act as tumor promoters (see Point 10). Nevertheless, for the most part, enzyme induction provides protection against chemical toxicity and carcinogenesis (Nebert and Dalton, 2006; Shimada, 2006; Ma and Lu, 2007).

Point 19 Although the small intestine and liver contain the highest concentrations, xenobiotic-biotransforming enzymes are nevertheless widely distributed throughout the body. In terms of

specific content (ie, the amount of enzyme on a per-milligram-protein basis), some of the highest concentrations of xenobiotic-metabolizing enzymes are to be found in nasal epithelium, a portal of entry for many volatile xenobiotics. The presence of high levels of xenobiotic-biotransforming enzymes in nasal epithelium is of interest because numerous xenobiotics cause nasal cytotoxicity and cancer in rodents (reviewed in Jeffrey *et al.*, 2006). Xenobiotic-biotransforming enzymes in the lung, eye, and skin can be especially important for the metabolism of drugs delivered by inhalation, eye drop, or topical application, respectively. The kidney expresses several xenobiotic-biotransforming enzymes, in addition to numerous transporters that actively secrete xenobiotics (especially acidic metabolites) into urine. The kidney also metabolizes GSH conjugates formed in the liver and converts them to mercapturic acids (*N*-acetylcysteine conjugates).

Point 20 Species differences in xenobiotic-biotransforming enzymes are often the basis for species differences in both the qualitative and quantitative aspects of xenobiotic biotransformation and toxicity. As mentioned in Point 15, species difference in coumarin metabolism and toxicity (activation by epoxidation in rats, detoxication by aromatic hydroxylation in humans) reflects a species difference in hepatic microsomal CYP, whereas species differences in GST activity account for the difference between rats and mice in terms of their susceptibility to aflatoxin-induced liver toxicity. Species differences in the fetal expression of xenobiotic-biotransforming enzymes have raised questions about the suitability of laboratory animals to assess the risk of human teratogenicity because human fetal liver expresses CYP3A7, an enzyme capable of activating aflatoxin to reactive metabolites, whereas no such enzyme is expressed in the fetus of rodents (Li *et al.*, 1997; Pang *et al.*, 2012). Biotransformation, inhibition, and induction can occur in a species-specific manner. For example, furafylline and omeprazole are inhibitors and inducers of human CYP1A2, respectively, but they do not inhibit or induce CYP1A2 in rodents. Such species differences are the impetus for the development of chimeric mice (in which the mouse hepatocytes are replaced with human hepatocytes) (Strom *et al.*, 2010) and so-called humanized mice, which involves substituting the murine genes that encode xenobiotic-metabolizing enzymes (and the receptors that regulate their expression) with their human counterparts (Gonzalez, 2003; Gonzalez and Yu, 2006).

In some species, entire pathways of xenobiotic biotransformation are low or absent from a particular species. For example, cats and dogs are considered poor glucuronidators and poor acetylators of xenobiotics, respectively. Because of their inability to glucuronidate drugs, cats are sensitive to acetaminophen hepatotoxicity (Baillie and Rettie, 2011). Dogs are poor acid secretors, which disfavors the gastric absorption of acidic drugs. Interestingly, although dogs can conjugate acidic drugs, they are poor metabolizers of acidic drugs in terms of oxidative biotransformation by CYP enzymes (Baillie and Rettie, 2011). Metabolism by gut microflora can occur in a species-dependent manner. For example, as shown in Fig. 6-1, quinic acid is converted to benzoic acid in humans and old-world monkeys but not in new-world monkeys, mice, rats, and most other laboratory animals (Adamson *et al.*, 1970).

Point 21 In sexually mature rats and, to a lesser extent, mice there are marked gender differences in the expression of certain xenobiotic-biotransforming enzymes (both oxidative and conjugating enzymes) (Waxman and Holloway, 2009). In other species, including humans, gender differences either do not exist or generally represent less than a 2-fold difference, whereas the differences in rodents can be an order of magnitude or greater (Parkinson *et al.*, 2004; Soldin *et al.*, 2011). Against a large background of interindividual variation in each gender, it is often difficult to discern gender

differences in xenobiotic biotransformation in humans, although, in general, women appear to have lower CYP1A2 and higher CYP3A4 activity than men (Parkinson *et al.*, 2004). It is particularly interesting that, compared with men, women appear to have a higher incidence of idiosyncratic drug toxicity (Walgren *et al.*, 2005), which has been the cause of a number of drug withdrawals and black box warnings (see Point 22).

Point 22 Idiosyncratic drug reactions (IDRs) are rare adverse events (generally <0.1%) that do not involve an exaggerated pharmacological response, do not occur in most patients at any dose, and typically do not occur immediately after exposure but do so after weeks or months of repeated administration (Walgren *et al.*, 2005). IDRs are also known as Type B or hypersensitivity reactions and they can be divided into allergic and nonallergic IDRs. The former tend to develop relatively quickly (in days or weeks) and, after the drug is discontinued, patients respond robustly when rechallenged with the same or a closely related drug, whereas the latter tend to develop relatively slowly (with symptoms sometimes appearing after 6 months or more of drug treatment) and patients may or may not respond to rechallenge with the drug. Evidence for an immune component (ie, an acquired immune response) to allergic IDRs is often circumstantial or lacking, as is the evidence for the lack of an immune component to nonallergic IDRs, which possibly involve an innate immune response. Hepatotoxicity is a prevalent IDR. Drugs that were withdrawn from the US market or carry a black box warning for idiosyncratic hepatotoxicity are listed in Table 6-3. The drugs are structurally diverse and fall into numerous therapeutic classes.

Several factors predispose to IDRs including gender (women are more prone than men), age (the elderly are more prone), ethnicity, viral infection (a particularly strong predisposing factor), and other disease states (such as diabetes and obesity), possibly alcohol consumption, comedications that cause pharmacokinetic drug–drug interactions, genetic polymorphisms in xenobiotic-biotransforming enzymes and transporters (discussed in Point 23), and genetic polymorphisms that affect immune function especially allelic variants of human leukocyte antigens (HLA haplotypes), part of the major histocompatibility complex (MHC) (Alfirevic and Pirmohamed, 2010; Chalasani and Björnsson, 2010).

The best understood IDR is the skin hypersensitivity reaction to the anti-HIV drug abacavir, which is determined in a highly predictable manner by an individual's HLA subtype (Alfirevic and Pirmohamed, 2010). Abacavir binds to the antigen-presenting groove of MHC I molecule in patients carrying the B*5701 allele (in patients of all ethnic groups). In vitro studies have demonstrated that treatment of antigen-presenting cells positive for B*5701, but not for the related alleles B*5702 or B*5801, with abacavir can stimulate a CD8+ T-cell response. Topical exposure to abacavir (patch test) reveals activated CD8+ T cells in skin biopsies. Genetic testing for B*5701 is highly predictive; abacavir hypersensitivity is almost never seen in individuals without the B*5701 allele and it is seen in about half of B*5701-positive carriers. Genetic testing for B*5701 prior to abacavir treatment is required by the FDA and is cost effective (the cost of treating the severe skin lesions that occur in 5%–9% of abacavir-treated patients outweighs the costs of genetic testing). The strongest association (odds ratio >1000) between HLA alleles (HAL B*1502) and IDR is seen with carbamazepine-induced skin lesions (Stevens–Johnson syndrome [SJR] and toxic epidermal necrolysis [TEN]) in Han Chinese, Thai, Malay, and Indian populations. However, B*1502 is neither predictive of SJS/TEN in Japanese or Caucasian populations (in whom HLA-A*3101 is a moderate risk factor) (McCormack *et al.*, 2011) nor predictive

of other carbamazepine-induced IDRs such as maculopapular exanthema or drug reaction with systemic symptoms (DRESS) in Asian populations (Alfirevic and Pirmohamed, 2010).

Hypersensitivity to abacavir is unusual for 2 reasons. First, an individual's HLA haplotype (the expression of B*5701) is the dominant determining factor. Second, the parent drug, which binds to the antigen-binding groove of B*5701, rather than a (reactive) metabolite, appears to be the precipitating factor, although it is possible that a metabolite formed in peripheral blood mononuclear cells (PBMCs) may contribute to or be responsible for the IDR. In other IDRs, especially drug-induced liver injury (DILI), there is evidence that a reactive metabolite triggers the idiosyncratic response by forming a protein adduct (hapten) that triggers an acquired immune response (activation of killer T cells and/or antibody-producing B lymphocytes). There is strong evidence including the production of antibodies against drug-modified proteins that the idiosyncratic DILI caused by halothane and tienilic acid are due to the formation of reactive metabolites, which is why, during the process of drug development, considerable attention is devoted to avoiding drug candidates that are converted to reactive metabolites that bind covalently to protein (see Point 12) (Obach *et al.*, 2008; Bauman *et al.*, 2009; Nakayama *et al.*, 2009; Tang and Lu, 2010; Ikeda, 2011; Park *et al.*, 2011; Walsh and Miwa, 2011). However, formation of reactive metabolites (which occurs in all individuals) is insufficient to account for the rarity of idiosyncratic DILI. For many drugs that cause idiosyncratic DILI, HLA haplotype is a factor but not to the extent seen with abacavir (Alfirevic and Pirmohamed, 2010).

In several cases, the drugs that cause idiosyncratic liver injury (those listed in Table 6-3) have closely related structures that do not cause idiosyncratic DILI. For example, rosiglitazone and pioglitazone contain the same thiazolidinedione ring that in troglitazone is converted to a reactive metabolite, and yet only troglitazone has been withdrawn from the market because of idiosyncratic hepatotoxicity. This difference may be due to the much larger daily dose of troglitazone (300 mg) compared with rosiglitazone (4–8 mg) and pioglitazone (15–45 mg). Uetrech (2001) has proposed the general rule that drugs administered at a daily dose of 10 mg or less do not cause idiosyncratic toxicity, and this rule is consistent with the dosing information shown in Table 6-3. Both dose (more than 50 mg/day) and extent of hepatic metabolism (greater than 50%) are now recognized as risk factors for idiosyncratic drug-induced liver injury (Lammert *et al.*, 2008 and 2010; Chalasani and Björnsson, 2010). Other examples of closely related drugs where one does and one does not cause hepatotoxicity include tolcapone/entacapone, ticlopidine/clopidogrel, amineptine/tianeptine, tamoxifen/toremifene, ibufenac/ibuprofen, ebrotidine/famotidine, and niperotidine/ranitidine (Walgren *et al.*, 2005). Labetalol has 2 chiral centers and is a racemic mixture of 4 enantiomers, one of which is dilevalol. Although labetalol carries a black box warning for hepatotoxicity, dilevalol was not approved by the FDA because it caused a high incidence of liver toxicity during clinical trials. In some cases the difference is thought to be due to differences in dose (which is invariably higher for the drug partner that causes hepatotoxicity), but in other cases the basis for the difference is not known. Furthermore, more than 20 drugs (many of which do not cause idiosyncratic toxicity) bind covalently to their pharmacological target, including aspirin, omeprazole (and other proton pump inhibitors), clopidogrel, and neratinib (Singh *et al.*, 2011).

Just as the acquired immune system can be activated by drugs that cause Type B toxicity (idiosyncratic toxicity) so the innate immune system can be activated by drugs that cause Type C (off-target) toxicity. For example, acetaminophen (Tylenol), which is a

Table 6-3

Drugs That Have Been Withdrawn or Carry a Black Box Warning for Idiosyncratic Hepatotoxicity*

DRUG NAME	TYPICAL DOSE	INDICATION	REACTIVE METABOLITE AND EVIDENCE OF METABOLISM-DEPENDENT ENZYME INHIBITION	INDUCTION, [†] IMMUNOLOGICAL AND OTHER MECHANISTIC ASPECTS
Drugs withdrawn				
Benoxaprofen	300-600 mg	NSAID	Acyl glucuronide	Inducer (rat AhR and PPAR α agonist)
Bromfenac	25-50 mg	NSAID	Acyl glucuronide	
Iproniazid	25-150 mg	Depression	Multiple. MDI of MAO-B	Anti-MAO-B and antimitochondria
Nefazodone	200 mg	Depression	Quinoneimine. MDI of CYP3A4	
Tienilic acid	250-500 mg	Diuretic	Thiophene epoxide, sulfoxide. MDI of CYP2C9	Anti-LKM ₂ (anti-CYP2C9)
Troglitazone	400 mg	Diabetes	Quinone methide, sulfenic acid, α -ketoisocyanate	Inducer (CAR/PXR agonist)
Black box warnings				
Acitretin	25-50 mg	Psoriasis	No. Acitretin, a retinoid, is esterified to etretinate	Etretinate was withdrawn in 2002
Bosentan	125-250 mg	PAH	No	Inhibits BSEP. Inducer (PXR agonist)
Dacarbazine	140-315 mg	Melanoma, lymphoma	Methyl diazohydroxide and methyl cation (CH ₃ ⁺)	Hepatotoxic to laboratory animals
Dantrolene	300-400 mg	Muscle relaxant	Nitro-reduction intermediates bind to GSH	Inducer (AhR agonist)
Felbamate	1200 mg	Epilepsy	2-Phenylpropenal (atropaldehyde)	Inducer (PXR agonist)
Flutamide	750 mg	Prostate cancer	Nitro-reduced, nitrogen radicals, and <i>ortho</i> -quinoneimines bind to protein and GSH [‡]	Inhibits mitochondrial respiration
Gemtuzumab	9 mg/m ²	AML	Reductive activation to a diradical	Designed to intercalate and bind DNA
Isoniazid	300 mg	Tuberculosis	Multiple. MDI of CYP1A1, 2A6, 2C19, and 3A4	Radicals formed by myeloperoxidase
Ketoconazole	200 mg	Fungal infections	Dialdehyde	Autoinhibitor (inhibits CYP3A4)
Naltrexone	50 mg	Alcoholism, addiction	No	
Nevirapine	200-400 mg	AIDS	Quinonemethide. MDI of CYP3A4 [§]	Inducer (PXR agonist)
Pemoline	37.5-112.5 mg	Hyperactivity	No	
Tolcapone	300 mg	Parkinsonism	Nitro-reduction and then quinoneimine formation	Uncouples mitochondrial respiration
Trovafloxacin	100-500 mg	Antibiotic	No, but it has a lipophilic difluorinated side chain present in a toxic fluoroquinolone—now withdrawn	Eosinophilia suggests an immune-mediated hepatitis
Valproic acid (VPA)	1000-4200 mg	Epilepsy	CoA thioesterification and epoxidation of 4-ene-VPA	Disrupts mitochondrial β -oxidation

AhR, aryl hydrocarbon receptor; AIDS, acquired immunodeficiency syndrome; AML, acute myeloid leukemia; anti-LKM₂, autoantibodies against liver and kidney microsomes (anti-LKM₁ contains antibodies against CYP2D6, whereas anti-LKM₂ contains antibodies against CYP2C9); BSEP, bile salt export pump (a bile canalicular transporter); CYP, cytochrome P450; GSH, glutathione; MAO, monoamine oxidase; MDI, metabolism-dependent inhibitor (aka suicide inactivator); NSAID, nonsteroidal anti-inflammatory drug; PAH, pulmonary arterial hypertension; PPAR α , peroxisome proliferator-activated receptor- α ; PXR, pregnane X receptor; VPA, valproic acid.

*Data adapted from Walgren et al. (2005).

[†]The receptor agonist assignment is based on the CYP-induced enzyme (CYP1A for AhR; CYP2B, CYP2C, and/or CYP3A for CAR/PXR; CYP4A for PPAR α).

[§]Chen et al. (2008).

leading cause of acute liver failure in humans (Kaplowitz, 2005), is activated to a reactive metabolite (*N*-acetylbenzo-p-quinoneimine) that binds covalently to mitochondrial proteins, which leads to cell death. The cell damage (necrosis) caused by acetaminophen causes the release of cellular constituents such as fragmented DNA (and other molecules that make up the so-called danger-associated

molecular pattern [DAMP]) that bind to Toll-like receptors and other receptors that activate macrophages, which in turn recruit neutrophils and monocytes to the site of injury (Jaeschke et al., 2012). Whether activation of the innate immune system in this way is detrimental (by leading to a second round of hepatocellular damage) or beneficial (by limiting damage and promoting tissue repair)

Table 6-4

The Relationship Between Genotype and Phenotype for the Polymorphically Expressed Enzyme CYP2D6 with Active (wt), Partially Active (*x), and Inactive (*y) Alleles

GENOTYPE	ALLELES	CONVENTIONAL	ACTIVITY SCORE*	ACTIVITY SCORE PHENOTYPE†
Duplication of active alleles ($n = 2$ or more)	(wt/wt) n	UM‡	$2 \times n$	UM
Two fully active wild-type (wt) alleles	wt/wt	EM	$1 + 1 = 2$	High EM
One fully active + 1 partially active allele	wt/*x	EM	$1 + 0.5 = 1.5$	Medium EM
One fully active + 1 inactive allele	wt/*y	EM	$1 + 0 = 1$	Low EM
Two partially active alleles	*x/*x	EM or IM	$0.5 + 0.5 = 1$	Low EM
One partially active + 1 inactive allele	*x/*y	IM	$0.5 + 0 = 0.5$	IM
Two inactive alleles	*y/*y	PM	$0 + 0 = 0$	PM

Data adapted from Gaedigk et al. (2008) and Zineh et al. (2004).

*In the case of CYP2D6, various activity scores have been assigned as follows:

Activity score = 1.0 for each *1 (wt), *2, *35, and *41 [2988G].

Activity score = 0.75 for each *9, *29, *45, and *46.

Activity score = 0.5 for each *10, *17, and *41 [2988A].

Activity score = 0 for each *3, *4, *5, *6, *7, *8, *11, *12, *15, *36, *40, and *42.

†Activity scores are classified as follows:

UM activity score ≥ 2.0 (eg, [$*1/*1$] n , where n is 2 or more gene duplications).

High EM activity score = 1.75 to 2.0 (eg, $*1/*1$).

Medium EM activity score = 1.5 (eg, $*1/*17$ or $*9/*9$).

Low EM activity score = 1.0 to 1.25 (eg, $*1/*4$, $*17/*17$, or $*9/*17$).

IM activity score = 0.5 to 0.75 (eg, $*4/*9$ or $*4/*17$).

PM activity score = 0 (eg, $*4/*4$).

‡The phenotypes are ultrarapid metabolizer (UM), extensive metabolizer (EM), intermediate metabolizer (IM), and poor metabolizer (PM), based on the particular combination of alleles that are fully active (wt), partially active (*x), or inactive (*y).

is controversial. However, it is noteworthy that, in the case of Type C toxicity, the innate immune system is activated by cellular components released from damaged cells (DAMP) and not by the drug or its metabolites (although in the example given it is recognized that the reactive metabolite of acetaminophen plays a critical role in causing the cell damage that subsequently activates the innate immune system). This contrasts with the direct role of the drug and/or its metabolites (including reactive metabolites) in Type B toxicity. In the case of idiosyncratic toxicity, the drug/metabolite plays a key role in activating the acquired immune system.

Point 23 The same dose of drug (or any other xenobiotic) administered to humans often results in large interindividual differences in exposure to the parent compound (typically measured as the plasma AUC). This variation can reflect genetically determined differences in the activity of xenobiotic-biotransforming enzymes or transporters (genetic polymorphisms) or environmental factors, such as drug–drug interactions.

The study of the causes, prevalence, and impact of heritable differences in xenobiotic-biotransforming enzymes is known as *pharmacogenetics*. It is the basis for the concept of individualized medicine, whereby the dosage of drugs with a narrow therapeutic index (such as anticancer drugs) is adjusted in accordance with an individual's genotype (ie, drug-metabolizing potential).

Genetic variation in a xenobiotic-metabolizing enzyme produces 4 discernible phenotypes: poor metabolizers (PMs), intermediate metabolizers (IMs), extensive metabolizers (EMs), and ultrarapid metabolizers (UMs), which arise from the expression of no functional alleles (–/–) for PMs, one nonfunctional allele and one partially functional allele or two partially active alleles (–/* or /*/*) for IMs, one or two functional alleles (+/–, +/*, or +/+) for

EMs, and gene duplication ([+/+] n) for UMs. This traditional classification scheme has been revised on the basis of an activity score, which assigns to each allelic variant a functional activity value from one (for the wild-type or *1 allele) to zero (for any completely non-functional allele), as shown in Table 6-4 (Zineh et al., 2004).

For those enzymes that are polymorphically expressed, such as CYP2D6, the incidence of the PM (and UM) genotype can vary widely from one ethnic group to the next. For example, the CYP2D6 PM genotype is common among Caucasians but not Asians, whereas the converse is true of the CYP2C19 PM genotype.

When the clearance of a drug is largely determined by a polymorphically expressed enzyme, such as CYP2D6, exposure to the parent drug follows the rank order: PMs > IMs > EMs > UMs. Exposure to metabolites (especially the maximum concentration, C_{max}) follows the opposite rank order. The difference in exposure between PMs and EMs (ie, the fold increase in C_{max} or AUC associated with the PM phenotype vs the EM phenotype) depends on fractional metabolism (fm), a measure of how much of the drug's clearance is determined by CYP2D6 (or whatever enzyme is responsible for metabolizing the drug in question). The fold increase in AUC (AUC_{PM}/AUC_{EM}) is equal to $1/(1 - fm)$; hence, the impact of the polymorphism increases dramatically as fm approaches unity. If CYP2D6 accounted for half of a drug's clearance ($fm = 0.5$), exposure to that drug would increase 2-fold in CYP2D6 PMs. However, if CYP2D6 accounted for 90% of a drug's clearance ($fm = 0.9$), then exposure to that drug would increase 10-fold in CYP2D6 PMs. This is why PMs are often at increased risk of ADEs either due to an exaggerated pharmacological response to the drug or due to its toxic side effects. An exception is omeprazole and other proton pump inhibitors, which actually provide improved control over

gastroesophageal reflux disease (GERD) in CYP2C19 PMs compared with EMs (Furuta *et al.*, 2005).

There are a minority of cases where the UMs, not the PMs, are at increased risk, especially in cases where the polymorphic enzyme catalyzes the formation of a pharmacologically active or toxic metabolite. For example, CYP2D6 converts the prodrug codeine to the active metabolite morphine, and there are reports of morphine intoxication in CYP2D6 UMs, one case being the death of a baby being breastfed by a CYP2D6 UM mother who was prescribed codeine (Gasche *et al.*, 2004; Koren *et al.*, 2006).

Many cases have now been described where the PM phenotype requires dosage adjustment to prevent off-target (Type C) toxicity or an exaggerated pharmacological response (Type A toxicity). For example, CYP2D6 PMs are at increased risk for perhexiline hepatotoxicity and at increased risk for an exaggerated pharmacological response to debrisoquine and sparteine, 3 drugs that were not approved in the United States because of the high incidence of adverse events in the PMs. On the other hand, when drugs are converted to active metabolites by CYP2D6, PMs derive inadequate therapeutic effect (Type F toxicity). For example, CYP2D6 converts codeine to morphine; hence, codeine is a less effective analgesic in PMs. Similarly, CYP2D6 converts the breast cancer drug tamoxifen to endoxifen (which is 30- to 100-fold more potent than tamoxifen in suppressing estrogen-dependent cell proliferation); hence, CYP2D6 PMs are at increased risk for breast cancer recurrence following tamoxifen adjuvant therapy (Goetz *et al.*, 2005). Other examples of genetic polymorphisms that affect drug disposition in humans include CYP2C8 (repaglinide, paclitaxel), CYP2C9 (warfarin), CYP2C19 (clopidogrel, omeprazole, lansoprazole, and pantoprazole), CYP3A5 (tacrolimus), UGT1A1 (irinotecan), UGT2B7 (morphine), thiopurine methyltransferase (TPMT) (6-mercaptopurine), *N*-acetyltransferase 2 (NAT2) (isoniazid), catechol-*O*-methyltransferase (COMT) (levodopa), dihydropyrimidine dehydrogenase (DPD) (5-fluorouracil), and the efflux transporter P-glycoprotein (digoxin) (Robert *et al.*, 2005; Relling and Giacomini, 2006). Details of these genetic polymorphisms are given later in the chapter. Many of the drugs identified in parentheses have a narrow therapeutic index. Some victim drugs have a high therapeutic index; hence, they are therapeutically effective in PMs to UMs and cause roughly the same incidence of adverse effects regardless of genotype. However, in the case of victim drugs with a narrow therapeutic index, dosage must be increased in UMs to achieve a therapeutic effect and/or it must be decreased in PMs to prevent ADEs.

Genetic polymorphisms in xenobiotic-biotransforming enzymes have an impact on the incidence of certain environmental diseases. For example, ethnic differences in the incidence of polymorphisms in alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) impact the incidence of alcoholism (Li, 2000). Genetic polymorphisms in CYP2A6 impact the incidence of cigarette-smoking-induced lung cancer. Individuals lacking CYP2A6 are PMs of nicotine (so they tend to smoke less than CYP2A6 EMs) and are poor activators of tobacco-specific mutagens (so they form fewer DNA-reactive metabolites than do CYP2A6 EMs) (Kamatani *et al.*, 2005).

Genetic polymorphisms can be the underlying cause of a disease. For example, the severe and mild hyperbilirubinemia associated with Crigler–Najjar syndrome and Gilbert syndrome, respectively, reflect a complete and partial loss of the UGT responsible for conjugating bilirubin, namely, UGT1A1. The hyperbilirubinemic Gunn rat is the rodent equivalent of Crigler–Najjar

syndrome. Genetic polymorphisms in CYP1B1 are associated with primary congenital glaucoma.

Genetic polymorphisms have been described in laboratory animals. For example, laboratory-bred rabbits have about 50:50 chance of being a poor or rapid acetylator of certain drugs (such as isoniazid) because NAT2 is polymorphically expressed in rabbits. CYP1A2 is polymorphically expressed in dogs.

Point 24 Environmental factors can introduce as much variation in drug metabolism as can genetic factors, and this is especially true of drug–drug interactions. To take CYP3A4 as an example, PMs can be created pharmacologically with inhibitors (such as ketoconazole and erythromycin), whereas UMs can be created pharmacologically with inducers (such as rifampin and the herbal agent St. John’s wort). Whereas the impact of genetic polymorphisms on drug disposition and safety is often identified during clinical trials, the impact of drug–drug interactions may not be identified until after the drug has been approved and is under postmarketing surveillance.

Drugs (and other xenobiotics) can be viewed from a *victim* and *perpetrator* perspective. A drug whose clearance is largely determined by a single route of elimination, such as metabolism by a single CYP enzyme, is considered a victim drug (also known as a sensitive or object drug). Such drugs have a high victim potential because a diminution or loss of that elimination pathway, either due to a genetic deficiency in the relevant CYP enzyme or due to its inhibition by another, concomitantly administered drug, will result in a large decrease in victim drug clearance and a correspondingly large increase in exposure (the magnitude of which will depend on fm, as indicated in Point 23). Perpetrators are those drugs (or other environmental factors) that inhibit or induce the enzyme that is otherwise responsible for clearing a victim drug. In other words, perpetrators are drugs that cause drug–drug interactions. Perpetrators are also known as precipitants. Genetic polymorphisms that result in the partial or complete loss of enzymatic activity can also be viewed as perpetrators inasmuch they cause a decrease in the clearance of—and an increase in exposure to—victim drugs. A combination of 2 perpetrators (such as 2 drugs that inhibit different enzymes or an inhibitory drug plus a genetic polymorphism) can have a dramatic effect on the disposition of a victim drug if they impair *parallel* pathways of clearance, a phenomenon called *maximum exposure* (Collins *et al.*, 2006). This is illustrated by voriconazole, whose metabolic clearance is determined by CYP2C19 and CYP3A4 (which represent 2 parallel pathways of clearance). Based on plasma AUC, CYP2C19 PMs (individuals lacking CYP2C19) are exposed to roughly twice as much voriconazole compared with CYP2C19 EMs. Loss of CYP3A4 (and only CYP3A4) by administering ritonavir to CYP2C19 EMs also causes about a doubling in systemic exposure to voriconazole. However, when ritonavir is administered to CYP2C19 PMs (such that *both* CYP2C19 and CYP3A4 are inactive), exposure to voriconazole increases more than 25-fold. This example illustrates how 2 drugs (ritonavir and voriconazole) can interact dramatically in some individuals (CYP2C19 PMs) but not others (CYP2C19 EMs). Conversely, a perpetrator drug that inhibited only CYP2C19 would cause such inhibition only in CYP2C19 EMs (the PMs having no enzyme to inhibit). Many other examples of perpetrator–perpetrator–victim interactions (maximum exposure) are reviewed in Ogilvie and Parkinson (in press).

Terfenadine (Seldane), cisapride (Propulsid), astemizole (Hismanal), and cerivastatin (Baycol) are all victim drugs, so much so that they have all been withdrawn from the market (Fung *et al.*, 2001). The first 3 are all victim drugs because they are extensively metabolized by CYP3A4. Inhibition of CYP3A4 by various

antimycotic drugs, such as ketoconazole, and antibiotic drugs, such as erythromycin, decreases the clearance of terfenadine, cisapride, and astemizole and increases their plasma concentrations to levels that, in some individuals, cause ventricular arrhythmias (QT prolongation) that can result in fatal heart attacks. Cerivastatin is extensively metabolized by CYP2C8. Its metabolism is inhibited by gemfibrozil (actually by gemfibrozil glucuronide), and the combination of cerivastatin (Baycol) and gemfibrozil (Lopid) is associated with a high incidence of fatal, cerivastatin-induced rhabdomyolysis (Ogilvie *et al.*, 2006).

Mibefradil (Posicor) is the only drug withdrawn from the US market largely because of its perpetrator potential. This calcium channel blocker not only causes extensive inhibition of CYP3A4 but also causes prolonged inhibition of the enzyme by virtue of being a metabolism-dependent inhibitor of CYP3A4. By inactivating CYP3A4 in an irreversible manner—such that restoration of normal CYP3A4 activity requires the synthesis of new enzyme—mibefradil inhibits CYP3A4 long after treatment with the drug is discontinued.

The *in vitro* technique of reaction phenotyping (also known as enzyme mapping) is the process of identifying which enzyme or enzymes are largely responsible for metabolizing a drug candidate (Williams *et al.*, 2003b; Ogilvie *et al.*, 2008). Reaction phenotyping allows an assessment of the victim potential of a drug candidate or other xenobiotic. Drug candidates can also be evaluated *in vitro* for their potential to inhibit or induce CYP enzymes, which allows an assessment of their perpetrator potential (Tucker *et al.*, 2001; Bjornsson *et al.*, 2003; <http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/DrugInteractionsLabeling/ucm080499.htm>; Huang *et al.*, 2008; EMA, 2012; FDA, 2012).

Herbal remedies can also interact with drugs. For example, St. John's wort contains hyperforin, which is a potent PXR agonist and, as such, is an inducer of CYP3A4 (along with several other xenobiotic-metabolizing enzymes) and *P*-glycoprotein (ABCB1). To prevent a loss of therapeutic efficacy, the use of St. John's wort is not recommended for patients on antirejection drugs (such as cyclosporine and tacrolimus), anti-HIV drugs (such as indinavir and nevirapine), anticoagulants (such as warfarin and phenprocoumon), or oral contraceptive steroids (Pal and Mitra, 2006). Food can affect drug disposition in a number of ways. It can affect absorption, which is why some drugs are taken with meals and others are taken between meals. Large quantities of cruciferous vegetables (eg, broccoli and Brussels sprouts) can induce hepatic CYP1A2 (Conney, 1982), whereas grapefruit juice can inhibit intestinal CYP3A4 (Paine *et al.*, 2006).

Point 25 Although drug–drug interactions can cause an increase in the incidence of adverse events or, in the case of induction, a loss of therapeutic efficacy, not all drug–drug interactions are undesirable. For example, some anti-HIV drugs, such as ritonavir, inhibit CYP3A4 and thereby improve the pharmacokinetic profile of other anti-HIV drugs, such as saquinavir and lopinavir. Tumors often overexpress various transporters and GSTs, which limit the effectiveness of several anticancer drugs. Drugs that inhibit transporters and GST are being developed to enhance the efficacy of anticancer drugs.

Point 26 Although the amount of functional enzyme determines whether an individual is a PM, IM, EM, or UM, disease states and cofactor levels can impact the rate of xenobiotic metabolism. Not surprisingly, severe liver disease decreases the rate of metabolism of a large number of drugs whose clearance is determined by hepatic metabolism, as can kidney disease that decreases the hepatic

expression of CYP2D6 (Rostami-Hodjegan *et al.*, 1999). For certain xenobiotic-metabolizing enzymes, particularly the conjugating enzymes, cofactor availability can impact the rate of xenobiotic biotransformation. The liver usually has sufficient NADPH to saturate reactions catalyzed by CYP, but it does not have sufficient levels of UDP-glucuronic acid (UDPGA) or 3'-phosphoadenosine-5'-phosphosulfate (PAPS) to saturate the enzymes responsible for glucuronidating or sulfonating xenobiotics. Consequently, alterations in the levels of these cofactors can impact the rate or extent of glucuronidation and sulfonation. For example, fasting lowers hepatic levels of these cofactors, and fasting decreases the extent to which acetaminophen is conjugated. Consequently, fasting increases the extent to which acetaminophen is metabolized to a toxic metabolite by CYP (including CYP2E1, which is induced by fasting), for which reason fasting is suspected of being one of the risk factors for acetaminophen hepatotoxicity (Whitcomb and Block, 1994).

Point 27 Stereochemical aspects can play an important role in the interaction between a xenobiotic and its biotransforming enzyme (from both a substrate and an inhibitor perspective), and xenobiotic-biotransforming enzymes can play a key role in converting one stereoisomer to another, a process known as *mutarotation* or *inversion of configuration*.

A xenobiotic that contains a chiral center can exist in 2 mirror-image forms called stereoisomers or enantiomers. The biotransformation of some chiral xenobiotics occurs stereoselectively, meaning that one enantiomer (stereoisomer) is biotransformed faster than its antipode. For example, the antiepileptic drug Mesantoin[®], which is a racemic mixture of *R*- and *S*-mephenytoin, is biotransformed stereoselectively in humans, such that the *S*-enantiomer is rapidly hydroxylated (by CYP2C19) and eliminated faster than the *R*-enantiomer. The ability of some chiral xenobiotics to inhibit xenobiotic-biotransforming enzymes can also occur stereoselectively. For example, quinidine is a potent inhibitor of CYP2D6, whereas quinine, its antipode, has relatively little inhibitory effect on this enzyme. In some cases, achiral molecules (or achiral centers) are converted to a mixture of enantiomeric metabolites, and this conversion may proceed stereoselectively such that one enantiomer is formed preferentially over its antipode. Inversion of configuration is the process whereby one enantiomer is converted to its antipode via an achiral intermediate. This interconversion can occur nonenzymatically, as in the case of thalidomide, or it can be catalyzed by a xenobiotic-metabolizing enzyme, as in the case of lisofylline, or by an endobiotic-metabolizing enzyme, as in the case of simvastatin (Fig. 6-3).

In the case of thalidomide, inversion of configuration (as shown in Fig. 6-3) occurs spontaneously, although the process is facilitated by albumin (Eriksson *et al.*, 1998). In the mid-to-late 1950s, mainly in Europe, thalidomide was prescribed to pregnant women in the first trimester to treat morning sickness. Unfortunately, whereas (*R*)-thalidomide is an effective sedative, the (*S*)-enantiomer is a teratogen that produces phocomelia (limb shortening) and other congenital defects in the offspring largely as a result of its ability to inhibit angiogenesis (vasculogenesis). The teratogenic effect of thalidomide cannot be circumvented by administering only the (*R*)-enantiomer because spontaneous or albumin-facilitated racemization quickly produces the teratogenic (*S*)-enantiomer. Thalidomide blocks the release of tumor necrosis factor- α (TNF α) and it has been approved for the treatment of erythema nodosum leprosum (an acute inflammatory reaction associated with lepromatous leprosy), and is useful in the treatment of several other inflammatory conditions and immune-mediated diseases. Because of its ability to inhibit angiogenesis (the process that supplies tumors with

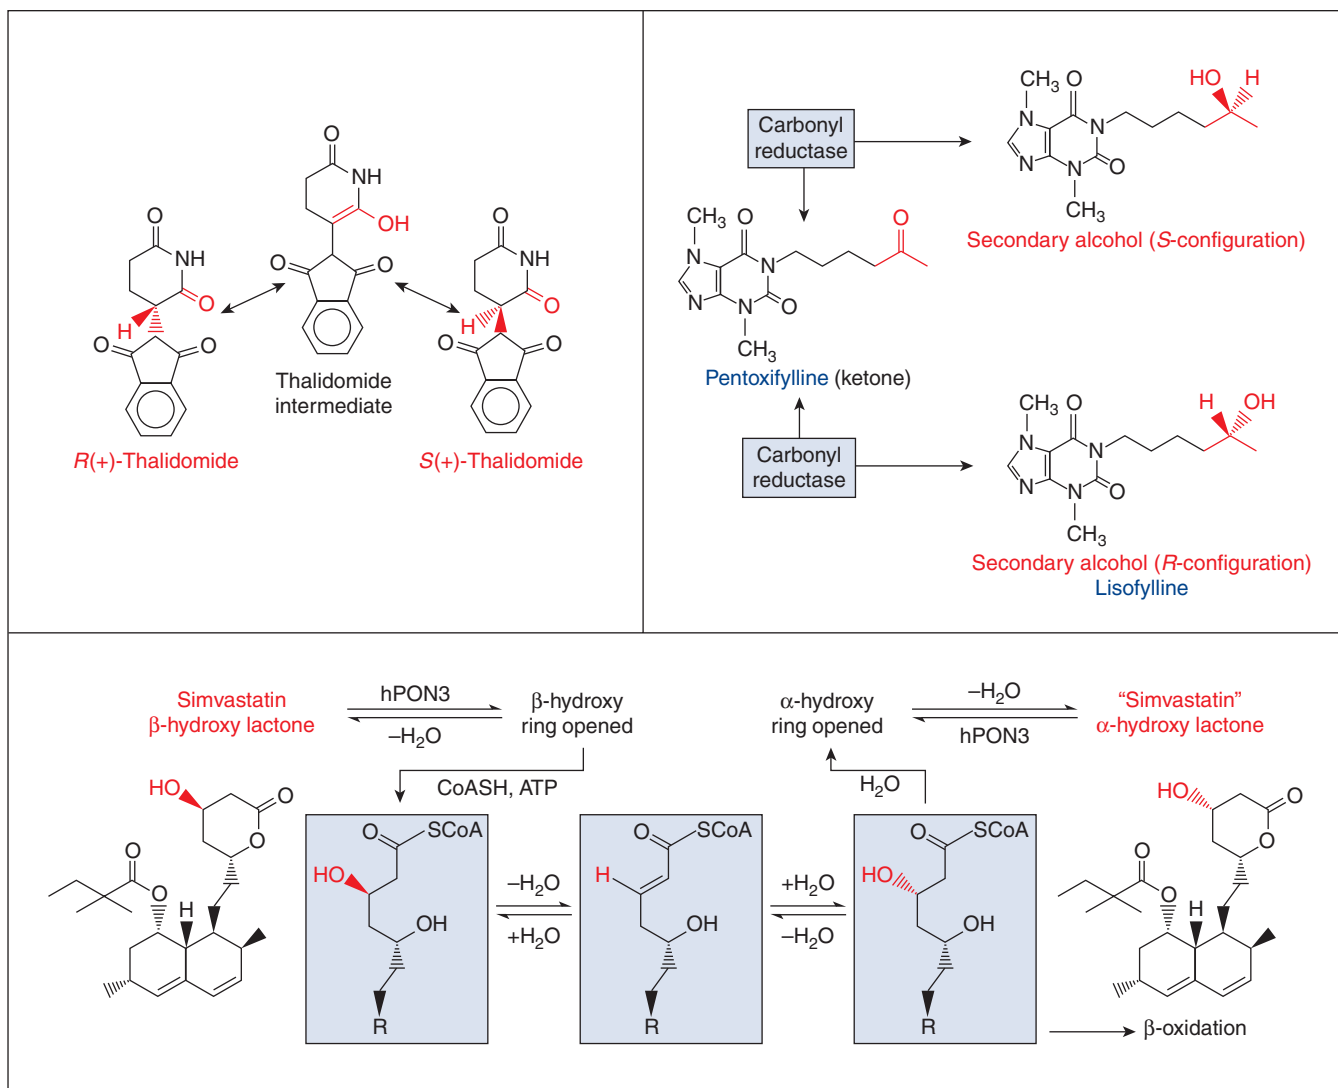

Figure 6-3. Stereochemical aspects of xenobiotic biotransformation: inversion of configuration by nonenzymatic means (thalidomide), by carbonyl reductase (lisofylline), and by hydrolysis and condensation (lactonization) of a lactone ring (simvastatin).

new blood vessels), thalidomide is also under investigation as an anticancer drug. It is ironic that a drug with antivasular side effects that was originally prescribed as a sedative is now in clinical trials for vascular diseases with sedation as a side effect (Franks *et al.*, 2004).

Ketones can be reduced by carbonyl reductases to a mixture of enantiomeric secondary alcohols, and this can occur with a high degree of stereoselectivity. For example, pentoxifylline is reduced by carbonyl reductases in blood and liver to a mixture of secondary alcohols with the major metabolite having an *S*-configuration, as shown in Fig. 6-3. Interestingly, the minor metabolite, a secondary alcohol with the *R*-configuration, has pharmacological properties distinct from those of its *S*-antipode and its ketone precursor, pentoxifylline. This minor metabolite is known as lisofylline, which is under clinical investigation for the treatment of various diseases. Through the action of carbonyl reductase, lisofylline is oxidized to pentoxifylline and then reduced to its antipode (ie, *R*-alcohol \rightarrow ketone \rightarrow *S*-alcohol), the net result being an inversion of configuration (Lillibridge *et al.*, 1996). The same type of interconversion explains why the administration of pure *R*-albuterol to human volunteers results in the formation of *S*-albuterol, just

as the administration of pure *S*-albuterol leads to the formation of *R*-albuterol (Boulton and Fawcett, 1997).

In the case of simvastatin (which contains a β -hydroxy lactone), the interconversion of 2 secondary alcohols (β -hydroxy lactone \leftrightarrow α -hydroxy lactone) involves hydrolysis of the lactone ring (by paroxonase 3 [PON3] in humans) followed by formation of an acyl-CoA thioester with CoA, the first step in the β -oxidation of fatty acids, followed by dehydration to an achiral intermediate. Reversal of the steps by a combination of hydrolysis and lactonization (condensation) restores the lactone ring with the hydroxyl group in the original β -configuration or in the opposing α -configuration. In humans, both the initial hydrolysis of the lactone ring and the final lactonization (condensation) reaction are catalyzed by PON3 (Draganov and La Du, 2004). Conversion to an acyl-CoA thioester also plays a role in the chiral inversion of ketoprofen. In this case, only the *R*-enantiomer is converted to an acyl-CoA thioester, which isomerizes and undergoes hydrolysis to the *S*-enantiomer. Although both *R*- and *S*-ketoprofen are converted to acyl glucuronides, the former is hydrolyzed twice as quickly as the latter, which further contributes to the accumulation of the *S*-enantiomer (Regan *et al.*, 2010).

Point 28 Mass spectrometry is widely used to characterize the structure of metabolites, and many instruments now come equipped with software to assist in this process, based on the fact that certain xenobiotic reactions are associated with discrete changes in mass (Holčapek *et al.*, 2008). For example, the loss of 2 atomic mass units (amu) signifies dehydrogenation, whereas the loss of 14 amu usually signifies demethylation ($-\text{CH}_2$). Several reactions result in an increase in mass, including reduction ($+2$ amu = 2H), methylation ($+14$ amu = CH_2), oxidation ($+16$ amu = O), hydration ($+18$ amu = H_2O), acetylation ($+42$ amu = $\text{C}_2\text{H}_2\text{O}$), glucosidation ($+162$ amu = $\text{C}_6\text{H}_{10}\text{O}_5$), sulfonation ($+80$ amu = SO_3), glucuronidation ($+176$ amu = $\text{C}_6\text{H}_8\text{O}_6$), carbamoyl glucuronidation ($+220$ amu = $\text{C}_7\text{H}_8\text{O}_8$), and conjugation with GSH ($+305$ amu = $\text{C}_{10}\text{H}_{15}\text{N}_3\text{O}_6\text{S}$), glycine ($+57$ amu = $\text{C}_2\text{H}_3\text{NO}$), taurine ($+107$ amu = $\text{C}_2\text{H}_5\text{NO}_2\text{S}$), and glutamine ($+107$ amu = $\text{C}_5\text{H}_7\text{NO}_3$) (Holčapek *et al.*, 2008). Conjugation of acidic drugs with CoA (to form acyl-CoA thioesters) increases mass by 749 amu, but these conjugates are not transported out of cells and, hence, are not detected in blood, bile, or urine.

Occasionally, routine changes in mass can arise from unexpected reactions. For example, ziprasidone is converted to 2 metabolites, each of which involves an increase of 16 amu, which normally indicates addition of oxygen (eg, hydroxylation, sulfoxidation, *N*-oxygenation). One of the metabolites is indeed formed by addition of oxygen to ziprasidone (sulfoxidation), as shown in Fig. 6-4 (Beedham *et al.*, 2003). However, the other metabolite is formed by a combination of reduction ($+2$ amu) and methylation ($+14$). Therefore, nominal changes in mass can sometimes leave in doubt the biotransformation event that led to metabolite formation, which accounts for the popularity of accurate mass spectrometry, a technique that can distinguish, in the case of ziprasidone, for example, oxidation from a combination of reduction and methylation.

Mass spectrometry can typically provide information on which region of a molecule has undergone biotransformation, but in some cases it cannot distinguish between several closely related possibilities. For example, based on mass spectrometry alone, it might be

possible to ascertain that a certain phenyl group has been hydroxylated. However, analysis by nuclear magnetic resonance (NMR) may be required to ascertain whether the hydroxylation occurred at the *ortho*, *meta*, or *para* position.

Point 29 As mentioned in Point 19, xenobiotic-biotransforming enzymes are widely distributed throughout the body. The advent of high-throughput assays based on quantitative real-time reverse-transcription polymerase chain reaction (QPCR) has facilitated comprehensive measurements of the levels of mRNA encoding numerous xenobiotic-biotransforming enzymes, transporters, and xenosensors in a wide range of human tissues (Nishimura *et al.*, 2003, 2004; Furukawa *et al.*, 2004; Nishimura and Naito, 2005, 2006). These data are very informative as far as mRNA expression is concerned, but it can be difficult to draw conclusions about the activity of a given enzyme in a given tissue based on mRNA levels alone. For instance, based on mRNA levels in human liver, the levels of the major xenobiotic-biotransforming CYP enzymes follow the rank order: CYP2E1 > 2A6 > 2C8 > 2C18 \approx 1A2 \approx 4A11 \approx 2C9 \approx 3A4 (Nishimura *et al.*, 2003). This contrasts substantially from the levels of CYP protein (as determined by LC-MS/MS), which follow the rank order: CYP2C9 > 3A4 \approx 2E1 \approx 2A6 > 2C8 > 1A2 > 2D6 > 2B6 \approx 2C19 > 3A5 \approx 3A43 \approx 3A7 (Kawakami *et al.*, 2011; Ohtsuki *et al.*, 2012). In the case of CYP2E1, hepatic mRNA levels are more than 17 times higher than the levels of CYP3A4 mRNA, but CYP2E1 protein levels in microsomes are comparable to those of CYP3A4. This discrepancy is due to the fact that, under normal conditions, most of the mRNA encoding CYP2E1 is sequestered in the cytoplasm and is not available for translation (Gonzalez, 2007). The mRNA for FMO2 is present at very high levels in human lung, but is not translated into functional enzyme due to the presence of a truncation mutation in Caucasians and Asians. However, about 33% of sub-Saharan Africans, 26% of African Americans, 7% of Puerto Ricans, and 2% of Mexicans have one normal allele and express a functional protein (Cashman and Zhang, 2006; Veeramah *et al.*, 2008). Human CYP2A7 and CYP4B1 are full-length genes that encode enzymes incapable of incorporating heme and are therefore nonfunctional.

Figure 6-4. Conversion of ziprasidone to 2 different metabolites, both involving a mass increase of 16 amu (relative to ziprasidone).

Mass spectrophotometric techniques for the quantitative analysis of proteins have been applied to drug-metabolizing enzymes and transporters (Kawakami *et al.*, 2011; Sakamoto *et al.*, 2011; Ohtsuki *et al.*, 2012). The levels of CYP and UGT enzymes in human liver microsomes have been determined by LC-MS/MS and are described in the sections “Cytochrome P450” and “Glucuronidation and Formation of Acyl-CoA Thioesters.”

HYDROLYSIS, REDUCTION, AND OXIDATION

Hydrolysis

Mammals contain a variety of enzymes that hydrolyze xenobiotics containing such functional groups as a carboxylic acid ester (delapril and procaine), amide (procainamide), thioester (spironolactone), carbamate (irinotecan), phosphoric acid ester (paraoxon),

acid anhydride (diisopropylfluorophosphate [DFP]), lactone (lovastatin), and thiolactone (erdosteine), most of which are shown in Figs. 6-5 and 6-6. The major hydrolytic enzymes are the carboxylesterases, cholinesterases, and paraoxonases (for which lactonase is a more encompassing name), but they are by no means the only hydrolytic enzymes involved in xenobiotic biotransformation. The first 2 classes of hydrolytic enzymes, the carboxylesterases and cholinesterases, are known as serine esterases because their catalytic site contains a nucleophilic serine residue that participates in the hydrolysis of various xenobiotic and endobiotic substrates and the stoichiometric (one-to-one) binding of organophosphorus (OP) compounds and other cholinergic neurotoxins.

Approximately 100 human gene products encode serine hydrolases that are classified as esterases, amidases, thioesterases, lipases, peptidases, or proteases (Evans and Cravatt, 2006; Ross and Crow, 2007; Testa and Krämer, 2008, 2010). The active-site serine residue of carboxylesterases, cholinesterases, and other

Figure 6-5. Examples of reactions catalyzed by carboxylesterases, cholinesterases, organophosphatases, and alkaline phosphatase. CES1 and CES2 (human carboxylesterases 1 and 2); PON1 and PON3 (human paraoxonase 1 and 3).

Figure 6-6. Activation of xenobiotics to toxic and tumorigenic metabolites by carboxylesterases.

serine hydrolases becomes phosphorylated (or phosphonylated) by OP compounds, such as those used as insecticides, herbicides, fungicides, nematocides, and plant growth regulators. Binding of OP compounds to carboxylesterases, cholinesterases, and other targets, some of which have been identified as receptors and enzymes involved in the hydrolysis of endobiotics (reviewed in Casida and Quistad, 2005), plays a key role in limiting the binding of OP compounds to acetylcholinesterase (AChE). Phosphorylation of AChE, which hydrolyzes acetylcholine and thereby terminates its neurotransmitter activity, is the principal mechanism of OP toxicity in mammals, insects, and nematodes, with 70% to 90% inhibition usually proving lethal. Reversal of this phosphorylation event with pyridinium oximes such as pralidoxime (2-PAM) and obidoxime (toxogonin) is one of the strategies to treat OP poisoning (Casida and Quistad, 2005).

Albumin, lipases, peptidases, proteases, ALDHs, and carbonic anhydrases have all been shown to have hydrolytic (esteratic) activity toward various xenobiotics. CYP can catalyze the cleavage of certain xenobiotics containing a carboxylic acid ester, phosphoric acid ester, or carbamate (see the section “Cytochrome P450” for examples).

In the presence of an alcohol, carboxylesterases and certain other hydrolytic enzymes can catalyze the transesterification of xenobiotics, which accounts for the conversion of cocaine (a methyl ester) to ethylcocaine (the corresponding ethyl ester) (Fig. 6-5). The same transesterification occurs with clopidogrel, which is converted from a methyl to an ethyl ester (Tang *et al.*, 2006). Transesterification occurs when ethanol, not water, cleaves the catalytic transition state, that is, the esteratic bond between the active serine residue on the enzyme and the carbonyl group on the xenobiotic:

In humans, the hydrolysis of xenobiotics (including many drugs) is largely catalyzed by microsomal carboxylesterases in liver (CES1 and CES2) and intestine (CES2), and by cholinesterases, paraoxonases, and albumin in blood (some of these enzymes are present in plasma; others are bound to erythrocytes in a species-dependent manner) (Li *et al.*, 2005). Compared with many other mammalian species humans are unusual because they lack a plasma carboxylesterase (Li *et al.*, 2005). However, human erythrocytes contain esterase D, a carboxylesterase used as a genetic marker for retinoblastoma (Wu *et al.*, 2009). On a case-by-case basis, specific enzymes other than those mentioned above can be involved in xenobiotic hydrolysis. For example, the valine ester prodrugs of acyclovir (valacyclovir) and ganciclovir (valganciclovir) are hydrolyzed by valacyclovirase (gene code BPHL), a serine- and α/β -fold-hydrolase that hydrolyzes other antiviral and anticancer nucleoside drugs such as zidovudine, floxuridine, and gemcitabine (Lai *et al.*, 2008).

In general, esters are hydrolyzed more rapidly than amides, which can impact the duration and site of action of drugs. For example, procaine, a carboxylic acid ester, is rapidly hydrolyzed, which is why this drug is used mainly as a local anesthetic. In contrast, procainamide, the amide analog of procaine, is hydrolyzed much more slowly; hence, this drug reaches the systematic circulation, where it is useful in the treatment of cardiac arrhythmia. In general, enzymatic hydrolysis of amides occurs more slowly than esters, although electronic factors can influence the rate of hydrolysis. The presence of electron-withdrawing substituents weakens an amide bond, making it more susceptible to enzymatic hydrolysis.

The hydrolysis of xenobiotics by carboxylesterases and other hydrolytic enzymes is not always a detoxication process. Fig. 6-5 shows some examples in which carboxylesterases convert xenobiotics to toxic and tumorigenic metabolites.

In 1953, Aldridge classified hydrolytic enzymes on the basis of their interaction with OP compounds, classifying those that hydrolyze OP compounds as A-esterases, those that are inhibited by OP compounds as B-esterases, and those that do not interact with OP compounds as C-esterases. Although the terms are still used, the classification system of Aldridge can be somewhat confusing because it divides the paraoxonases into the A- and C-esterase classes: the human paraoxonase PON1 hydrolyzes OP compounds and so can be classified as an A-esterase, whereas PON2 and PON3 can be classified as C-esterases because they neither hydrolyze OP compounds nor, in most cases, are inhibited by them. Furthermore, carboxylesterases and cholinesterases, 2 distinct classes of hydrolytic enzymes, are both B-esterases according to Aldridge because both are inhibited by OP compounds.

Carboxylesterases Carboxylesterases are predominantly microsomal enzymes (~60 kDa glycoproteins) that are present in liver, intestine, and a wide variety of tissues, including plasma in rats and mice but not humans. The 2 major human carboxylesterases involved in xenobiotic hydrolysis are CES1 and CES2, which differ in their tissue distribution and substrate specificity. Both enzymes are expressed in liver microsomes (although CES1 predominates) but only CES2 is expressed in intestinal microsomes (Nishimura and Naito, 2006; Ross and Crow, 2007). CES1 prefers to hydrolyze xenobiotics with a small alcoholic leaving group, whereas CES2 prefers to hydrolyze xenobiotics with a large alcoholic leaving group. In other words, methyl and ethyl esters tend to be hydrolyzed by CES1. This is illustrated in Fig. 6-5 for the hydrolysis of delapril by CES1 (which releases ethanol, a small alcohol) and the hydrolysis of procaine by CES2 (which releases a large alcohol). In the case of cocaine (the structure of which is shown in Fig. 6-5), the ethyl ester is hydrolyzed by CES1 (to release a small alcohol), whereas the benzoic ester is hydrolyzed by CES2 (to release a large alcohol). CES1 also catalyzes the transesterification of the methyl ester of cocaine, as shown in Fig. 6-5. CES1 is more active than CES2 at catalyzing the hydrolysis of oseltamivir, benazepril, cilazapril, quinapril, temocapril, imidapril, meperidine, delapril, and clopidogrel, whereas CES2 is more active than CES1 at hydrolyzing aspirin, heroin, cocaine benzoyl ester, 6-acetylmorphine, oxybutynin, and the anticancer drug irinotecan (also known as CPT-11) (Satoh and Hosokawa, 2006; Shi *et al.*, 2006; Tang *et al.*, 2006). Individual pyrethroids such as *trans*-permethrin represent an example of xenobiotics that are hydrolyzed by both CES1 and CES2 (Ross and Crow, 2007).

In addition to hydrolyzing xenobiotics, carboxylesterases hydrolyze numerous endogenous compounds, such as long- and short-chain acyl-glycerols (both monoacylglycerols and diacylglycerols), long-chain acyl-carnitine, long-chain acyl-CoA thioesters (eg, palmitoyl-CoA), retinyl ester, platelet-activating factor, and other esterified lipids. Carboxylesterases can also catalyze the synthesis of fatty acid ethyl esters, which represents a nonoxidative pathway of ethanol metabolism in adipose and certain other tissues. In the case of platelet-activating factor, carboxylesterases catalyze both the deacetylation of PAF and its subsequent esterification with fatty acids to form phosphatidylcholine (Satoh and Hosokawa, 1998).

In addition to CES1 and CES2, human liver microsomes contain another serine hydrolase known as AADAC, which stands for arylacetamide deacetylase. This enzyme catalyzes the hydrolysis of the

phenacetin (a discontinued drug), 2-acetylaminofluorene (2-AAF; a carcinogen), and flutamide (an antiandrogen drug) (Watanabe *et al.*, 2010). AADAC deacetylates phenacetin and 2-aminofluorene (2-AF) to aromatic amines that can be *N*-hydroxylated by CYP and then conjugated to form reactive metabolites. Examples of this type of metabolic activation are given later in the sections “Azo- and Nitro-Reduction” and “Conjugation”.

CES1 (the major liver form, which is also expressed in lung and other tissues) and CES2 (the major intestinal form, which is also expressed in kidney and brain) represent 2 of the 5 families of human carboxylesterases (Satoh and Hosokawa, 2006; Holmes *et al.*, 2010). The other enzymes are CES3 (expressed in brain, liver, and colon), CES4A (previously called CES6 or CES8, which is expressed in brain, lung, and kidney), and CES5A (previously called CES7, which is expressed in brain, lung, and testis). A larger number of carboxylesterases have been identified in rats and mice (Holmes *et al.*, 2010). Human CES1 is encoded by 2 genes (CSE1A1 and CSE1A2) that differ only in the amino acid sequence of the encoded signal recognition peptide (SRP) that directs the enzyme to the endoplasmic reticulum (Satoh and Hosokawa, 2006).

Genetic polymorphisms that affect carboxylesterase activity or expression levels underscore the importance of CES1 and CES2 in drug metabolism. Genetic polymorphisms of CES1 affect the disposition of methylphenidate (Ritalin, a methyl ester) and the antiviral prodrug oseltamivir (an ethyl ester) (Zhu and Markowitz, 2009). A phenotype for CES1 that might be classified as high EM has been described. It arises from a single-nucleotide polymorphism (SNP) in the promoter region of CES1A2 (but not CES1A1) that increases the expression of CES1 and thereby increases the rate of hydrolysis of imidapril to its active metabolite imidaprilat, an angiotensin-converting enzyme (ACE) inhibitor, which increases its antihypertensive effect (Geshi *et al.*, 2005). Genetic polymorphisms of CES2 affect the disposition of the anticancer drug irinotecan (CPT-11, a carbamate), which is converted by CES2 to the active metabolite SN-38, a topoisomerase inhibitor (Kubo *et al.*, 2005). However, genetic polymorphisms of UGT1A have a greater impact on the disposition and toxicity of irinotecan, as detailed in the section “Glucuronidation and Formation of Acyl-CoA Thioesters.”

Certain carboxylesterases also have a physiological function in anchoring other proteins to the endoplasmic reticulum. For example, the lysosomal enzyme β -glucuronidase is also present in the endoplasmic reticulum, where it is anchored in the lumen by egasyn, a microsomal carboxylesterase designated Ces1e in mouse and rat (Holmes *et al.*, 2010). Egasyn binds to β -glucuronidase at its active-site serine residue, which effectively abolishes the carboxylesterase activity of egasyn, although there is no corresponding loss of β -glucuronidase activity. Binding of OP compounds to egasyn causes the release of β -glucuronidase into plasma, which serves as the basis for a test for OP exposure (Fujikawa *et al.*, 2005). The retention of β -glucuronidase in the lumen of the ER is thought to be physiologically significant. Glucuronidation by microsomal UGTs is a major pathway in the clearance of many of the endogenous aglycones (such as bilirubin) and xenobiotics (such as drugs). However, hydrolysis of glucuronides by β -glucuronidase complexed with egasyn in the lumen of the ER appears to be an important mechanism for recycling endogenous compounds, such as steroid hormones (Dwivedi *et al.*, 1987). The acute-phase response protein, C-reactive protein, is similarly anchored in the endoplasmic reticulum by egasyn.

The mechanism of catalysis by carboxylesterases is analogous to the mechanism of catalysis by serine proteases. In the case of carboxylesterases, it involves charge relay among a catalytic triad comprising an acidic amino acid residue (glutamate [Glu₃₃₅]),

Figure 6-7. Catalytic cycle of microsomal carboxylesterase (left) and microsomal epoxide hydrolase (right), α/β -hydrolase fold enzymes.

a basic residue (histidine [His₄₄₈]), and a nucleophilic residue (serine [Ser₂₀₃]) (Yan *et al.*, 1994; Satoh and Hosokawa, 1998). (These amino acid residues, numbered for a rat carboxylesterase, differ slightly in other species, but the overall location and function of these residues are the same in all mammalian carboxylesterases.) The mechanism of catalysis of carboxylesterases is shown in Fig. 6-7, and is discussed in more detail in the section “Epoxide Hydrolases.” OP compounds bind to the nucleophilic OH-group on the active-site serine residue to form a phosphorus–oxygen bond, which is not readily cleaved by water. Therefore, OP compounds bind stoichiometrically to carboxylesterases and inhibit their enzymatic activity, for which reason they are also classified as B-esterases (Aldridge, 1953). Surprisingly, the stoichiometric binding of OP compounds to carboxylesterases and cholinesterases is

an important determinant of OP toxicity, as outlined in the section “Cholinesterases (AChE and BChE).”

As mentioned previously in this section, a plasma carboxylesterase, namely, Ces1c (previously known as Es1), is present in mouse plasma but not human plasma and accounts, at least in part, for the relative resistance of mice to the OP nerve agent soman. Duysen *et al.* (2011) demonstrated that plasma carboxylesterase knockout mice are considerably more susceptible to soman toxicity than wild-type mice.

Given the lack of plasma carboxylesterase in humans, the hydrolysis of xenobiotics in human blood is catalyzed by cholinesterases and paraoxonases (with a significant contribution from albumin on a case-by-case basis), as described in the following sections.

Cholinesterases (AChE and BChE) Humans have 2 cholinesterases, namely, acetylcholinesterase (AChE; gene name *ACHE*) and butyrylcholinesterase (BChE, also known as pseudocholinesterase; gene name *BCHE*), which are related enzymes (about 54% identical). They are present in most tissues. The levels of BChE are higher than those of AChE except in brain and muscle, tissues where AChE terminates the action of the neurotransmitter acetylcholine. In human plasma, the levels of BChE are 100- to 1000-fold greater than those of AChE, although the latter enzyme is present in erythrocytes (Li *et al.*, 2005). As the names imply, AChE and BChE have high activity toward acetylcholine and butyrylcholine, respectively. AChE is highly selective for acetylcholine and plays little or no significant role in the hydrolysis of xenobiotics, whereas BChE hydrolyzes numerous drugs (and other xenobiotics) including aspirin, bambuterol, chlorpropaine, cocaine, flestolol, heroin, irinotecan, isosorbide diaspinate, methylprednisolone acetate, mivacurium, moxislyte, *n*-octanoyl ghrelin, procaine, succinylcholine (suxamethonium), and tetracaine (Li *et al.*, 2005). Eserine (physostigmine) is an inhibitor of both enzymes, and iso-OMPA, bambuterol, tolserine, and bis-norcymserine are selective inhibitors of BChE (Liederer and Borhardt, 2006; Masson and Lockridge, 2010). Drugs that selectively inhibit brain AChE and BChE activity, such as rivastigmine (Exelon[®]), have been used to treat Alzheimer disease. Other drugs that inhibit AChE and are used to treat Alzheimer disease include tacrine (Cognex[®]), gelantamine (Reminyl[®]), and donepezil (Aricept[®]).

Both enzymes exist in 6 different forms with differing solubility: monomer (G1), dimer (G2), tetramer (G4), tailed tetramers (A4), double tetramers (A8), and triple tetramers (A12). G1, G2, and G4 contain 1, 2, and 4 subunits, each with a catalytic site. These various forms can each exist in 3 states: soluble (hydrophilic), immobilized (asymmetric), and amphiphilic globular (membrane-bound through attachment to the phospholipid bilayer) (Nigg and Knaak, 2000). All forms are expressed in muscle. In the case of AChE, the major form in brain is the tetramer G4 (anchored with a 20-kDa side chain containing fatty acids), but the major form in erythrocytes is the dimer G2 (anchored with a glycolipid-phosphatidylinositol side chain). In the case of BChE, the major form in plasma is the tetramer G4 (a glycoprotein with Mr 342 kDa). In both AChE and BChE, the esteratic site (containing the active-site serine residue) is adjacent to an anionic (negatively charged) site that interacts with the positively charged nitrogen on acetylcholine and butyrylcholine.

Genetic variants of AChE that eliminate its activity have not been described, which is not surprising given the key role that AChE plays in terminating neurotransmission by acetylcholine, although AChE knockout mice (AChE^{-/-}) are born alive and, despite developmental abnormalities, survive up to 21 days (Xie *et al.*, 2000).

Based on measurements of erythrocyte AChE activity, familial reductions of 30% have been reported, and a reduction of 50% has been linked to paroxysmal nocturnal hemoglobinuria (Nigg and Knaak, 2000).

More than 70 genetic variants of BChE have been described following the discovery of poor metabolizers (PMs) of succinylcholine (suxamethonium) and, later, mivacurium. Succinylcholine and mivacurium are muscle relaxants whose duration of action is determined by plasma BChE. Succinylcholine (1.5–2.0 mg/kg) is a rapidly acting muscle relaxant (the onset of paralysis takes 30–60 seconds) with a short duration of action (8–15 minutes) making it well suited for intubating patients. In some individuals, succinylcholine causes prolonged (60–120 minutes) paralysis (muscular relaxation and apnea), which led to the discovery of 2 BChE genetic polymorphisms (now known as BCHE**A* and BCHE**K*) (Cerf *et al.*, 2002). The so-called *A* variant of BChE (Asp₇₀Gly) has markedly reduced enzymatic activity (less than 10% of the wild-type enzyme) but is relatively rare; about 1 in 300 Caucasians are homozygous for the *A* variant. The *K* variant (Ala₅₃₉Thr) is considerably more common (with one in 63 individuals being homozygous) but the *K* variant still retains approximately two thirds of its enzymatic activity. Consequently, the *A* variant causes a greater impairment of succinylcholine (and mivacurium) metabolism than does the *K* variant (La Du, 1992; Lockridge, 1992; Levano *et al.*, 2008). Although the *A* variant has markedly diminished activity toward succinylcholine (due to a ~100-fold decrease in affinity [K_m]), it nevertheless has appreciable activity toward other substrates, such as acetylcholine and benzoylcholine. Wild-type BChE and the *A* variant are equally sensitive to the inhibitory effect of OP compounds, but the allelic variant is relatively resistant to the inhibitory effect of dibucaine, a local anesthetic, which forms the basis of a diagnostic test for its presence (frequently called a test for atypical pseudocholinesterase). The percent inhibition of hydrolysis of benzoylcholine by dibucaine (with both the substrate and inhibitor at 10 μ M) is called the dibucaine number; it is 80% or more with wild-type BChE and about 40% with the *A* variant in most but not all cases (Cerf *et al.*, 2002). The discovery of the *A* variant of BChE (the so-called atypical pseudocholinesterase) is of historical interest because it ushered in the new field of pharmacogenetics, a field pioneered by Dr Werner Kalow, after whom the *K* variant of BChE is named.

Carboxylesterases and cholinesterases in the blood and tissues play an important role in limiting the amount of cholinergic neurotoxins that reach AChE in the brain, marked inhibition (70%–90%) of which is lethal to mammals, insects, and nematodes. The cholinergic neurotoxins that are bound covalently to—or are hydrolyzed by—these enzymes include OP nerve agents (such as soman and sarin), OP pesticides (such as parathion, malathion, and chlorpyrifos, which are converted to oxons by CYP), carbamate pesticides (such as aldicarb, carbaryl, carbofuran), the naturally occurring OP compound anatoxin-a(S) from blue-green algae, physostigmine (eserine) from the Calabar bean, huperzine A from the club moss *Huperzia serrata*, solandine from green potatoes, and cocaine from the *Erythroxylum coca* plant. The covalent interaction between OP compounds and brain AChE is analogous to their binding to the active-site serine residue in all serine esterases (B-esterases). As previously mentioned, certain OP compounds are hydrolyzed by A-esterases (the paraoxonase PON1) but bind stoichiometrically and, for the most part, irreversibly to B-esterases (carboxylesterases and cholinesterases). Surprisingly, stoichiometric binding of OP compounds to carboxylesterase and cholinesterase (and perhaps to numerous other enzymes and receptors that have structural features common to serine esterases) plays an important role in limiting

the toxicity of OP compounds. Numerous studies have shown an inverse relationship between serine esterase activity and susceptibility to the toxic effect of OP compounds. Factors that decrease serine esterase activity potentiate the toxic effects of OP compounds, whereas factors that increase serine esterase activity have a protective effect. For example, the susceptibility of animals to the toxicity of parathion, malathion, and diisopropylfluorophosphate (DFP) is inversely related to the level of plasma esterase activity (which reflects BChE activity and, in some species, carboxylesterase activity). Differences in the susceptibility of several mammalian species to OP toxicity can be abolished by pretreatment with selective serine esterase inhibitors such as cresylbenzodioxaphosphorin oxide, the active metabolite of tri-*ortho*-tolylphosphate (which is also known as tri-*ortho*-cresylphosphate [TOCP]). Knockout mice that lack plasma carboxylesterase (Ces1c, previously known as Es1) or AChE are more susceptible to the toxic effects of OP compounds, as are PON1 knockout mice in some but not all cases (discussed in the section “Paraoxonases (Lactonases)”) (Xie *et al.*, 2000; Duysen *et al.*, 2011). Somewhat surprisingly, BChE knockout mice are not more sensitive to OP toxicity than wild-type mice (Duysen *et al.*, 2007), but this may not reflect the situation in humans because mouse plasma contains a carboxylesterase, whereas humans do not (see the section “Carboxylesterases”). In humans, BChE plays an important role in preventing OP compounds from reaching AChE in the brain. Carboxylesterases, cholinesterases, and paraoxonases are not the only enzymes involved in the detoxication of OP pesticides. Certain OP compounds are detoxified by CYP, flavin monooxygenases, and GSTs. However, paraoxonases, enzymes that catalyze the hydrolysis of certain OP compounds, appear to play a limited role in determining susceptibility to OP toxicity, as outlined in the following section.

Once bound to the active site of cholinesterase or carboxylesterase, OP compounds can undergo dealkylation reactions that further retard their release from the active-site serine residue of these enzymes. This process is called “aging.” In many cases the phosphorylated or phosphonylated enzyme can be reactivated by displacement of the OP adduct with nucleophilic compounds such as fluoride, hydroxamates, and oximates. The pyridinium oximes pralidoxime (2-PAM) and obidoxime (toxogonin) are used therapeutically as antidotes to OP poisoning. More potent oximes (HI-6 and MMB-4) are under development (Masson and Lockridge, 2010). Cocaine is hydrolyzed by CES1 and CES2 in liver and intestine, and by BChE in plasma. Genetic polymorphisms that reduce BChE activity toward succinylcholine (such as the *A* variant described earlier in this section) also reduce its activity toward cocaine (again by decreasing K_m), which exacerbates cocaine toxicity (Masson and Lockridge, 2010). Despite its important role in cocaine toxicity, BChE hydrolyzes cocaine slowly. Masson and Lockridge (2010) reviewed efforts based on molecular dynamics simulation to improve the hydrolytic function of BChE through site-directed mutagenesis. A BChE variant with 4 mutations hydrolyzes cocaine with a catalytic efficiency 1500- to 5000-fold greater than that of the wild-type enzyme, whereas a variant with 5 mutations is 6500 times more active. The latter man-made variant is of therapeutic interest for the treatment of cocaine overdose. Other variants of BChE are being developed with improved hydrolysis of OP compounds for the treatment of OP poisoning and protection against OP nerve agents.

Paraoxonases (Lactonases) Paraoxonases catalyze the hydrolysis of a broad range of organophosphates, organophosphinites, aromatic carboxylic acid esters (such as phenylacetate), cyclic carbonates, lactones, and oxidized phospholipids. They

are calcium-dependent enzymes containing a critical sulfhydryl (–SH) group; as such they are inhibited by EDTA, metal ions (Cu and Ba), and various mercurials such as phenylmercuric acetate (PMA), *para*-chloromercuribenzoate (PCMB), and the PCMB hydrolysis product, *para*-hydroxymercuribenzoate. (Note: Calcium must be added to measure paraoxonase activity in plasma prepared from EDTA-anticoagulated blood.) Based on the observation that A-esterases are inhibited by PCMB but not OP compounds, Augustinsson (1966) postulated that, in the case of paraoxonases, OP compounds bind to a nucleophilic SH-group on an active-site cysteine residue and form a phosphorus–sulfur bond, which is readily cleaved by water. A strong argument against this postulate is the fact that there is no loss of enzymatic activity when the only potential active-site cysteine residue in human paraoxonase (Cys₂₈₃) is substituted with serine or alanine (Sorenson *et al.*, 1995). However, substitution with serine or alanine renders paraoxonase resistant to inhibition by PCMB, placing Cys₂₈₃ near but not in the active site of paraoxonase. Paraoxonase requires Ca²⁺, for both stability and catalytic activity, which raises the possibility that the hydrolysis of OP compounds by paraoxonase involves metal-catalyzed hydrolysis, analogous to that proposed for calcium-dependent phospholipase A2 or zinc-dependent phosphotriesterase activity (Sorenson *et al.*, 1995). A structurally modified but catalytically active form of recombinant PON1 has been crystallized and shown by x-ray analysis to contain 2 calcium ions in a 6-fold β-propeller protein similar to that found in squid diisopropylfluorophosphatase (DFPase), a paraoxonase-like enzyme (Otto *et al.*, 2009).

Humans express 3 paraoxonases designated PON1, PON2, and PON3. PON1 is present in liver microsomes and plasma, where it is associated exclusively with high-density lipoprotein (HDL). PON2 is not present in plasma but it is expressed in the inner mitochondrial membrane of vascular cells and many tissues (Devarajan *et al.*, 2011). PON3 is expressed in liver and kidney microsomes and plasma. Only PON1 has appreciable arylesterase activity and the ability to hydrolyze the toxic oxon metabolites of OP insecticides such as parathion (paraoxon), diazinon (diazoxon), and chlorpyrifos (chlorpyrifos oxon) (Gupta and DuBois, 1998; Draganov and La Du, 2004). However, all 3 enzymes can catalyze the hydrolysis of various lactones, for which reason the name “lactonase” is more encompassing. A lactone derived from arachidonic acid (5-hydroxy-cicosate traecom acid-1,5-lactone) is one of the few substrates hydrolyzed by all 3 paraoxonases (Gupta *et al.*, 2009). Lactone hydrolysis of the statins lovastatin and simvastatin is catalyzed only by PON3. Reports of the same reaction being catalyzed by PON1 appear to be attributable to trace contamination with PON3 (Draganov and La Du, 2004). However, both PON1 and PON3 hydrolyze the lactone form of atorvastatin, which reverses the lactonization of atorvastatin, a reaction that involves formation of an acyl glucuronide of atorvastatin by UGT1A3 (Riedmaier *et al.*, 2011). PON1 hydrolyzes thiolactones such as homocysteine thiolactone (an endobiotic substrate) and a thiolactone metabolite of clopidogrel (discussed later in the section “CYP2C19”), whereas PON3 hydrolyzes the lactone spironolactone (a diuretic drug) (Gupta *et al.*, 2009). PON1 is the major plasma enzyme responsible for hydrolyzing the prodrug olmesartan medoxomil to its active metabolite (Ishizuka *et al.*, 2012) and is one of the plasma enzymes responsible for hydrolyzing the structurally related prodrugs prulifloxacin and ceftobiprole medocartil to their active metabolite (Eichenbaum *et al.*, 2012).

PON2, located on the inner mitochondrial membrane, appears to play no significant role in xenobiotic biotransformation, although it can hydrolyze the lactone dihydrocoumarin. In the inner mitochondrial membrane, PON2 is bound to coenzyme Q₁₀

and complexed with respiratory complex III where it protects the mitochondrion from oxidative damage from superoxide anion and its derivative ROS (hydrogen peroxide, peroxyxynitrate, and hydroxy radicals) (Devarajan *et al.*, 2011).

PON1 has 2 prominent polymorphisms in the coding region, namely, Q₁₉₂R (Glu₁₉₂Arg) and L₅₅M (Leu₅₅Met), and several polymorphisms in the promoter region. Polymorphisms in the promoter region and the L₅₅M polymorphism in the coding region do not affect PON1 activity but they do affect expression levels (Gupta *et al.*, 2009; Furlong *et al.*, 2010). The commonest genetic polymorphism, Q₁₉₂R, affects PON1 activity in a substrate-dependent manner. The glutamine (Q₁₉₂) and arginine (R₁₉₂) allelozymes have the same hydrolytic activity toward *para*-nitrophenylacetate (a measure of arylesterase activity) and diazoxon (the oxon of diazinon) but R₁₉₂ is more active toward paraoxon (the oxon of parathion), chlorpyrifos oxon, the prodrugs olmesartan medoxomil and prulifloxacin, and the lactone pilocarpine, whereas Q₁₉₂ is more active toward soman, sarin, the thiolactone metabolite of clopidogrel (Bouman *et al.*, 2011; discussed later in the section “CYP2C19”), and lipid peroxides, the significance of which is discussed later in this section (Gupta *et al.*, 2009; Furlong *et al.*, 2010; Eichenbaum *et al.*, 2012; Ishizuka *et al.*, 2012).

There is evidence to suggest that PON1 protects against atherosclerosis by hydrolyzing specific derivatives of oxidized cholesterol and/or phospholipids in atherosclerotic lesions and in oxidized low-density lipoprotein (LDL). For example, mice lacking PON1 (knockout mice or PON1 null mice) are predisposed to atherogenesis, whereas mice overexpressing PON1 are protected (Draganov and La Du, 2004; Gupta *et al.*, 2009). Some studies show that individuals who are homozygous for the R₁₉₂ allele are at increased risk of atherosclerosis and ischemic stroke compared with individuals who are homozygous for the Q₁₉₂ allele, suggesting that the absence of the latter enzyme, the PON1 allelozyme with high activity toward lipid peroxides and offering more protection against LDL oxidation, is a risk factor for cardiovascular disease (Gupta *et al.*, 2009; Dahabreh *et al.*, 2010). However, the association is controversial. A complicating factor is that the R₁₉₂ allelozyme is expressed at higher levels than the Q₁₉₂ enzyme, which may partially offset its lower ability to hydrolyze lipid peroxides. Bayrak *et al.* (2011) proposed that, in terms of assessing the risk of atherosclerosis, an assessment of both plasma PON1 activity and genotype is more reliable than genotype alone. This seems appropriate in view of the finding that several environmental factors affect PON1 levels, which are upregulated by hypolipidemic drugs (fenofibrate and statins) and cardioprotective dietary components such as polyphenols (such as resveratrol), oleic acid, and olive oil, and downregulated by diabetes and a high-fat (proatherogenic) diet (Gupta *et al.*, 2009).

It seems reasonable to assume that PON1 would play an important role in determining the susceptibility of humans to OP toxicity based on 3 considerations: first, PON1 hydrolyzes OP compounds (rather than simply bind them stoichiometrically like BChE). Second, the concentration of PON1/3 in human plasma is 10 times greater than that of BChE (50 mg/mL vs 5 mg/mL) (Li *et al.*, 2005). Third, human plasma does not contain carboxylesterase (Li *et al.*, 2005). PON1/3 may protect against OP toxicity in some but not all cases. PON1 knockout mice are no more susceptible than wild-type mice to the toxic effects of paraoxon (the active metabolite of parathion), and administration of human PON1 (either the R₁₉₂ or the Q₁₉₂ allelozyme) to PON1 knockout mice does not confer protection against paraoxon. However, administration of either the R₁₉₂ or Q₁₉₂ human allelozymes to PON1 knockout mice does protect against diazoxon toxicity, and administration

of the R_{192} allelozyme (but not the Q_{192} allelozyme) protects against chlorpyrifos oxon (Cole *et al.*, 2010). The allelozyme-dependent pattern of protection corresponds with the rate of hydrolysis of these OP oxons by R_{192} and Q_{192} (high and equal for diazoxon, high but greater with R_{192} for chlorpyrifos oxon, and low but greater with R_{192} for paraoxon). Although the concentration of BChE in human plasma is only one tenth that of PON1/3 (~50 nM vs 500 nM), its apparent second-order rate constant with OP compounds is very high (10^7 to 10^9 M⁻¹ min⁻¹) compared with the catalytic efficiency of PON1 (10^5 M⁻¹ min⁻¹) (Masson and Lockridge, 2010).

Diisopropylfluorophosphatase (DFPase), a squid enzyme that catalyzes the release of fluoride from DFP (Fig. 6-5), is a hydrolytic enzyme related to the paraoxonases. It hydrolyzes the nerve gas agents sarin and soman (Liederer and Borchardt, 2006). Human paraoxonases do not hydrolyze DFP but are inhibited by this OP compound.

Prodrugs and Alkaline Phosphatase Many prodrugs are designed to be hydrolyzed by hydrolytic enzymes (Liederer and Borchardt, 2006). Some prodrugs, such as propranolol ester, are hydrolyzed by both carboxylesterases and cholinesterases (both AChE and BChE), whereas others are preferentially or specifically hydrolyzed by carboxylesterases (capecitabine, irinotecan), BChE (bambuterol, methylprednisolone acetate), hPON1 (prulifloxacin, olmesartan medoxomil), or PON3 (lovastatin, simvastatin). On a case-by-case basis, specific enzymes other than those mentioned above can be involved in xenobiotic hydrolysis. For example, the valine ester prodrugs of acyclovir (valacyclovir) and ganciclovir (valganciclovir) are hydrolyzed by valacyclovirase (gene code BPHL), a serine- and α/β -fold-hydrolase that hydrolyzes other antiviral and anticancer nucleoside drugs such as zidovudine, floxuridine, and gemcitabine (Lai *et al.*, 2008). Some prodrugs are hydrolyzed with a high degree of stereoselectivity. For example, in the case of prodrugs of ibuprofen and flurbiprofen, the *R*-enantiomer is hydrolyzed about 50 times faster than the *S*-enantiomer. The acyl glucuronides of ibuprofen and other NSAIDs are also hydrolyzed stereoselectively (see the section “Glucuronidation and Formation of Acyl-CoA Thioesters”).

Some prodrugs, such as fosphenytoin (Cerebyx[®]) and fosamprenavir (Lexiva[®]), are designed to be hydrolyzed by alkaline phosphatase, high concentrations of which are present on the luminal surface of the enterocytes lining the wall of the small intestine. Hydrolysis of these prodrugs by alkaline phosphatase releases the active drug at the surface of the enterocytes, where it can be readily absorbed. Soluble epoxide hydrolase (sEH) is a bifunctional enzyme; its C-terminus contains an epoxide hydrolase domain, whereas its N-terminus contains a phosphatase domain, as described in the section “Epoxide Hydrolases.” Although it may play a role in the hydrolysis of endogenous phosphates, such as polyisoprenyl phosphates and lysophosphatidic acids (Oguro and Imaoka, 2012), sEH is an intracellular enzyme and, as such, can play no significant role in the hydrolysis of phosphate/phosphonate prodrugs.

As a result of their ability to hydrolyze prodrugs, hydrolytic enzymes may have clinical applications in the treatment of certain cancers. They might be used, for example, to activate prodrugs in vivo and thereby generate potent anticancer agents in highly selected target sites (eg, at the surface of tumor cells, or inside the tumor cells themselves). For example, carboxylesterases might be targeted to tumor sites with hybrid monoclonal antibodies (ie, bifunctional antibodies that recognize the carboxylesterase and the tumor cell), or the cDNA encoding a carboxylesterase might be targeted to the tumor cells via a viral vector. In the case of irinotecan, this therapeutic strategy would release the anticancer drug SN-38 in the vicinity of the tumor cells, which would reduce the systemic

levels and side effects of this otherwise highly toxic drug (Senter *et al.*, 1996). Some prodrugs, such as capecitabine, are activated by hydrolytic enzymes in the tumors themselves.

Peptidases With the advent of recombinant DNA technology, numerous human peptides have been mass-produced for use as therapeutic agents, and several recombinant peptide hormones, growth factors, cytokines, soluble receptors, and humanized monoclonal antibodies currently are used clinically. To avoid acid precipitation and proteolytic degradation in the gastrointestinal tract, peptides are administered parenterally. Nevertheless, peptides are hydrolyzed in the blood and tissues by a variety of peptidases, including aminopeptidases and carboxypeptidases, which hydrolyze amino acids at the N- and C-terminus, respectively, and endopeptidases, which cleave peptides at specific internal sites (trypsin, for example, cleaves peptides on the C-terminal side of arginine or lysine residues) (Humphrey and Ringrose, 1986; Testa and Krämer, 2008, 2010). Peptidases cleave the amide linkage between adjacent amino acids; hence, they function as amidases. As in the case of carboxylesterases, the active site of peptidases contains either a serine or cysteine residue, which initiates a nucleophilic attack on the carbonyl moiety of the amide bond. As previously noted, the mechanism of catalysis by serine proteases, such as chymotrypsin, is similar to that by serine esterases (B-esterases).

β -Glucuronidase β -Glucuronidase is present in liver lysosomes and microsomes (where it is bound to the lumen of the endoplasmic reticulum by egasyn [Ces1e], as mentioned in the section “Carboxylesterases”) and in gut microflora. The enzyme hydrolyzes xenobiotic glucuronides (in which the glucuronide is in the β -configuration). When a drug is glucuronidated directly and excreted in bile, hydrolysis by β -glucuronidase in the gut can release the aglycone (the parent drug) and result in a second phase of drug absorption, a process called enterohepatic circulation. In the case of the anticancer drug irinotecan, which is hydrolyzed to SN-11 (the pharmacologically active and toxic metabolite) and then glucuronidated, hydrolysis of SN-11-glucuronide by microflora β -glucuronidase is undesirable because it releases SN-11 in the colon and causes dose-limiting diarrhea. To reduce the risk of such an adverse event, an inhibitor of gut β -glucuronidase has been developed, which is described in more detail in the section “Glucuronidation and Formation of Acyl-CoA Thioesters.”

Epoxide Hydrolases Epoxide hydrolases catalyze the *trans*-addition of water to alkene epoxides and arene oxides (oxiranes), which can form during the CYP-dependent oxidation of aliphatic alkenes and aromatic hydrocarbons, respectively. As shown in Fig. 6-8, the products of this hydrolysis are vicinal diols with a *trans*-configuration (ie, *trans*-1,2-dihydrodiols), a notable exception being the conversion of leukotriene A₄ (LTA₄) to leukotriene B₄ (LTB₄), in which case the 2 hydroxyl groups that result from epoxide hydrolysis appear on nonadjacent carbon atoms. Epoxide hydrolases play an important role in detoxifying electrophilic epoxides that might otherwise bind to proteins and nucleic acids and cause cellular toxicity and genetic mutations. In the case of PAHs, however, microsomal epoxide hydrolase plays a critical role in forming diol epoxides, the ultimate carcinogenic metabolites of benzo[*a*]pyrene (B[*a*]P), 7,12-dimethylbenz[*a*]anthracene (DMBA), and many other PAHs (discussed later in this section).

There are 4 distinct forms of epoxide hydrolase in mammals: microsomal epoxide hydrolase (mEH; gene name EPHX1), soluble epoxide hydrolase (sEH; gene name EPHX2), cholesterol-5,6-epoxide hydrolase (ChEH; gene yet to be characterized), and leukotriene A₄ hydrolase (LTA₄ hydrolase; gene name LTA4H) (Fretland

Figure 6-8. Examples of the hydrolyation of an alkene epoxide (top) and an arene oxide (bottom) by epoxide hydrolase.

and Omiecinski, 2000; Morisseau and Hammock, 2005). Hepoxilin A₃ hydrolase was thought to represent a fifth class of epoxide hydrolase but it was subsequently identified as being the same enzyme as sEH (Cronin *et al.*, 2011). As their names imply, cholesterol-5,6-epoxide hydrolase (ChEH) and LTA₄ hydrolase hydrolyze endogenous epoxides specifically, and have virtually no capacity to detoxify xenobiotic oxides. LTA₄ hydrolase is distinct from the other epoxide hydrolases because it is a bifunctional zinc metalloenzyme that has both epoxide hydrolase and peptidase activity, and because the 2 hydroxyl groups introduced during the conversion of LTA₄ to LTB₄ are 8 carbon atoms apart. sEH is a bifunctional enzyme; its C-terminus contains an epoxide hydrolase domain, whereas its N-terminus contains a phosphatase domain. The latter domain is structurally related to members of haloacid dehalogenase (HAD) superfamily, which includes dehalogenases, phosphonatas, phosphomutases, phosphatases, and ATPases. The phosphatase domain of sEH is thought to play a role in the hydrolysis of endogenous phosphates, such as polyisoprenyl phosphates (which regulate cholesterol levels) and lysophosphatidic acids (Imig and Hammock, 2009; Oguro and Imaoka, 2012).

mEH hydrolyzes a wide variety of xenobiotics with an alkene epoxide or arene oxide. sEH hydrolyzes some xenobiotic epoxides and oxides, such as *trans*-stilbene oxide, but it also plays an important role in the hydrolysis of endogenous fatty acid epoxides, such as the epoxyeicosatrienoic acids (EETs) that are formed by epoxidation of arachidonic acid by CYP (particularly CYP2J2 and CYP2C9) and the leukotoxins that are formed by the epoxidation of linoleic acid by leukocytes (Fretland and Omiecinski, 2000; Morisseau and Hammock, 2005; Imig and Hammock, 2009). EETs are endothelin-derived hyperpolarizing factors (EDHFs) (ie, vasodilators) that possess anti-inflammatory properties and protect tissues from ischemic injury. Hydrolysis of EETs by sEH terminates their vasodilatory and anti-inflammatory effects. Accordingly, sEH is a potential therapeutic target for the treatment of various cardiovascular diseases such as hypertension and atherosclerosis (Imig and Hammock, 2009; Wang *et al.*, 2010c). Several disubstituted ureas (including the anticancer drug sorafenib) have been identified as competitive inhibitors of sEH that are both potent (K_i values in the nanomolar range) and specific (they do not inhibit the phosphatase domain of sEH and they do not potently inhibit mEH). In addition to their vasodilatory and anti-inflammatory effects, EETs promote endothelial cell proliferation and migration; hence, they are angiogenic (ie, they stimulate blood vessel supply). A potential

Figure 6-9. Stereoselective hydrolylation of stilbene oxide by microsomal and soluble epoxide hydrolase.

side effect of sEH inhibitors, therefore, may be potentiation of EET-mediated angiogenic resulting in accelerated tumorigenesis (Imig and Hammock, 2009; Wang *et al.*, 2010c).

Although the levels vary from one tissue to the next, mEH has been found in the microsomal fraction (and in some cases the plasma membrane) of virtually all tissues, including the liver, testis, ovary, lung, kidney, skin, intestine, colon, spleen, thymus, brain, and heart. sEH is also widely distributed in tissues; high levels of sEH are present in the cytosol (and in some cases the lysosomes) of liver, kidney, brain, and vasculature and lower levels are present in lung, spleen, and testis. In general, mEH prefers monosubstituted epoxides and disubstituted epoxides with a *cis* configuration, such as *cis*-stilbene oxide, whereas sEH prefers tetrasubstituted and trisubstituted epoxides and disubstituted epoxides with a *gem* configuration (both substituents on the same carbon atom) or the *trans* configuration, such as *trans*-stilbene oxide, as shown in Fig. 6-9. In rodents, both sEH and mEH are inducible enzymes; sEH is under the control of PPAR α , so it is induced following treatment of rats and mice with peroxisome proliferators, whereas mEH is under the control of Nrf2, so it is induced in response to oxidative stress or exposure to electrophiles and GSH depletors (see the section “Quinone Reduction—NQO1 and NQO2”). Treatment of mice with the CAR agonist phenobarbital induces mEH about 2- to 3-fold, whereas treatment with Nrf2 activators such as butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), and ethoxyquin induces mEH by an order of magnitude or more. mEH is one of several proteins (so-called preneoplastic antigens) that are overexpressed in chemically induced foci and nodules that eventually develop into liver tumors.

Many epoxides and oxides are intermediary metabolites formed during the CYP-dependent oxidation of unsaturated aliphatic and aromatic xenobiotics. These electrophilic metabolites might otherwise bind to proteins and nucleic acids and cause cellular toxicity and genetic mutations. In general, sEH and mEH are found in the same tissues and cell types that contain CYP. For example, the distribution of epoxide hydrolase parallels that of CYP in liver, lung, and testis. In other words, both enzymes are located in the centrilobular region of the liver (zone 3), in Clara and type II cells in the lung, and in Leydig cells in the testis. The colocalization of epoxide hydrolase and CYP presumably ensures the rapid detoxication of alkene epoxides and arene oxides generated during the oxidative metabolism of xenobiotics.

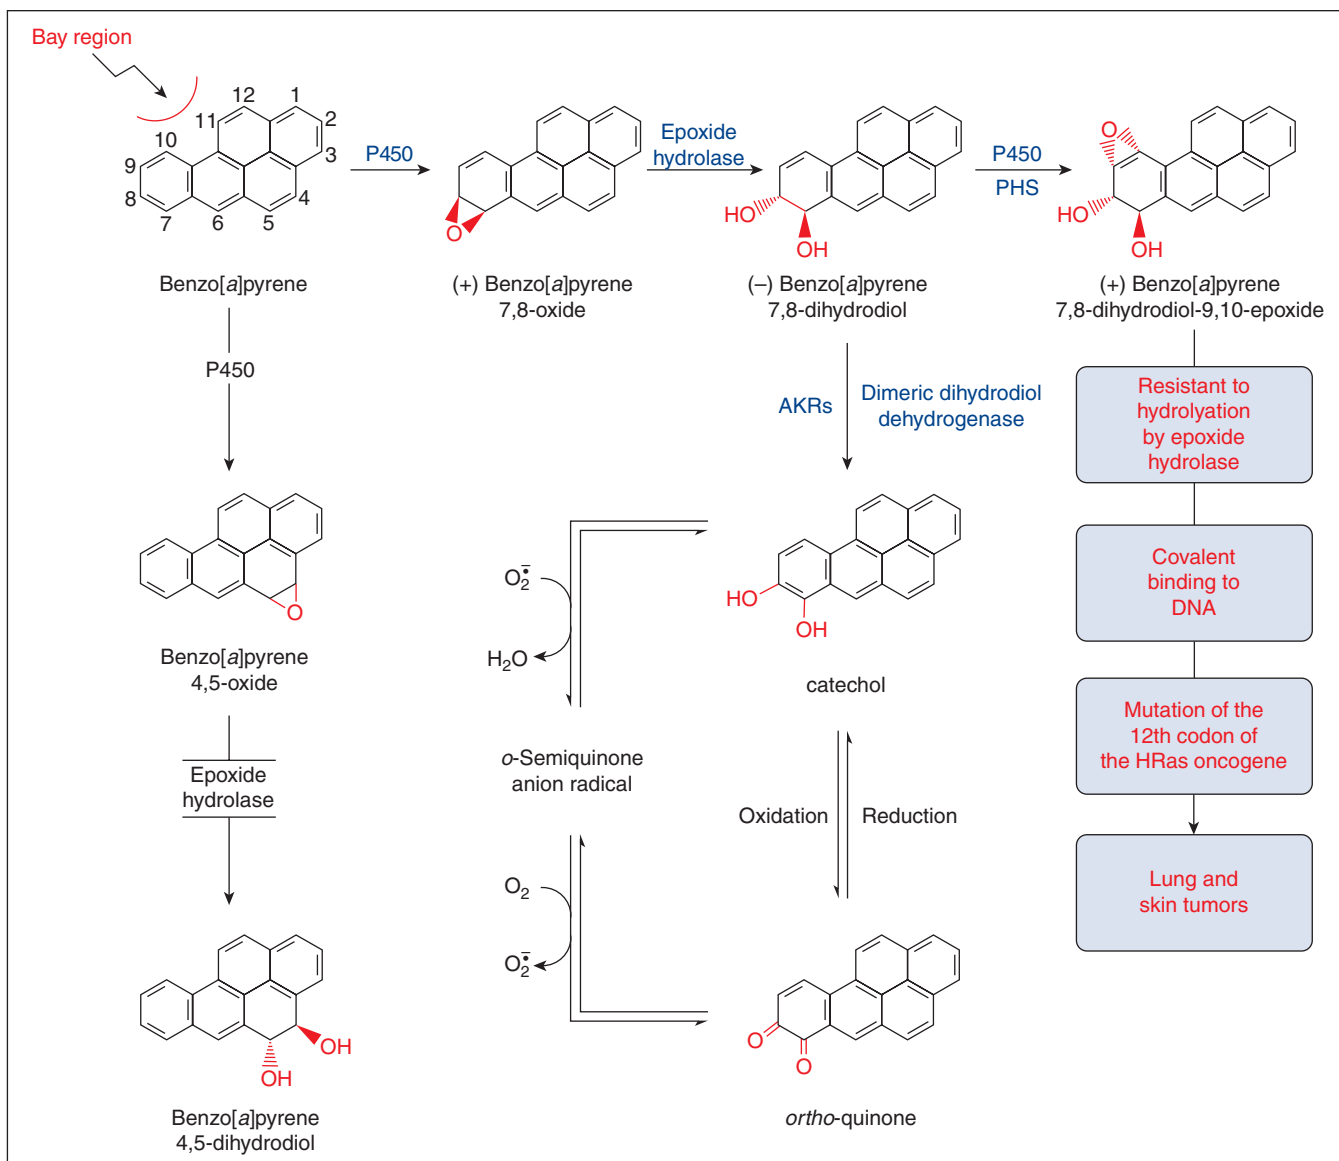

Figure 6-10. Role of epoxide hydrolase in the inactivation of benzo[a]pyrene 4,5-oxide and in the conversion of benzo[a]pyrene to its tumorigenic bay-region diol epoxide. Also shown is the role of dimeric dihydrodiol dehydrogenase, and the aldo-keto reductase (AKR) superfamily, in the formation of reactive catechol and *ortho*-quinone metabolites of benzo[a]pyrene.

Electrophilic epoxides and arene oxides are constantly produced during the CYP-dependent oxidation of unsaturated aliphatic and aromatic xenobiotics, and are potentially reactive to cellular macromolecules such as DNA and protein. Epoxide hydrolase can rapidly convert these potentially toxic metabolites to the corresponding dihydrodiols, which are less reactive and easier to excrete. Thus, epoxide hydrolases are widely considered as a group of detoxication enzymes. In some cases, however, further oxidation of a dihydrodiol can lead to the formation of diol epoxide derivatives that are no longer substrates for epoxide hydrolase because the oxirane ring is protected by bulky substituents that sterically hinder interaction with the enzyme. This point proved to be extremely important in elucidating the mechanism by which PAHs cause tumors in laboratory animals (Conney, 1982). Tumorigenic PAHs, such as B[a]P, are converted by CYP (particularly by CYP1B1 and CYP1A1) to a variety of arene oxides that bind covalently to DNA, making them highly mutagenic to bacteria. One of the major arene oxides formed from B[a]P, namely, the 4,5-oxide, is highly mutagenic to bacteria but weakly mutagenic to mammalian cells. This discrepancy reflects the

rapid inactivation of B[a]P 4,5-oxide by epoxide hydrolase in mammalian cells. However, one of the arene oxides formed from B[a]P, namely, B[a]P 7,8-dihydrodiol-9,10-oxide, is not a substrate for epoxide hydrolase and is highly mutagenic to mammalian cells and considerably more potent than B[a]P as a lung tumorigen in mice.

B[a]P 7,8-dihydrodiol-9,10-oxide is known as a bay-region diol epoxide, and analogous bay-region diol epoxides are now recognized as tumorigenic metabolites of numerous PAHs. A feature common to all bay-region epoxides is their resistance to hydrolylation by mEH, which results from steric hindrance from the nearby dihydrodiol group. As shown in Fig. 6-10, B[a]P 7,8-dihydrodiol-9,10-oxide is formed in 3 steps: B[a]P is converted to the 7,8-oxide, which is converted to the 7,8-dihydrodiol, which is converted to the corresponding 9,10-epoxide (which can exist in 4 diastereomeric forms). The first and third steps are epoxidation reactions catalyzed by CYP (especially CYP1B1 and CYP1A1) or prostaglandin H synthase, but the second step is catalyzed by mEH. Consequently, even though mEH plays a major role in detoxifying several B[a]P, such as the 4,5-oxide, it nevertheless plays a role in converting B[a]P to

its ultimate tumorigenic metabolite, B[a]P 7,8-dihydrodiol-9,10-oxide. Diol epoxides are also the carcinogenic metabolites of DMBA and many other PAHs (Shimada, 2006).

The importance of mEH in the conversion of PAHs to their ultimate carcinogenic metabolites, namely, diol epoxides, is illustrated by the observation that mEH knockout mice (mEH-null mice) are completely resistant to the tumorigenic effects of DMBA (Shimada, 2006). Genetic polymorphisms of human mEH also impact cigarette-smoking-induced cancer of the lung and upper aerodigestive tract (UADT) in a manner consistent with the protective effect conferred by a lack of mEH in DMBA-treated mice (Li *et al.*, 2011b). More than 110 SNPs have been identified in the human EPHX1 gene, 2 of which have been studied in detail: One of them (Tyr₁₁₃His) decreases mEH activity (by about 40%) and the other (His₁₃₉Arg) increases mEH activity (by about 25%). The low-activity mEH (observed in individuals who are homozygous or heterozygous for the His₁₃₃ allele) protects from tobacco-induced cancer of the lung and UADT, whereas the high-activity variant (observed in individuals who are homozygous or heterozygous for the Arg₁₃₉ allele) predisposes to these cancers (Li *et al.*, 2011b).

Not all epoxides are highly reactive and toxic to the cells that produce them. Some drugs actually contain an epoxide, such as scopolamine, tiotropium, and troleandomycin. Vitamin K epoxide is also a nontoxic epoxide, which is formed and consumed during the vitamin K-dependent γ -carboxylation of prothrombin and other clotting factors in the liver. Vitamin K epoxide is not hydrated by mEH but is reduced by vitamin K epoxide reductase. This enzyme is inhibited by warfarin and related coumarin anticoagulants, which interrupts the synthesis of several clotting factors. The major metabolite of carbamazepine is an epoxide, which is so stable that carbamazepine 10,11-epoxide is a major circulating metabolite in patients treated with this antiepileptic drug. (Carbamazepine is converted to a second epoxide, which is less stable and more cytotoxic, as shown in the section "Cytochrome P450.") Circulating levels of carbamazepine 10,11-epoxide are elevated in individuals expressing the low-activity variant of mEH (the His₁₃₃ allele) but, with one possible exception, this genetic polymorphism is not associated with an increase in the adverse effects of this or other anticonvulsant drugs (Daly, 1999). The exception is a case report of a man who had a defect in mEH expression and suffered acute and severe phenytoin toxicity (Morisseau and Hammock, 2005). Certain drugs, such as valpromide (the amide analog of valproic acid) and progabide (a γ -aminobutyric acid [GABA] agonist), cause clinically significant inhibition of mEH and may impair epoxide hydrolase activity more than genetic polymorphisms. These 2 drugs potentiate the neurotoxicity of carbamazepine by inhibiting mEH, leading to increased plasma levels of carbamazepine 10,11-epoxide and presumably its more toxic 2,3-epoxide (Kroetz *et al.*, 1993). mEH can be inhibited *in vitro* by certain epoxides, such as 1,1,1-trichloropropene oxide and cyclohexene oxide, and stimulated by several alcohols, ketones, and imidazoles.

The microsomal and soluble forms of epoxide hydrolase show no evident sequence identity and, accordingly, are immunologically distinct proteins (Beetham *et al.*, 1995). Nevertheless, mEH and sEH catalyze reactions by the same mechanism, and similar amino acids are involved in catalysis, namely, a nucleophilic acid (Asp₂₂₆ in mEH and Asp₃₃₄ in sEH), a basic histidine (His₄₃₁ in mEH and His₅₂₃ in sEH), an orienting acid (Glu₄₀₄ in mEH and Asp₄₉₅ in sEH), and polarizing tyrosine residues (Tyr₂₉₉ and Tyr₃₇₄ in mEH and Tyr₃₈₂ and Tyr₄₆₅ in sEH) (Morisseau and Hammock, 2005). The mechanism of catalysis by epoxide hydrolase is similar to that of carboxylesterase, in that the catalytic site comprises 3 amino acid

residues that form a catalytic triad, as shown in Fig. 6-7. The attack of the nucleophile Asp₂₂₆ on the carbon of the oxirane ring initiates enzymatic activity, leading to the formation of an α -hydroxyester-enzyme intermediate, with the negative charge developing on the oxygen atom stabilized by a putative oxyanion hole. The His₄₃₁ residue (which is activated by Glu₃₇₆ and Glu₄₀₄) activates a water molecule by abstracting a proton (H⁺). The activated (nucleophilic) water then attacks the C γ atom of Asp₂₂₆, resulting in the hydrolysis of the ester bond in the acyl-enzyme intermediate, which restores the active enzyme and results in formation of a vicinal diol with a *trans*-configuration (Armstrong, 1999). The second step, namely, cleavage of the ester bond in the acyl-enzyme intermediate, resembles the cleavage of the ester or amide bond in substrates for serine esterases and proteases.

Although both epoxide hydrolase and carboxylesterase have a catalytic triad comprising a nucleophilic, basic, and acidic amino acid residue, there are striking differences in their catalytic machinery, which account for the fact that carboxylesterases primarily hydrolyze esters and amides, whereas epoxide hydrolases primarily hydrolyze epoxides and oxides. In the triad, both enzymes have histidine as the base and either glutamate or aspartate as the acid, but they differ in the type of amino acids for the nucleophile. Even during catalysis, there is a major difference. In carboxylesterases, the same carbonyl carbon atom of the substrate is attacked initially by the nucleophile Ser₂₀₃ to form an α -hydroxyester-enzyme ester that is subsequently attacked by the activated water to release the alcohol product. In contrast, 2 different atoms in epoxide hydrolase are targets of nucleophilic attacks. First the less hindered carbon atom of the oxirane ring is attacked by the nucleophile Asp₂₂₆ to form a covalently bound ester, and next this ester is hydrolyzed by an activated water molecule that attacks the C γ atom of the Asp₂₂₆ residue, as illustrated in Fig. 6-7. Therefore, in carboxylesterase, the oxygen introduced to the product is derived from the activated water molecule. In contrast, in epoxide hydrolase, the oxygen introduced to the product is derived from the nucleophile Asp₂₂₆ (Fig. 6-7).

Carboxylesterases and epoxide hydrolases exhibit no primary sequence identity, but they share surprising similarities in the topology of the structure and sequential arrangement of the catalytic triad. Both are members of the α/β -hydrolase fold enzymes, a superfamily of proteins that includes lipases, esterases, and haloalkane dehydrogenases (Beetham *et al.*, 1995). Functionally, proteins in this superfamily all catalyze hydrolytic reactions; structurally, they all contain a similar core segment that is composed of 8 β -sheets connected by α -helices. They all have a catalytic triad and the arrangement of the amino acid residues in the triad (ie, the order of the nucleophile, the acid, and the base in the primary sequence) is the mirror image of the arrangement in other hydrolytic enzymes such as trypsin. All 3 active-site residues are located on loops that are the best conserved structural features in the fold, which likely provides catalysis with certain flexibility to hydrolyze numerous structurally distinct substrates.

Reduction

Certain metals (eg, pentavalent arsenic) and xenobiotics containing an aldehyde, ketone, alkene, disulfide, sulfoxide, quinone, *N*-oxide, hydroxamic acid, amidoxime, isoxazole, isothiazole, azo, or nitro group are often reduced *in vivo*, although it is sometimes difficult to ascertain whether the reaction proceeds enzymatically or nonenzymatically by interaction with reducing agents (such as the reduced forms of glutathione, FAD, FMN, and NAD[P]). Some of these functional groups can be either reduced or oxidized.

Figure 6-11. Examples of drugs that undergo azo-reduction (prontosil) and nitro-reduction (chloramphenicol and nitrobenzene).

For example, aldehydes ($R-CHO$) can be reduced to an alcohol ($R-CH_2OH$) or oxidized to a carboxylic acid ($R-COOH$), whereas sulfoxides (R_1-SO-R_2) can be reduced to a sulfide (R_1-S-R_2) or oxidized to a sulfone ($R_1-SO_2-R_2$). Likewise, some enzymes, such as alcohol dehydrogenase (ADH), aldehyde oxidase (AO), and CYP, can catalyze both reductive and oxidative reactions depending on the substrate or conditions (eg, aerobic vs anaerobic). In the case of halogenated hydrocarbons, such as halothane, dehalogenation can proceed by an oxidative or reductive pathway, both of which are catalyzed by the same enzyme (namely, CYP). In some cases, such as azo-reduction, nitro-reduction, and the reduction of certain alkenes, the reaction is largely catalyzed by intestinal microflora.

Azo- and Nitro-Reduction Prontosil and chloramphenicol are examples of drugs that undergo azo- and nitro-reduction, respectively, as shown in Fig. 6-11. Reduction of prontosil is of historical interest. Treatment of streptococcal and pneumococcal infections with prontosil marked the beginning of specific antibacterial chemotherapy. Subsequently, it was discovered that the active drug was not prontosil but its metabolite, sulfanilamide (*para*-aminobenzene sulfonamide), a product of azo-reduction. During azo-reduction, the nitrogen–nitrogen double bond is sequentially reduced and cleaved to produce two primary amines, a reaction requiring four reducing equivalents. Nitro-reduction requires six reducing equivalents, which are consumed in three sequential reactions, as shown in Fig. 6-11 for the conversion of nitrobenzene to aniline.

Azo- and nitro-reduction reactions are generally catalyzed by intestinal microflora. However, under certain conditions, such as low oxygen tension, the reactions can be catalyzed by liver microsomal CYP and NAD(P)H-quinone oxidoreductase (NQO1, a cytosolic flavoprotein that is also known as DT-diaphorase) and,

in the case of nitroaromatics, by cytosolic AO. The anaerobic environment of the lower gastrointestinal tract is well suited for azo- and nitro-reduction, which is why intestinal microflora contributes significantly to these reactions. The reduction of quinic acid to benzoic acid is another example of a reductive reaction catalyzed by gut microflora, as shown in Fig. 6-1.

Nitro-reduction by intestinal microflora is thought to play an important role in the toxicity of several nitroaromatic compounds including 2,6-dinitrotoluene, which is hepatotumorigenic to male rats. The role of nitro-reduction in the metabolic activation of 2,6-dinitrotoluene is shown in Fig. 6-12 (Long and Rickert, 1982; Mirsalis and Butterworth, 1982). The biotransformation of 2,6-dinitrotoluene begins in the liver, where it is oxidized by CYP and conjugated with glucuronic acid. This glucuronide is excreted in bile and undergoes biotransformation by intestinal microflora. One or both of the nitro groups are reduced to amines by nitroreductase, and the glucuronide is hydrolyzed by β -glucuronidase. The reduced/deconjugated metabolites are absorbed and transported to the liver, where the newly formed amine group is *N*-hydroxylated by CYP and conjugated with acetate or sulfonate. These conjugates form good leaving groups, which renders the nitrogen highly susceptible to nucleophilic attack from proteins and DNA; this ostensibly leads to mutations and the formation of liver tumors. Compared with females, male rates are more susceptible to hepatotumorigenicity of 2,6-dinitrotoluene due to their higher rate of bile secretion and therefore their higher rate of biliary excretion of 2,6-dinitrobenzylalcohol glucuronide. The complexity of the metabolic scheme shown in Fig. 6-12 underscores an important principle, namely, that the activation of some chemical tumorigens to DNA-reactive metabolites involves several different biotransforming enzymes and may take place in more than one

Figure 6-12. Role of nitro-reduction by intestinal microflora in the activation of the rat liver tumorigen, 2,6-dinitrotoluene.

tissue. Consequently, the ability of 2,6-dinitrotoluene to bind to DNA and cause mutations is not revealed in most of the short-term assays for assessing the genotoxic potential of chemical agents. These *in vitro* assays for genotoxicity do not make allowance for biotransformation by intestinal microflora or, in some cases, the conjugating enzymes.

Nitro-reduction by intestinal microflora also plays an important role in the biotransformation of musk xylene (1,3,5-trinitro-2-*t*-butyl-4,6-dimethylbenzene). Reduction of one or both of the nitro groups is required for musk xylene to induce (as well as markedly inhibit) liver microsomal CYP (namely, CYP2B) in rodents (Lehman-McKeeman *et al.*, 1999).

Carbonyl Reduction—AKRs and SDRs A variety of xenobiotics contain a carbonyl function (R-CHO and R₁-CO-R₂) that undergoes reduction *in vivo*. The reduction of aldehydes to primary alcohols and of ketones to secondary alcohols is generally catalyzed in mammals by NAD(P)H-dependent reductases belonging to one of several superfamilies, the aldo keto reductases (AKRs), the short-chain dehydrogenases/reductases (SDRs), the medium-chain dehydrogenases/reductases (MDRs), ALDHs, and NAD(P)H-quinone oxido reductases (NQO) as shown in Table 6-5 (Jez and Penning, 2001; Oppermann *et al.*, 2001; Matsunaga *et al.*, 2006; Malatkova *et al.*, 2010; Skarydova and Wsol, 2011). The AKRs are members of a superfamily of cytosolic enzymes that reduce both xenobiotic and endobiotic compounds, as their alternative names imply (Table 6-5). Dimeric dihydrodiol dehydrogenase and various members of the AKR superfamily, functioning as dihydrodiol dehydrogenases, can oxidize the *trans*-dihydrodiols of various polycyclic aromatic hydrocarbon oxiranes (formed by epoxide hydrolase) to the corresponding *ortho*-quinones, as shown previously in Fig. 6-10. The role of AKR as an oxidizing enzyme is

discussed in the section “Dimeric Dihydrodiol Dehydrogenase.” As mentioned earlier (see Point 9 in the section “Introduction”), one of the AKRs, namely, AKR7A (also known as aflatoxin aldehyde reductase), is one of the many enzymes induced following activation of Nrf2 by oxidative stress, exposure to electrophiles, or depletion of GSH. Humans contain at least 71 SDR members, three of which, namely, cytosolic carbonyl reductases (CBR1 and CBR3) and a microsomal carbonyl reductase (HSD11B1), play a role in the reduction of a wide variety of carbonyl-containing xenobiotics (other species express more than two carbonyl reductases) (see <http://www.sdr-enzymes.org>). Erythrocytes also contain carbonyl reductase, which contributes significantly to the reduction of haloperidol, as shown in Fig. 6-13. From the alternative names given in Table 6-5, it is apparent that the both cytosolic and microsomal carbonyl reductases have been studied for their role in endobiotic metabolism, namely, the reduction of prostaglandin derivatives and 11 β -hydroxysteroids, respectively (Kavanagh *et al.*, 2008).

In certain cases, the reduction of aldehydes to alcohols can be catalyzed by ADH, as shown in Fig. 6-13 for the conversion of the sedative-hypnotic, chloral hydrate, to trichloroethanol. As shown in Table 6-5, ADHs belong to the medium chain dehydrogenases/reductases (MDRs). They typically convert alcohols to aldehydes, for which reason they are discussed later in the section “Alcohol Dehydrogenase.” In the case of chloral hydrate, the reverse reaction is favored by the presence of the trichloromethyl group, which is a strong electron-withdrawing group.

The SDR carbonyl reductases are monomeric, NADPH-dependent enzymes present in erythrocytes and both the cytosolic and microsomal fractions of the liver, kidney, brain, and many other tissues. The major circulating metabolite of the antipsychotic drug, haloperidol, is a secondary alcohol formed by carbonyl reductases in the blood and liver, as shown in Fig. 6-13. Other xenobiotics

NQO, NAD(P)H-quinone oxidoreductase. Members of the aldo-keto reductase superfamily can be found at <http://www.med.upenn.edu/akr/members.shtml>. Information on human SDR membranes can be found at <http://www.sdr-enzymes.org/resources.htm>.

that are reduced by carbonyl reductases include pentoxifylline (see Fig. 6-3), acetohexamide, daunorubicin, doxorubicin, loxoprofen, menadione, 4-nitroacetophenone, timiperone, and *R*-warfarin (Rosemond and Walsh, 2004). As shown in Fig. 6-3, the reduction of ketones to secondary alcohols by carbonyl reductases may proceed with a high degree of stereoselectivity, as in the case of pentoxifylline (Lillibridge *et al.*, 1996).

Liver cytosol contains at least two carbonyl reductases (CBR1 and CBR3) and microsomes contain at least one other form of carbonyl reductase (HSD11B1), and these can differ in the degree to which they stereoselectively reduce ketones to secondary alcohols. For example, keto-reduction of pentoxifylline produces two enantiomeric secondary alcohols: one with the *R*-configuration (which is known as lisofylline) and one with the *S*-configuration, as shown in Fig. 6-3. Reduction of pentoxifylline

by cytosolic carbonyl reductases results in the stereospecific formation of the optical antipode of lisofylline, whereas the same reaction catalyzed by microsomal carbonyl reductase produces both lisofylline and its optical antipode in a ratio of about 1 to 5 (Lillibridge *et al.*, 1996).

The well-known microsomal carbonyl reductase is 11 β -hydroxysteroid dehydrogenase (gene symbol HSD11B1, aka SDR26C1) (Skarydova and Wsol, 2011). However, there are several other microsomal carbonyl-reducing enzymes, such as the six human retinol dehydrogenases (eg, RDHs) and the six human 17 β -hydroxysteroid dehydrogenases. Although these enzymes have not been well characterized for their ability to reduce carbonyl-containing xenobiotics, there is indirect evidence from the ratio of enantiomers of metabolites that multiple microsomal enzymes may play a role in the metabolism of some

Figure 6-13. Reduction of xenobiotics by carbonyl reductase (A) and alcohol dehydrogenase (B).

xenobiotics such as 7 α -methyl-19-nortestosterone (Skarydova and Wsol, 2011). There are at least two monomeric cytosolic carbonyl reductases (gene symbols CBR1 [aka SDR21C1] and CBR3 [aka SDR21C2]) that have broad, and somewhat overlapping, substrate specificities toward many endobiotics and xenobiotics such as menadione, isatin, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), daunorubicin, and doxorubicin (Malatkova *et al.*, 2010). A human tetrameric mitochondrial carbonyl reductase, namely, CBR4 (aka SDR45C1), has also been identified with activity toward 9,10-phenanthrenequinone and 1,4-benzoquinone, and therefore acts as a mitochondrial quinone reductase (Malatkova *et al.*, 2010).

In rat liver cytosol, the reduction of quinones is primarily catalyzed by NQO1 and NQO2 (see the section “Quinone Reduction—NQO1 and NQO2”), whereas in human liver cytosol, quinone reduction is catalyzed by both NQO and carbonyl reductases.

Various members of the AKR superfamily have been implicated in the reduction of such carbonyl-containing xenobiotics as the tobacco-specific nitrosamine NNK, acetohexamide, daunorubicin, naloxone, naltrexone, buprenorphine, ethacrynic acid, ketoprofen, ketotifen, haloperidol, loxoprofen, metyrapone, oxo-nortryptiline, and numerous aromatic and aliphatic aldehydes (Rosemond and Walsh, 2004). Putative AKR1A, 1B, 1C1 to 4, or 1D1-selective inhibitors, statil, flufenamic acid, phenolphthalein, and finasteride, respectively, can aid in the evaluation of which reductive enzyme(s) is(are) involved in the formation of specific metabolites. Many of the xenobiotics reduced by AKRs are also reduced by SDRs, and in most cases the relative contribution of individual carbonyl-reducing enzymes is not known. Genetic polymorphisms of human AKR1C3, AKR1C4, AKR7A2, and cytosolic carbonyl reductase (CBR1) have been associated with decreased metabolism of carbonyl-containing xenobiotics such as doxorubicin and daunorubicin *in vitro* (Gonzalez-Covarrubias *et al.*, 2007; Bains *et al.*, 2010).

Allelic variants of human cytosolic AKR1C2 with reduced enzymatic activity toward the androgen 5 α -dihydrotestosterone (DHT) have also been identified (Takahashi *et al.*, 2009). There appear to be no reports of clinically significant drug–drug interactions involving the inhibition or induction of AKRs or SDRs (Rosemond and Walsh, 2004).

Disulfide Reduction Some disulfides are reduced and cleaved to their sulfhydryl components, as shown in Fig. 6-14 for the alcohol deterrent, disulfiram (Antabuse). As shown in Fig. 6-14, disulfide reduction by glutathione is a 3-step process, the last of which is catalyzed by glutathione reductase. The first steps can be catalyzed by glutathione transferase, or they can occur nonenzymatically.

Sulfoxide and N-Oxide Reduction Thioredoxin-dependent enzymes in liver and kidney cytosol have been reported to reduce sulfoxides, which themselves may be formed by CYP or flavin monooxygenases (Anders *et al.*, 1981). Recycling through these counteracting enzyme systems, a process known as retro-reduction or futile cycling (Hinrichs *et al.*, 2011), may prolong the half-life of certain xenobiotics. As shown in Fig. 6-15 sulindac is a sulfoxide that undergoes reduction to a sulfide, which is excreted in bile and reabsorbed from the intestine (Ratnayake *et al.*, 1981). This enterohepatic cycling prolongs the duration of action of the drug such that this NSAID need only be taken twice daily. In human liver, glutaredoxin (GLRX) and thioredoxin may also be involved in reducing the mixed disulfide formed between xenobiotics and glutathione, as is the case in the formation of the pharmacologically active metabolite of the P2Y₁₂ inhibitor prasugrel (Hagihara *et al.*, 2011).

Sulfoxide reduction may also occur nonenzymatically at an appreciable rate, as in the case of the proton pump inhibitor rabeprazole (Miura *et al.*, 2006). Diethyldithiocarbamate methyl ester, a metabolite of disulfiram, is oxidized to a sulfine, which is reduced

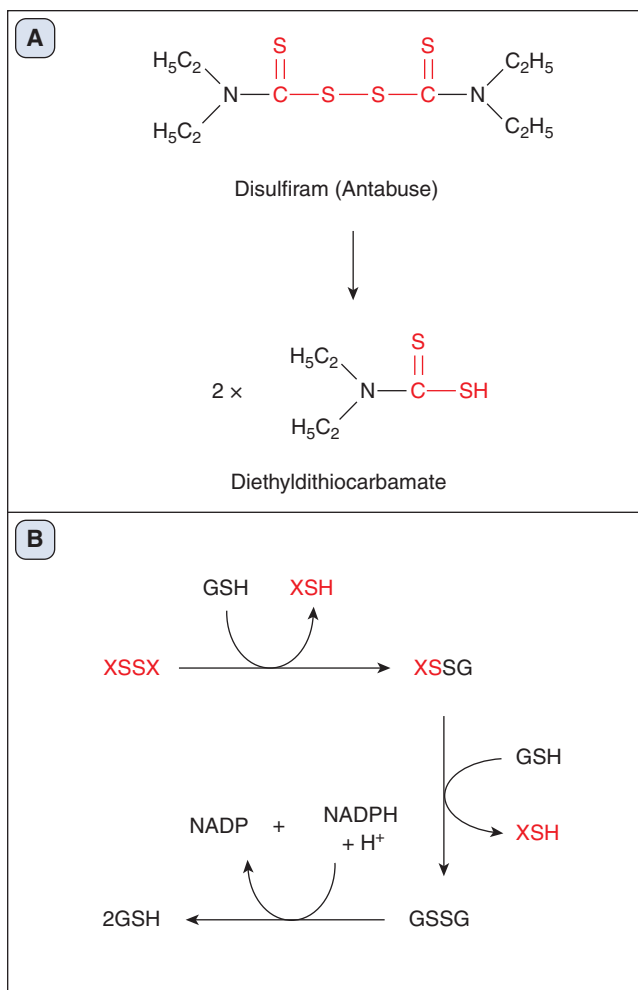

Figure 6-14. Biotransformation of disulfiram by disulfide reduction (A) and the general mechanism of glutathione-dependent disulfide reduction of xenobiotics (B). GSH, glutathione; XSSX, xenobiotic disulfide; GSSG, reduced glutathione. The last reaction in “B” is catalyzed by glutathione reductase.

to the parent methyl ester by glutathione. In the latter reaction, two molecules of glutathione are oxidized with reduction of the sulfine oxygen to water (Madan *et al.*, 1994) as shown below:

Just as sulfoxide reduction can reverse the effect of sulfoxidation, so the reduction of *N*-oxides can reverse the *N*-oxygenation of amines, which is catalyzed by flavin monooxygenases and CYP. Under reduced oxygen tension, reduction of the *N*-oxides of imipramine, tiaramide, indicine, and *N,N*-dimethylaniline can be catalyzed by mitochondrial and/or microsomal enzymes in the presence of NADH or NADPH (Sugiura and Kato, 1977). The NADPH-dependent reduction of *N*-oxides in liver microsomes appears to be catalyzed by CYP (Sugiura *et al.*, 1976), although in some cases NADPH-cytochrome P450 reductase may play an important role.

As a class, *N*-oxides are not inherently toxic compounds. However, certain aromatic and aliphatic *N*-oxides have been exploited as bioreductive drugs (also known as DNA-affinic drugs) for the treatment of certain cancers and infectious diseases (Wardman *et al.*, 1995). In these cases, *N*-oxides have been used as prodrugs that are converted to cytotoxic or DNA-binding drugs under hypoxic conditions. The fact that *N*-oxides of certain drugs

are converted to toxic metabolites under hypoxic conditions is the basis for their selective toxicity to certain solid tumors (namely, those that are hypoxic and, hence, resistant to radiotherapy) and anaerobic bacteria. For example, tirapazamine (SR 4233) is a benzotriazine di-*N*-oxide that is preferentially toxic to hypoxic cells, such as those present in solid tumors, apparently due to its rapid activation by one-electron reduction of the *N*-oxide to an oxidizing nitroxide radical, as shown in Fig. 6-15 (Walton *et al.*, 1992). This reaction is catalyzed by CYP and NADPH-cytochrome P450 reductase (Saunders *et al.*, 2000). Two-electron reduction of the di-*N*-oxide, SR 4233, produces a mono-*N*-oxide, SR 4317, which undergoes a second *N*-oxide reduction to SR 4330. Like SR 4233, the antibacterial agent, quinoxin, is a di-*N*-oxide whose cytotoxicity is dependent on reductive activation, which is favored by anaerobic conditions. AQ4N is a di-*N*-oxide prodrug that is converted by *N*-oxide reduction to the potent topoisomerase II inhibitor 4QA (1,4-bis{[2-(dimethylamino)ethyl]amino}-5,8-dihydroxy-anthracene-9,10-dione) (Nishida *et al.*, 2010). The reductive reaction is catalyzed by CYP2S1 and CYP2W1, two hypoxia-inducible CYP enzymes expressed in many solid tumors. The induction of CYP2S1 and CYP2W1 in hypoxic tumor cells provides a basis for their application in the selective bioreductive activation of antineoplastic drugs (Nishida *et al.*, 2010).

Bioreductive alkylating agents, which include such drugs as mitomycins, anthracyclins, and aziridinylbenzoquinones, represent another class of anticancer agents that require activation by reduction. However, for this class of agents, bioactivation also involves a two-electron reduction reaction, which is largely catalyzed by NQO, which is described in the next section.

Quinone Reduction—NQO1 and NQO2 Quinones can be reduced to hydroquinones by two closely related, cytosolic flavoproteins, namely, NQO1 and NQO2. The former enzyme, NAD(P)H-quinone oxidoreductase-1, is also known as DT-diaphorase. The latter enzyme, NAD(P)H-quinone oxidoreductase-2, is also known as NRH-quinone oxidoreductase because it prefers the unusual electron donor dihydronicotinamide riboside (NRH) over NAD(P)H. Although they are closely related enzymes (both contain two 27-kDa subunits each with an FAD prosthetic group), NQO1 and NQO2 have different substrate specificities, and they can be distinguished on the basis of their differential inhibition by dicoumarol and quercetin (which are selective inhibitors of NQO1 and NQO2, respectively). NQO2 may have a physiological role in the metabolism of vitamin K hydroquinone (Chen *et al.*, 2000).

An example of the type of reaction catalyzed by NQO is shown in Fig. 6-16. Formation of the hydroquinone involves a two-electron reduction of the quinone with stoichiometric oxidation of NAD[P]H without oxygen consumption. (The two-electron reduction of certain quinones can also be catalyzed by carbonyl reductase, especially in humans.) In contrast, NADPH-cytochrome P450 reductase, a microsomal flavoprotein, catalyzes the one-electron reduction of quinones to semiquinone radicals that, in addition to being reactive metabolites themselves, cause oxidative stress by reacting with oxygen to form reactive oxygen species, which leads to nonstoichiometric oxidation of NADPH and oxygen consumption, as shown in Fig. 6-16. The two-electron reduction of quinones is a nontoxic reaction—one that is not associated with semiquinone formation and oxidative stress—provided the resultant hydroquinone is sufficiently stable to undergo glucuronidation or sulfonation. However, there are quinone-containing xenobiotics that, despite undergoing two-electron reduction by NQO, produce semiquinone free radicals, oxidative stress, DNA damage, and cytotoxicity. Many of these xenobiotics are being developed as anticancer drugs because

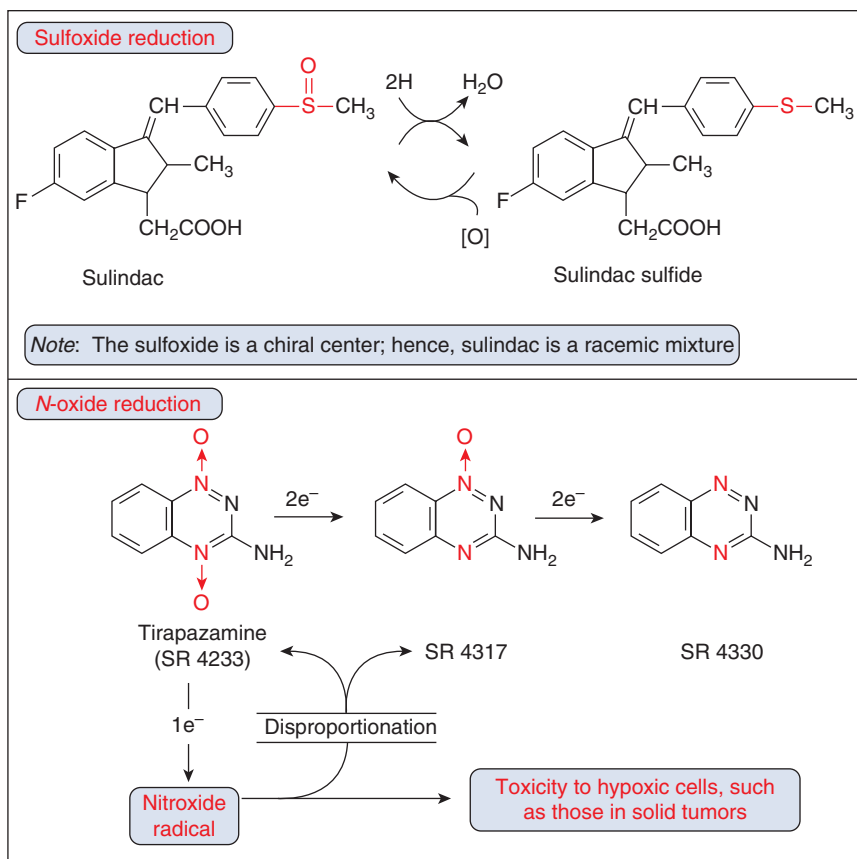

Figure 6-15. Examples of sulfoxide and N-oxide reduction. Note that tirapazamine (3-amino-1,2,4-benzotriazine-1,4-dioxide) is a representative of a class of agents that are activated by reduction, which may be clinically useful in the treatment of certain tumors.

Figure 6-16. Two-electron reduction of menadione to a hydroquinone, and production of reactive oxygen species during its 1-electron reduction to a semiquinone radical.

NQO1 is often overexpressed in tumor cells. The impact of the null allele NQO1*2 (discussed below in this section) on the sensitivity and resistance to antitumor quinones remains to be established (Siegel *et al.*, 2011). The properties of the hydroquinone determine whether, during the metabolism of quinone-containing xenobiotics, NQO functions as a protective antioxidant or a pro-oxidant activator leading to the formation of reactive oxygen species and reactive semiquinone free radicals. The latter are thought to form not from the one-electron reduction of the quinone but from the two-electron reduction of the quinone (Q) to the hydroquinone (QH₂), which then undergoes one-electron oxidation or perhaps disproportionation to form the reactive semiquinone (QH):

Drugs or drug candidates that are activated by NQO to anticancer agents include the aziridinylbenzoquinone diaziquone, the anthraquinone mitoxantrone, the indolquinones mitomycin C and EO9 (an analog of mitomycin C that is more rapidly reduced by NQO1), and the anthracycline antibiotics daunorubicin and doxorubicin (Gutierrez, 2000). These so-called bioreductive alkylating agents are reduced by NQO1 to generate semiquinone free radicals and other reactive intermediates that undergo nucleophilic additions with DNA, resulting in single-strand DNA breaks. The reason such drugs are preferentially toxic to tumor cells is that tumor cells, especially those in solid tumors, are hypoxic, and hypoxia induces the synthesis of NQO1 (by a mechanism that involves the activator protein 1 [AP-1] and NF- κ B response elements in the 5'-promoter region of the NQO1 gene). Therefore, tumor cells often express high levels of NQO1, which predisposes them to the toxic effects of quinone-reductive anticancer drugs such as mitomycin C. Interestingly, mitomycin C also upregulates the expression of NQO1, which may enable this anticancer drug to stimulate its own metabolic activation in tumor cells (Yao *et al.*, 1997). Some cancer chemotherapeutic agents, such as the *N*-oxide SR 4233 (tirapazamine), are inactivated, not activated, by NQO, as shown in Fig. 6-15.

NQO can activate certain nitroaromatic compounds (R-NO₂) to the corresponding hydroxylamine (R-NHOH), which can be activated by acetylation or sulfonation (by pathways analogous to those shown in Fig. 6-12). Dinitropyrenes and the nitroaromatic compound CB 1954 are activated by NQO. The latter compound was under consideration as an anticancer agent. However, although it is activated by reduction by rat NQO, the nitroaromatic compound CB 1954 is not activated by human NQO.

Oxidative stress is an important component to the mechanism of toxicity of several xenobiotics that either contain a quinone or can be biotransformed to a quinone (Anders, 1985). The production of superoxide anion radicals and oxidative stress are responsible, at least in part, for the cardiotoxic effects of doxorubicin (adriamycin) and daunorubicin (daunomycin), the pulmonary toxicity of paraquat and nitrofurantoin, and the neurotoxic effects of 6-hydroxydopamine. Oxidative stress also plays an important role in the destruction of pancreatic β cells by alloxan and dialuric acid. Tissues, low in superoxide dismutase activity, such as the heart, are especially susceptible to the oxidative stress associated with the redox cycling of quinones. This accounts, at least in part, for the cardiotoxic effects of adriamycin and related anticancer agents, although other susceptibility factors have been proposed (Mordente *et al.*, 2001).

As already mentioned in this section, it is now apparent that the structure of the hydroquinones produced by NQO determines whether the two-electron reduction of quinones results in xenobiotic detoxication or activation. Hydroquinones formed by two-electron reduction of unsubstituted or methyl-substituted

1,4-naphthoquinones (such as menadione) or the corresponding quinone epoxides are relatively stable to autoxidation, whereas the methoxyl, glutathionyl, and hydroxyl derivatives of these compounds undergo autoxidation with production of semiquinones and reactive oxygen species. The ability of glutathionyl derivatives to undergo redox cycling indicates that conjugation with glutathione does not prevent quinones from serving as substrates for NQO. The glutathione conjugates of quinones can also be reduced to hydroquinones by carbonyl reductases, which actually have a binding site for glutathione. In human carbonyl reductase, this binding site is Cys₂₂₇, which is involved in binding both substrate and glutathione (Tinguely and Wermuth, 1999). Although oxidative stress is an important mechanism by which quinones cause cellular damage (through the intermediacy of semiquinone radicals and the generation of reactive oxygen species), it should be noted that quinones are Michael acceptors, and cellular damage can occur through direct alkylation of critical cellular proteins and/or DNA (Bolton *et al.*, 2000).

NQO1 is inducible up to 10-fold by two classes of inducers, which have been categorized as *bifunctional* and *monofunctional* inducers (Prochaska and Talalay, 1988). The bifunctional inducers include compounds such as β -naphthoflavone, benzo[*a*]pyrene, 3-methylcholanthrene, and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD or dioxin), which are AhR agonists that induce both oxidative enzymes (such as the CYP enzyme CYP1A1) and conjugating enzymes (such as GST and UGT). The monofunctional inducers are Nrf2 activators that tend to induce conjugating and other non-CYP enzymes (although in mice, monofunctional inducers can induce CYP2C55 and 2U1, as well as AO). The AhR agonists (the so-called bifunctional inducers) signal through the xenobiotic-response element (XRE), whereas Nrf2 activators (the so-called monofunctional inducers) signal through the antioxidant response element (ARE), which is also known as the electrophilic response element (EpRE). (Response elements are short sequences of DNA, often located in the 5'-promoter region of a gene, that bind the transcription factors that control gene expression.) The monofunctional inducers can be subdivided into two chemical classes: those that activate Nrf2 by causing oxidative stress through redox cycling (eg, the quinone, menadione, and the phenolic antioxidants *tert*-butylhydroquinone and 3,5-di-*tert*-butylcatechol) and those that activate Nrf2 by causing oxidative stress by depleting glutathione (eg, fumarates, maleates, acrylates, isothiocyanates, and other Michael acceptors that react with glutathione).

NQO1 is under the control of both AhR and Nrf2. The flavonoid β -naphthoflavone and the PAH B[*a*]P induce NQO1 (and other enzymes) by both mechanisms; the parent compound activates AhR, whereas electrophilic and/or redox active metabolites activate Nrf2. The situation with B[*a*]P is quite intriguing. This PAH binds directly to AhR, which binds to XRE and induces the synthesis of CYP1A1 and CYP1B1, which in turn convert B[*a*]P to electrophilic metabolites (such as arene oxides and diol epoxides) and redox active metabolites (such as catechols), as shown in Fig. 6-10. These electrophilic and redox active metabolites activate Nrf2 and induce various enzymes that protect against oxidative stress. However, the catechol metabolites of B[*a*]P are further converted by AKRs and/or dimeric dihydrodiol dehydrogenase to *ortho*-quinones (Fig. 6-10), and are thereby converted back into planar, hydrophobic compounds that are highly effective ligands for the AhR (Buczynski and Penning, 2000). This may be toxicologically important, because the AhR may translocate *ortho*-quinone metabolites of B[*a*]P into the nucleus, where they might damage DNA (Bolton *et al.*, 2000).

Sulforaphane and various isothiocyanates are Nrf2 activators that are present in broccoli and are thought to be responsible for

the anticarcinogenic effects of this cruciferous vegetable (Zhang *et al.*, 1992). These Nrf2 activators induce GST (GSTA1), mEH, AKR (AKR7A, also known as aflatoxin aldehyde reductase), NQO1 (also known as DT-diaphorase), glutamate cysteine ligase, as well as genes involved in apoptosis. One isothiocyanate in particular, phenethyl isothiocyanate, has been found to activate Nrf2 and activate numerous genes in addition to those encoding xenobiotic-biotransforming enzymes and oxidant defense systems. Microarray studies carried out in wild-type and Nrf2 knockout mice treated with phenethyl isothiocyanate showed that the most highly inducible genes include the very low-density lipoprotein (VLDL) receptor, G-protein signaling modulator 2, early growth response 1, pancreatic lipase-related protein 2, histocompatibility 2 (K region), general transcription factor IIB, myoglobin, potassium voltage-gated channel Q2, and SLC39A10 (Hu *et al.*, 2006). As with other xenosensors, activation of Nrf2 results in a pleiotypic response in which a large number of genes are activated (or repressed). As mentioned above (this section), hypoxia and the anticancer agent mitomycin C are also inducers of NQO1, which has implications for cancer chemotherapy.

NQO1 and NQO2 are polymorphically expressed enzymes, and several lines of evidence suggest that NQO1 and/or NQO2 plays a key role in protecting bone marrow from the hematotoxic effects of benzene or other environmental factors (Iskander and Jaiswal, 2005). In humans, a high percentage of individuals with myeloid and other types of leukemia are homozygous or heterozygous for a null mutant allele of NQO1. This polymorphism, NQO1*2, is a SNP (C₆₀₉T) that changes Pro₁₈₇ to Ser₁₈₇, which destabilizes the protein and targets it for rapid degradation by the

ubiquitin proteasomal pathway; this polymorphism is also associated with increased risk of colorectal and esophageal cancers (Ross, 2005; Chen *et al.*, 2012). Mice lacking NQO1 or NQO2 (knockout or null mice) have no developmental abnormalities but have increased granulocytes in the blood and myelogenous hyperplasia of the bone marrow (due to decreased apoptosis). Mice lacking NQO1 are substantially more susceptible than wild-type mice to benzene-induced hematotoxicity (Iskander and Jaiswal, 2005; Ross, 2005). The hematotoxicity of benzene is thought to involve its conversion to hydroquinone in the liver and its subsequent oxidation to benzoquinone by myeloperoxidase in the bone marrow (discussed later in the section “Peroxidase-Dependent Cooxidation”). NQO would be expected to play a role in detoxifying benzoquinone, as predicted, loss of NQO potentiates benzene hematotoxicity. However, loss of NQO also impairs apoptosis, which also represents a plausible explanation for the association between loss of NQO and increased susceptibility to benzene hematotoxicity. The latter mechanism (ie, impaired apoptosis) likely accounts for the observation that NQO1 and NQO2 null mice are more susceptible than wild-type mice to skin carcinogenesis by B[a]P and DMBA, an effect attributable to the diol epoxides, not the quinone metabolites, of these PAHs (Iskander and Jaiswal, 2005).

Dihydropyrimidine Dehydrogenase In 1993, 15 Japanese patients died as a result of an interaction between two oral medications: sorivudine (a new antiviral drug for herpes zoster) and tegafur (a prodrug that is converted in the liver to the anticancer agent, 5-fluorouracil). The deaths occurred within 40 days of the Japanese

Figure 6-17. Reduction of 5-fluorouracil by dihydropyrimidine dehydrogenase and its inhibition (suicide inactivation) by sorivudine. Note: Inhibition of dihydropyrimidine dehydrogenase is the mechanism of fatal interactions between sorivudine and the 5-fluorouracil prodrug, tegafur.

government's approval of sorivudine for clinical use. The mechanism of the lethal interaction between sorivudine and tegafur is illustrated in Fig. 6-17, and involves inhibition of dihydropyrimidine dehydrogenase (DPD), an NADPH-requiring, homodimeric protein (Mr ~210 kDa) containing FMN/FAD and an iron–sulfur cluster in each subunit. The enzyme is located mainly in liver cytosol, where it catalyzes the reduction of 5-fluorouracil and related pyrimidines. Sorivudine is converted in part by gut flora to (*E*)-5-(2-bromovinyl) uracil (BVU), which lacks antiviral activity but which is converted by DPD to a metabolite that binds covalently to the enzyme. The irreversible inactivation (aka suicidal inactivation) of DPD by sorivudine causes a marked inhibition of 5-fluorouracil metabolism, which increases blood levels of 5-fluorouracil to toxic and, in some cases, lethal levels (Ogura *et al.*, 1998; Kanamitsu *et al.*, 2000).

Several genetic polymorphisms that result in a partial or complete loss of DPD activity, affecting ~8% of the population, have been described (van Kuilenburg *et al.*, 2004; Robert *et al.*, 2005). Severe 5-fluorouracil toxicity has also been documented in individuals who are heterozygous for loss-of-function allelic variants of DPD, and 5-fluorouracil lethality has been documented in rare individuals who are completely deficient in DPD (1 individual in about 10,000). 5-Fluorouracil is one of the most frequently prescribed anticancer drugs, for which reason assessing an individual's DPD genotype (by analyzing DNA for allelic variants) or phenotyping (by measuring DPD activity in peripheral blood mononuclear cells) is advocated prior to 5-fluorouracil or capecitabine (a 5-fluorouracil prodrug) therapy so that the dosage of these anticancer drugs can be adjusted on an individual basis.

Dehalogenation There are three major mechanisms for removing halogens (F, Cl, Br, and I) from aliphatic xenobiotics (Anders, 1985). The first, known as *reductive dehalogenation*, involves replacement of a halogen with hydrogen, as shown below:

In the second mechanism, known as *oxidative dehalogenation*, a halogen and hydrogen on the same carbon atom are replaced with oxygen. Depending on the structure of the haloalkane, oxidative dehalogenation leads to the formation of an acylhalide or aldehyde, as shown below:

A third mechanism of dehalogenation involves the elimination of two halogens on adjacent carbon atoms to form a carbon–carbon double bond, as shown below:

Figure 6-18. Reductive dehalogenation of carbon tetrachloride to a trichloromethyl free radical that initiates lipid peroxidation. RH, unsaturated lipid; R•, lipid dienyl radical; GSH, reduced glutathione; GSSG, oxidized glutathione.

A variation on this third mechanism is *dehydrohalogenation*, in which a halogen and hydrogen on adjacent carbon atoms are eliminated to form a carbon–carbon double bond.

Both reductive and oxidative dehalogenations are catalyzed by CYP. (The ability of CYP to catalyze both reductive and oxidative reactions is explained later in the section “Cytochrome P450.”) Dehalogenation reactions leading to double bond formation are catalyzed by CYP and GST. These reactions play an important role in the biotransformation and metabolic activation of several halogenated alkanes, as the following examples illustrate.

The hepatotoxicity of carbon tetrachloride (CCl_4) and several related halogenated alkanes is dependent on their biotransformation by reductive dehalogenation (Plaa, 2000). The first step in reductive dehalogenation is a one-electron reduction catalyzed by CYP, which produces a potentially toxic, carbon-centered radical and inorganic halide. In the case of CCl_4 , reductive dechlorination produces a trichloromethyl radical ($\cdot\text{CCl}_3$), which initiates lipid peroxidation and produces a variety of other metabolites, as shown in Fig. 6-18.

Halothane can also be converted by reductive dehalogenation to a carbon-centered radical, as shown in Fig. 6-19. The mechanism is identical to that described for carbon tetrachloride, although in the case of halothane the radical is generated through loss of

Figure 6-19. Activation of halothane by reductive and oxidative dehalogenation and their role in liver toxicity in rats and humans.

bromine, which is a better leaving group than chlorine. Fig. 6-19 also shows that halothane can undergo oxidative dehalogenation, which involves oxygen insertion at the C–H bond to generate an unstable halohydrin (CF₃COHClBr) that decomposes to a reactive acylhalide (CF₃COCl), which can bind to cellular proteins (particularly to amine groups) or further decompose to trifluoroacetic acid (CF₃COOH).

Both the oxidative and reductive pathways of halothane metabolism generate reactive intermediates capable of binding to proteins and other cellular macromolecules. The relative importance of these two pathways to halothane-induced hepatotoxicity is species dependent. In rats, halothane-induced hepatotoxicity is promoted by those conditions favoring the reductive dehalogenation of halothane, such as moderate hypoxia (10%–14% oxygen) plus treatment with the CYP inducers, phenobarbital, and pregnenolone-16 α -carbonitrile (PCN). In contrast to the situation in rats, halothane-induced hepatotoxicity in guinea pigs is largely the result of oxidative dehalogenation of halothane (Lunam *et al.*, 1989). In guinea pigs, halothane hepatotoxicity is not enhanced by moderate hypoxia and is diminished by the use of deuterated halothane, which impedes the oxidative dehalogenation of halothane because the CYP-dependent insertion of oxygen into a carbon–deuterium bond is energetically less favorable (and therefore slower) than inserting oxygen into a carbon–hydrogen bond.

Halothane hepatitis in humans is a rare but severe form of liver necrosis associated with repeated exposure to this volatile anesthetic. In humans, as in guinea pigs, halothane hepatotoxicity

results from the oxidative dehalogenation of halothane, as shown in Fig. 6-19. Serum samples from patients suffering from halothane hepatitis contain antibodies directed against neoantigens formed by the trifluoroacetylation of proteins. These antibodies have been used to identify which specific proteins in the endoplasmic reticulum are targets for trifluoroacetylation during the oxidative dehalogenation of halothane (Pohl *et al.*, 1989).

The concept that halothane is activated by CYP to trifluoroacetylhalide, which binds covalently to proteins and elicits an immune response, has been extended to other volatile anesthetics, such as enflurane, methoxyflurane, and isoflurane. In other words, these halogenated aliphatic hydrocarbons, like halothane, may be converted to acylhalides that form immunogens by binding covalently to proteins. In addition to accounting for rare instances of enflurane hepatitis, this mechanism of hepatotoxicity can also account for reports of a *cross-sensitization* between enflurane and halothane, in which enflurane causes liver damage in patients previously exposed to halothane.

One of the metabolites generated from the reductive dehalogenation of halothane is 2-chloro-1,1-difluoroethylene (Fig. 6-19). The formation of this metabolite involves the loss of two halogens from adjacent carbon atoms with formation of a carbon–carbon double bond. This type of dehalogenation reaction can also be catalyzed by GSTs. GSH initiates the reaction with a nucleophilic attack either on the electrophilic carbon to which the halogen is attached (mechanism A) or on the halogen itself (mechanism B), as shown in Fig. 6-20 for the dehalogenation of 1,2-dihaloethane to ethylene.

Figure 6-20. Glutathione-dependent dehalogenation of 1,2-dihaloethane to ethylene. (A) Nucleophilic attack on carbon and (B) nucleophilic attack on halide.

The insecticide DDT is detoxified by dehydrochlorination to DDE by a lyase (ie, DDT-dehydrochlorinase), as shown in Fig. 6-21. The activity of this GSH-dependent reaction correlates well with resistance to DDT in houseflies.

Dehydroxylation—mARC, Cytochrome b_5 , b_5 Reductase, and Aldehyde Oxidase Mitochondrial amidoxime reducing component (mARC) is a molybdenum-containing enzyme that, in the presence of NADH, cytochrome b_5 , and NADH-cytochrome b_5 reductase, can catalyze the *N*-dehydroxylation of various amidoximes and related *N*-hydroxy compounds, as shown in Fig. 6-22 (Havemeyer *et al.*, 2010). Reactions catalyzed by mARC/cytochrome b_5 /NADH-cytochrome b_5 reductase include the *N*-dehydroxylation of amidoximes formed during the activation of the antiparasitic pro-drug pafuramidine (DB-289), the *N*-dehydroxylation of *N*-hydroxy-sulfonamides, and the *N*-dehydroxylation of *N*-hydroxy-valdecoxib

to its active principal, a cyclooxygenase-2 (COX-2) inhibitor (Saulter *et al.*, 2005; Havemeyer *et al.*, 2010). The mARC complex can also *N*-dehydroxylate the aryl hydroxylamine metabolites of carcinogenic arylamines such as 4-aminobiphenyl and 2-amino-1-methyl-6-phenyl-imidazol[4,5-*b*]pyridine (PhIP), *N*-hydroxy metabolites that are formed by CYP1A1, 1A2, 1B1, lactoperoxidase, and myeloperoxidase (see the sections “Cytochrome P450” and “Peroxidase-Dependent Cooxidation”) (Kurian *et al.*, 2006). Because these carcinogenic aryl hydroxylamines can be further activated by glucuronidation, sulfonation, or acetylation in various tissues (see the sections “Glucuronidation and Formation of Acyl-CoA Thioesters,” “Sulfonation,” and “Acetylation”), reduction by mARC/cytochrome b_5 /NADH-cytochrome b_5 reductase represents a competing detoxication pathway. Gut microflora can also catalyze dehydroxylation reactions as shown in Fig. 6-1 for quinic acid. Gut microflora can also reduce *N*- and *S*-oxides formed by FAD-containing monooxygenase (FMO) and/or CYP, as described for trimethylamine (TMA) *N*-oxide in the section “Flavin Monooxygenases.”

Aldehyde Oxidase—Reductive Reactions Aldehyde oxidase (AO) is a cytosolic molybdoenzyme that catalyzes the oxidation of some xenobiotics and the reduction of others. The types of oxidative and reductive reactions catalyzed by AO are shown in Fig. 6-23. In contrast to the large number of drugs that are known to be (or suspected of being) oxidized by AO *in vivo*, only a few drugs are known to be (or suspected of being) reduced by AO *in vivo*, including nitrofurazone, zonisamide, and ziprasidone. The reductive metabolism of ziprasidone by AO is shown in Fig. 6-4. The features of AO and the oxidative reactions it catalyzes are discussed later in the section “Aldehyde Oxidase.”

Oxidation

Alcohol, Aldehyde, Ketone Oxidation–Reduction Systems

Alcohols, aldehydes, and ketones are oxidized by a number of enzymes, including alcohol dehydrogenase, aldehyde dehydrogenase, AKRs (such as those with dihydrodiol dehydrogenase activity), the molybdenum-containing enzymes (namely, AO and xanthine dehydrogenase [XD]/xanthine oxidase [XO]), and CYP. For example, simple alcohols (such as methanol and ethanol) are oxidized to aldehydes (namely, formaldehyde and acetaldehyde) by ADH. These aldehydes are further oxidized to carboxylic acids (formic acid and acetic acid) by ALDH, as shown in Fig. 6-24. Many of the aforementioned enzymes can also catalyze the reduction of xenobiotics, as discussed in the section “Reduction.”

Alcohol Dehydrogenase ADHs belong to the MDRs, as shown in Table 6-5. ADHs are zinc-containing, cytosolic enzymes present in several tissues including liver (which has the highest levels), kidney, lung, and gastric mucosa (Agarwal, 1992; Ramchandani, 2004). These enzymes oxidize several types of alcohols including hydroxysteroids, retinol, ethanol, lipid peroxidation products, and other simple and complex (eg, ring-containing) alcohols. Human ADHs are dimeric proteins consisting of two ~40-kDa subunits designated α , β , γ , π , χ , σ (also previously known as μ), or ADH6

Figure 6-21. Dehydrochlorination of the pesticide DDT to DDE, a glutathione-dependent reaction.

Figure 6-22. Dehydroxylation reactions catalyzed by the molybdoenzyme mitochondrial amidoxime-reducing component (mARC), cytochrome b_5 , and NADH-cytochrome b_5 reductase. Note: Aldehyde oxidase can also catalyze dehydroxylation reactions as shown in Fig. 6-23.

(the latter having no subunit designation). As shown in Table 6-5, there are 7 human ADHs, and these are categorized into 5 classes (I-V) based on patterns of tissue-specific expression, catalytic properties, and amino acid sequence. Class I comprises 3 hepatically expressed genes: ADH1A, ADH1B, and ADH1C, which were formerly known as ADH1, -2, and -3, respectively. The class I isozymes consist of homodimeric and heterodimeric forms of the 3 subunits (eg, $\alpha\alpha$, $\alpha\beta$, $\beta\beta$, $\beta\gamma$, $\gamma\gamma$, etc). Class II contains ADH4, which is composed of 2 pi subunits ($\pi\pi$). Class III contains ADH5, which is composed of 2 chi subunits ($\chi\chi$). Class IV contains ADH7, which is composed of 2 sigma subunits ($\sigma\sigma$). Class V contains ADH6 (for which there is no subunit designation) (Brennan

et al., 2004; Ramchandani, 2004). Therefore, there are over 20 human ADH isozymes and these differ in their substrate specificity and catalytic efficiency toward ethanol (Ramchandani, 2004). The human ADH genes have similar sequences (ie, 60%–70% identical coding regions), and all have 9 exons and 8 introns with the exception of ADH6, which lacks the last exon (Han *et al.*, 2005). In addition, several hundred genetic variants have been described across the human ADH cluster which lies on chromosome 4q (Li *et al.*, 2008). Alcohols can be oxidized to aldehydes by non-ADH enzymes in microsomes and peroxisomes, although these are quantitatively less important than ADH for ethanol oxidation (Lieber, 2004). The microsomal ethanol oxidizing system (formerly known

Figure 6-23. Examples of oxidation and reduction catalyzed by aldehyde oxidase.

as MEOS) is the CYP enzyme, CYP2E1. The corresponding peroxisomal enzyme is catalase. The oxidation of ethanol to acetaldehyde by these 3 enzyme systems is shown in Fig. 6-25.

Class I (ADH1A, 1B, 1C) The class I ADH isozymes (ADH1A or α -ADH, ADH1B or β -ADH, and ADH1C or γ -ADH) are responsible for the oxidation of ethanol and other small, aliphatic alcohols, and they are strongly inhibited by pyrazole and its 4-alkyl derivatives (eg, 4-methylpyrazole). High levels of class I ADH isozymes are expressed in liver and adrenals, with lower levels in kidney, lung, blood vessels (in the case of ADH1B), gastric mucosa (in the case of ADH1C), and other tissues, but not brain. It is noteworthy that the liver expresses a very large amount of ADHs (approximately 3% of all soluble protein) and also expresses the widest variety of isozymes (Ramchandani, 2004).

The class I ADH isozymes differ in their capacity to oxidize ethanol. Polymorphisms have been well described for the class I ADH isozymes. Even the allelozymes, which differ in a single amino acid, differ markedly in their affinity (K_m) and/or capacity

(V_{max}) for oxidizing ethanol to acetaldehyde. There are at least 3 allelic variants of ADH1B (ie, *1, *2, and *3), with a single amino acid change at position 48. The homodimer, $\beta_2\beta_2$, and heterodimers containing at least 1 β_2 subunit (ie, the ADH1B*2 allelozymes) are especially active in oxidizing ethanol at physiological pH. ADH1B*2 (formerly known as ADH2*2) is known as *atypical* ADH, and is responsible for the unusually rapid conversion of ethanol to acetaldehyde in up to 90% of the Pacific Rim Asian population (eg, Japanese, Chinese, Korean), whereas only ~10% of Caucasians express this allele. The ADH1B*3 is relatively common in individuals of African descent. The latter 2 alleles have greater activity toward ethanol than the ADH1B*1 allele (Kimura and Higuchi, 2011). These population differences in ADH1B allelozyme expression contribute to ethnic differences in alcohol consumption and toxicity, as discussed in the section “Aldehyde Dehydrogenase.”

Unlike the allelic variants of ADH1B, the allelic variants of ADH1C do not differ markedly in their ability to oxidize ethanol.

Figure 6-24. Oxidation of alcohols to aldehydes and carboxylic acids by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH).

Figure 6-25. Oxidation of alcohol to acetaldehyde by alcohol dehydrogenase (ADH), cytochrome P450 (CYP2E1), and catalase. Note: The oxidation of alcohol to acetic acid involves multiple organelles.

However, as in the case of the ADH1B allelozymes, the expression of the ADH1C allelozymes also varies from one ethnic group to the next. The 2 allelozymes of ADH1C, namely, ADH1C*1 (γ_1 -ADH) and ADH1C*2 (γ_2 -ADH), are, respectively, expressed ~50:50 in Caucasians and 90:10 in Pacific Rim Asians, with the *2 allele having somewhat higher activity toward ethanol than the *1 allele (Li, 2000; Kimura and Higuchi, 2011). An additional SNP in ADH1C has been found in up to 20% of some Native American populations (Ramchandani, 2004).

Class II (ADH4) The class II enzyme ADH4 (π -ADH) is mainly expressed in liver (and to some extent in other gastrointestinal tissues), where it preferentially oxidizes larger alcohols (Ramchandani, 2004). ADH4 differs from the ADH1 isozymes in that it is less sensitive to pyrazole inhibition, but may play some role in ethanol oxidation, especially at high concentrations (Lockley *et al.*, 2005; Edenberg, 2007; Kimura and Higuchi, 2011). Some studies support a role for polymorphisms of ADH4 in the susceptibility to alcoholism (Kimura and Higuchi, 2011).

Class III (ADH5) The class III enzyme ADH5 (a homodimer of the χ -subunit) preferentially oxidizes long-chain alcohols (pentanol and larger), omega-hydroxy-fatty acids, and other alcohols (such as cinnamyl alcohol). Like ADH4, ADH5 is less sensitive to pyrazole inhibition than ADH1 enzymes. However, in contrast to ADH4, which is largely confined to the liver, ADH5 is ubiquitous, being present in virtually all tissues (including brain), where it catalyzes the rate-limiting step in detoxifying formaldehyde through oxidation of *S*-hydroxymethylglutathione

(which is formed spontaneously from formaldehyde and GSH) to *S*-formylglutathione. In fact, ADH5 and the GSH-dependent formaldehyde dehydrogenase (also referred to in literature as FDH, ADH3, or *S*-nitrosoglutathione reductase [GSNOR]) are identical enzymes (Koivusalo *et al.*, 1989; Edenberg, 2007; Just *et al.*, 2011). This enzyme appears to be the ancestral form of ADH from which all other vertebrate ADHs have evolved, and so far functional polymorphisms have not been identified in ADH5 (Just *et al.*, 2011).

Class IV (ADH7) The class IV enzyme ADH7 (σ -ADH; also referred to as the μ subunit) is a low-affinity (high K_m), high-capacity (high V_{max}) enzyme, and is the most active of the medium-chain ADHs in oxidizing retinol (a member of the vitamin A family). It is the major ADH expressed in human stomach and other areas of the UADT (eg, stomach, esophagus, pharynx, gingiva, mouth, and tongue), as well as the eyes (Han *et al.*, 2005). In contrast to the other ADHs, ADH7 is not expressed in adult human liver (Ramchandani, 2004). Among the human ADH forms, ADH7 has the highest activity toward ethanol (Han *et al.*, 2005). Inasmuch as ADH7 is expressed in the upper gastrointestinal tract, where chronic alcohol consumption leads to cancer development, there is considerable interest in the role of ADH7 in the preabsorptive conversion of ethanol to acetaldehyde (a suspected upper GI tract carcinogen or cocarcinogen) and in its role in the metabolism of retinol (a vitamin required for epithelial cell growth and differentiation), which might be inhibited by alcohol consumption (Seitz and Oneta, 1998). The role for a protective effect of high-activity

polymorphisms against alcoholism remains to be fully elucidated, with some studies showing a positive association (Han *et al.*, 2005), and others no association (Duell *et al.*, 2011). However, the A92G SNP (rs1573496; C → G) in ADH7 has been found to confer a reduced risk of squamous cell carcinoma of the head and neck in Caucasians (Wei *et al.*, 2010).

Compared with hepatic ADH, gastric ADH has a lower affinity (higher K_m) but higher capacity (larger V_{max}) for oxidizing ethanol, the former being dominated by the class I ADH isozymes and the latter by the class IV enzyme ADH7. Although ethanol is largely biotransformed by hepatic ADH1, gastric ADH7 nevertheless can limit the systemic bioavailability of alcohol. This first-pass elimination of alcohol by gastric ADH7 can be significant depending on the manner in which the alcohol is consumed; large doses over a short time produce high ethanol concentrations in the stomach, which compensate for the low affinity (high K_m) of gastric ADH7. Young women have lower gastric ADH7 activity than do men, and gastric ADH7 activity tends to be lower in alcoholics (Frezza *et al.*, 1990). Some alcoholic women have no detectable gastric ADH7, and blood levels of ethanol after oral consumption of alcohol are the same as those that are obtained after intravenous administration. Gastric ADH7 activity decreases during fasting, which is one reason alcohol is more intoxicating when consumed on an empty stomach. Several commonly used drugs (eg, cimetidine, ranitidine, aspirin) are non-competitive inhibitors of gastric ADH7. Under certain circumstances these drugs increase the systemic availability of alcohol, although the effect is too small to have serious medical, social, or legal consequences (Levitt, 1993). About 30% of Asians appear to be genetically deficient in ADH7, the main gastric ADH. In addition to biotransforming ethanol and retinol, ADH7 also detoxifies the dietary carcinogen, nitrobenzaldehyde. It has been suggested that a lack of ADH7 in some Japanese subjects may impair their ability to detoxify nitrobenzaldehyde and may possibly be linked to the high rate of gastric cancer observed in the Japanese population (Seitz and Oneta, 1998).

Class V (ADH6) The mRNA for class V ADH (namely, ADH6, for which there is no subunit designation) (Brennan *et al.*, 2004; Ramchandani, 2004) has been found in fetal and adult liver (Edenberg, 2007). However, the protein has not yet been isolated from human tissue, so little is known about its *in vivo* function. ADH6 has been expressed *in vitro* and metabolizes ethanol with a K_m of approximately 28 mM and has higher affinity for benzyl alcohol (K_m 0.12 mM) and propanol (K_m 3.2 mM) (Zhi *et al.*, 2000).

Aldehyde Dehydrogenase ALDHs oxidize 4 major types of aldehydes: (1) saturated alkanals (eg, formaldehyde, acetaldehyde), (2) unsaturated alkenals (eg, acrolein), (3) aromatic aldehydes (eg, benzaldehyde), and (4) dicarbonyls (eg, glyoxal, malondialdehyde) to their corresponding carboxylic acids, generally with NAD^+ as the cofactor. However, it should be noted that ALDH1L1 prefers $NADP^+$ over NAD^+ , and ALDH3B1 can use either cofactor in a substrate-dependent manner. In addition, ALDH6A1 requires acetyl- or propionyl-CoA (Marchitti *et al.*, 2007, 2008). Most of the enzymes also have esterase activity (Yoshida *et al.*, 1998; Marchitti *et al.*, 2008). Several ALDH enzymes are involved in the oxidation of xenobiotic aldehydes, such as those formed from ethanol, allyl alcohol, carbon tetrachloride, cyclophosphamide, and ifosfamide (Marchitti *et al.*, 2007). Formaldehyde dehydrogenase, which specifically oxidizes formaldehyde that is complexed with GSH, is not a member of the ALDH family but is a class III ADH (ADH5) (Koivusalo *et al.*, 1989; Edenberg, 2007; Just *et al.*, 2011). At least 19 ALDH genes have been identified in humans, and a correspondingly large number of ALDH genes appear to be present in other

mammalian species (Sládek, 2003; Vasiliou *et al.*, 2004; Marchitti *et al.*, 2007, 2008). The name, tissue distribution, subcellular location, and major substrate for the human ALDHs are summarized in Table 6-6. The ALDHs differ in their primary amino acid sequences. They may also differ in the quaternary structure. For example, ALDH3A1 is a dimer of two 85-kDa subunits, whereas ALDH1A1 and ALDH2 are homotetramers of 54-kDa subunits (Goedde and Agarwal, 1992; Marchitti *et al.*, 2008).

As shown in Fig. 6-25, ALDH2 is a mitochondrial enzyme that, by virtue of its high affinity, is primarily responsible for oxidizing simple aldehydes, such as acetaldehyde (K_m for acetaldehyde $<1 \mu M$) and, by acting as a nitrate reductase, ALDH2 is the principal enzyme necessary for the activation of nitroglycerin (Marchitti *et al.*, 2008). In fact, the genetic polymorphism ALDH2*2 is associated with decreased nitroglycerin efficacy in certain Chinese populations (Marchitti *et al.*, 2008). Several genetic polymorphisms in human ALDH2 have been described, including the well-described ALDH2*2 point mutation (Glu₄₈₇ → Lys₄₈₇), which results in a loss of activity due to a greatly diminished affinity for NAD^+ (Marchitti *et al.*, 2008). The mutant ALDH2*2 allele is dominant, such that heterotetrameric ALDH2 proteins containing even a single ALDH2*2 subunit are inactive (Marchitti *et al.*, 2008). A high percentage (40%–50%) of individuals of Asian descent are deficient in ALDH2 activity due to the presence of the ALDH2*2 allele. This same population also has a high incidence of the atypical form of ADH1B (ie, ADH1B*2), which means that they rapidly convert ethanol to acetaldehyde but only slowly convert acetaldehyde to acetic acid. (They also have a relatively high prevalence of a deficiency of ADH7 activity, which impairs gastric metabolism of ethanol.) As a result, many Asian subjects experience a flushing syndrome after consuming alcohol due to a rapid buildup of acetaldehyde, which triggers the dilation of facial blood vessels through the release of catecholamines. Some Native American populations also experience a flushing syndrome after consuming alcohol, possibly because they express ADH1B*2 (Ramchandani, 2004) or a different allelic variant of ALDH2 and/or because acetaldehyde oxidation in blood erythrocytes is impaired in these individuals, possibly due to the expression of a variant form of ALDH1A1. Both the functional genetic variants of ADH that rapidly convert ethanol to acetaldehyde (ie, ADH1B*2) and the genetic variants of ALDH that slowly detoxify acetaldehyde (ie, ALDH2*2) protect against heavy drinking and alcoholism. Inhibition of ALDH by disulfiram (Antabuse) causes an accumulation of acetaldehyde in alcoholics. The nauseating effect of acetaldehyde serves to deter continued ethanol consumption (Goedde and Agarwal, 1992). However, it is important to note that a predisposition toward alcoholism is not simply determined by factors that affect the pharmacokinetics of ethanol and its metabolites. Studies in humans and rodents implicate 5-HT1B, 2A, 3A, and 3B receptors, dopamine-related genes, GABA receptors, cholinergic muscarinic receptor 2, the endogenous opioid system, tryptophan hydroxylase, and neuropeptide Y as candidate targets of genetic susceptibility in the pharmacodynamic actions of ethanol (Li, 2000; Kimura and Higuchi, 2011). MAO may also be a risk factor for alcoholism, as discussed later (see the section “Amine Oxidases”).

Genetic deficiencies in other ALDHs impair the metabolism of other aldehydes, which is the underlying basis of certain diseases. For example, polymorphisms in certain ALDH genes may alter the risk for, or cause, the following: spina bifida (ALDH1A2), Sjögren–Larsson syndrome (ALDH3A2), paranoid schizophrenia (ALDH3B1), type II hyperprolinemia (ALDH4A1), γ -hydroxybutyric aciduria (ALDH5A1), methylmalonic aciduria (ALDH6A1), pyridoxine-dependent seizures

Table 6-6

Properties of the Human Aldehyde Dehydrogenases (ALDHs)

ALDH	ALTERNATIVE NAMES	FORM	TISSUE	SUBCELLULAR LOCALIZATION	MAJOR SUBSTRATE
1A1	ALDH1, ALDH11, RALDH1	Homotetramer	Liver, kidney, lung, stomach, testis, lens, retina, CNS, etc	Cytosol	Retinal
1A2	RALDH2	Homotetramer	Intestine, testis, lung, liver, kidney, retina, CNS, etc	Cytosol	Retinal, nitroglycerin
1A3	ALDH6, RALDH3	Homodimer	Prostate, salivary gland, stomach, kidney, breast, CNS, etc	Cytosol	Retinal, aliphatic aldehydes
1B1	ALDH5	Homotetramer	Muscle, liver, kidney, lung, testis, muscle, heart, CNS, etc	Mitochondria	Acetaldehyde, aliphatic aldehydes
1L1	FDH	Homotetramer	Liver, kidney, pancreas, lung, prostate, heart, muscle, testis, ovary, CNS, etc	Cytosol, mitochondria	10-Formyltetrahydrofolate, propanal, and acetaldehyde
1L2	mtFDH	Homotetramer	Spleen, cervix, uterus, corpus callosum	Mitochondria	10-Formyltetrahydrofolate
2	ALDM, ALDHI	Homotetramer	Liver, kidney, lung, heart, stomach, muscle, CNS, etc	Mitochondria	Acetaldehyde
3A1	ALDH3	Homodimer	Cornea, esophagus, trachea, stomach, lung, bladder, etc	Cytosol, nucleus	Aromatic and medium-chain aliphatic aldehydes
3A2	ALDH10, FALDH	Homodimer	Adrenals, kidney, liver, lung, intestine, pancreas, stomach, heart, muscle, CNS, etc	Microsomes, peroxisomes	Fatty and aromatic aldehydes
3B1	ALDH4, ALDH7	Unknown	Kidney, lung, liver, cerebral astrocytes, testis, macrophages, pancreas, spleen	Cytosol (membrane-bound in some tissues)	Medium- and long-chain aliphatic and aromatic aldehydes
3B2	ALDH8	Unknown	Parotid, adrenals, prostate, lung, kidney, liver, CNS	Microsomes	Unknown*
4A1	ALDH4, P5CDH	Homodimer	Liver, muscle, kidney, CNS	Mitochondria	Glutamate γ -semialdehyde, short- and medium-chain aliphatic aldehydes
5A1	SSDH, SSADH	Homotetramer	Liver, kidney, muscle, heart, CNS	Mitochondria	Succinate semialdehyde
6A1	MMSDH	Homotetramer	Kidney, liver, heart, muscle, CNS	Mitochondria	Malonate semialdehyde
7A1	ATQ1, EPD	Homotetramer	Cochlea, eye, ovary, heart, kidney, liver, CNS, etc	Cytosol, nucleus, mitochondria	α -Aminoadipic semialdehyde
8A1	ALDH12	Unknown	Liver, kidney, CNS, breast, testis, prostate, etc	Cytosol	9- <i>cis</i> -Retinal
9A1	ALDH4, ALDH7, ALDH9, γ ABHD	Homotetramer	Liver, kidney, muscle, CNS	Cytosol	γ -Aminobutyraldehyde
16A1	MGC10204	Unknown	CNS, uterus, placenta, bone marrow, heart, kidney, lung	Cytosol	Unknown
18A1	GSAS, Δ^1 -P5CS [†]	Unknown	Pancreas, ovary, testis, kidney, heart, colon, muscle, CNS, etc	Mitochondria	Glutamic γ -semialdehyde

γ ABHD, 4-aminobutyraldehyde; FALDH, fatty aldehyde dehydrogenase; SSDH, succinic dehydrogenase; MMSDH, methylmalonate semialdehyde dehydrogenase. Data from Strickland et al. (2011), Marchitti et al. (2007, 2008, 2010), Sládek (2003), and Vasiliou et al. (2004).

*ALDH3B2 contains an in-frame stop codon, suggesting the possibility that it is a pseudogene, although transcripts have been found in various tissues.

[†] Δ^1 -Pyrroline-5-carboxylate synthase, P5CS.

(ALDH7A1), nonalcoholic steatohepatitis (NASH) (ALDH9A1), and hyperammonemia and/or hypoprolinemia (ALDH18A1) (Marchitti *et al.*, 2008).

The toxicological consequences of an inherited (ie, genetic) or acquired (eg, drug-induced) deficiency of ALDH illustrate that aldehydes are more cytotoxic than the corresponding alcohol. This is especially true of allyl alcohol ($\text{CH}_2=\text{CHCH}_2\text{OH}$), which is converted by ADH to the highly hepatotoxic aldehyde, acrolein ($\text{CH}_2=\text{CHCHO}$) (Marchitti *et al.*, 2007, 2008).

The oxidation of ethanol by ADH and ALDH leads to the formation of acetic acid, which is rapidly oxidized to carbon dioxide and water. However, in certain cases, alcohols are converted to toxic carboxylic acids, as in the case of methanol and ethylene glycol, which are converted via aldehyde intermediates to formic acid and oxalic acid, respectively. Formic and oxalic acids are considerably more toxic than acetic acid. For this reason, methanol and ethylene glycol poisonings are commonly treated with ethanol, which competitively inhibits the oxidation of methanol and ethylene glycol by ADH and ALDH. The potent inhibitor of ADH, 4-methylpyrazole (fomepizole) (Lockley *et al.*, 2005), is also used to treat methanol and ethylene glycol poisonings.

The reduction of aldehydes and ketones to primary and secondary alcohols by carbonyl reductases has already been discussed (see the section “Carbonyl Reduction—AKRs and SDRs”). In contrast to ADH and ALDH, carbonyl reductases typically use NADPH as the source of reducing equivalents. Aldehydes, especially aromatic aldehydes, can also be oxidized by AO and xanthine oxidoreductase (XOR), which are discussed in the section “Molybdenum Hydroxylases (Molybdoenzymes).”

Dimeric Dihydrodiol Dehydrogenase As mentioned in the section “Carbonyl Reduction—AKRs and SDRs,” several members of the AKR superfamily are dihydrodiol dehydrogenases that oxidize the *trans*-dihydrodiols of various PAHs to the corresponding *ortho*-quinones, as shown in Fig. 6-10 (Penning, 1997; Burczynski and Penning, 2000). There is also a dihydrodiol dehydrogenase (gene symbol DHDH; completely unrelated to AKRs or SDRs) that encodes a dimeric enzyme that oxidizes *trans*-dihydrodiols of aromatic hydrocarbons to the corresponding catechols in a NADP⁺-dependent manner (Carbone *et al.*, 2008). The overall reaction catalyzed by dimeric dihydrodiol dehydrogenase is a 2-electron oxidation of one of the hydroxyl groups of a *trans*-dihydrodiol to an intermediate ketol, which rapidly enolizes to the catechol (Carbone *et al.*, 2008). It also activates naphthalene *trans*-dihydrodiol to 1,2-dihydroxynaphthalene, which rapidly auto-oxidizes to 1,2-naphthoquinone, a cytotoxic *ortho*-quinone that may be responsible for naphthalene-induced cataracts (Carbone *et al.*, 2008). Dimeric dihydrodiol dehydrogenase is not active toward hydroxysteroids, but it does oxidize several endogenous sugars, including D-glucose and D-xylose, and may therefore play a role in the metabolism of dietary sugars with subsequent generation of NADPH. Dimeric dihydrodiol dehydrogenase can also catalyze reductions in the presence of NADPH, such as the carbonyl reduction of methylglyoxal and 3-deoxyglucosone, nitrobenzaldehydes, and camphoroquinone (Carbone *et al.*, 2008). Dimeric dihydrodiol dehydrogenase can be inhibited by L-ascorbic and isoascorbic acids and also by 4-hydroxyphenylketones and 2,6-dihydroxyanthraquinone, and is inactivated by magnesium chloride and some phosphate salts (Carbone *et al.*, 2008). This enzyme was first characterized in rabbit liver, where it oxidizes benzene dihydrodiol to the genotoxic and immunotoxic catechol. It has also been isolated from pig, dog, and cynomolgus monkey (*Macaca fascicularis*). The purified enzyme is composed of identical subunits with molecular

weights of 32 to 36 kDa, and amino acid sequence in humans indicates that each subunit is composed of 335 amino acids (Carbone *et al.*, 2008). Dimeric dihydrodiol dehydrogenase is ubiquitously expressed in dogs and pigs, but only in the kidney of monkey, lens and intestine of rabbit, and apparently only the intestine of humans (Carbone *et al.*, 2008).

It should be noted that PAHs can be oxidized by CYP to an arene oxide, an electrophilic and potentially toxic metabolite that is detoxified by its conversion to a *trans*-dihydrodiol by epoxide hydrolase. By oxidizing the *trans*-dihydrodiol to an *ortho*-quinone, AKRs generate yet another potentially toxic metabolite. These roles of AKRs (which can act as monomeric dihydrodiol dehydrogenases) in the metabolism of PAHs are well known but the activity of dimeric dihydrodiol dehydrogenase toward the *trans*-dihydrodiols of PAHs has not yet been reported (Carbone *et al.*, 2008). In terms of their ability to cause oxidative stress and cellular toxicity, *ortho*-quinones can be considered equivalent to *para*-quinones, which were discussed earlier in the section “Quinone Reduction—NQO1 and NQO2.”

Molybdenum Hydroxylases (Molybdoenzymes) There are 5 human molybdenum-containing enzymes (molybdoenzymes), namely, AO (gene symbol AOX1), XOR (also known as XO or XD, gene symbol XDH), sulfite oxidase (gene symbol SUOX), and the more recently discovered “mitochondrial amidoxime-reducing component” (mARC-1 and -2; gene symbols MOSC1 and MOSC2) (Havemeyer *et al.*, 2011). AO and XOR are the 2 major molybdoenzymes that participate in the biotransformation of xenobiotics. The human mARC (consisting of mARC-1 and -2) is involved in the activation of amidoxime prodrugs and detoxication of some *N*-hydroxylated xenobiotics, as described in the section “Dehydroxylation—mARC, Cytochrome *b*₅, *b*₅ Reductase, and Aldehyde Oxidase.” Sulfite oxidase will not be described in detail here except that, as its name implies, the enzyme oxidizes sulfite, an irritating air pollutant, to sulfate, which is relatively innocuous, and is also required to metabolize the sulfur-containing amino acids cysteine and methionine in foods.

Genetic polymorphisms can affect all molybdoenzymes or individual enzymes. Homozygosity for nonfunctional forms of some of the genes involved in the synthesis of the active molybdenum cofactor (MoCo), namely, MOCS1, MOCS2, MOCOS, or GPHN, results in a complete lack of activity of all molybdoenzymes, and is clinically indistinguishable from isolated SUOX deficiency (Reiss and Hahnewald, 2010), a rare condition that gives rise to progressive neurological damage and death in early childhood (Reiss and Johnson, 2003; Feng *et al.*, 2007). Isolated XOR deficiency results in the classical type I xanthinuria, which can lead to xanthine stones (calculi) because of the inability to oxidize xanthine and hypoxanthine to uric acid, but it is not life-threatening (Reiss and Hahnewald, 2010). Although no isolated forms of AO deficiency have been described, type II xanthinuria results from a combined deficiency of XOR and AO as evidenced by the inability to oxidize both xanthine and hypoxanthine as well as allopurinol to oxypurinol. Certain polymorphisms in AO do appear to cause a decrease or complete loss of activity toward certain substrates, as discussed in the section “Aldehyde Oxidase” (Hartmann *et al.*, 2012). Not surprisingly, given its recent discovery, isolated mARC deficiency has not yet been described.

XOR and AO comprise the human members of the “XO family” of molybdoenzymes. Both enzymes are only active as homodimers, each with an ~145-kDa monomer consisting of an N-terminal region that binds 2 nonidentical iron-sulfur clusters of the [2Fe-2S] type, followed by an FAD-binding region and C-terminal domains

that bind the molybdenum center (Wahl *et al.*, 2010). In XOR, however, an additional NAD⁺ binding site is present. In XOR and AO, the molybdenum is ligated to an oxo ligand, a hydroxyl group, 2 dithiolene sulfurs, and a sulfido group (as shown in the upper left panel of Fig. 6-27). The molybdenum–sulfur bond is inserted through a posttranslational reaction catalyzed by MoCo sulfurase (gene symbol MOCOS), which substitutes one of the oxo groups of the MoCo with a sulfo double bond and is essential for the activity of these enzymes (Garattini *et al.*, 2008). In contrast, in sulfite oxidase (the only fully accepted human member of the “sulfite oxidase family” of molybdoenzymes), the molybdenum is coordinated by the 2 sulfurs on the pterin, 2 oxo ligands, and a protein-derived cysteinyl sulfur (Wahl *et al.*, 2010). Sulfite oxidase does not require posttranslational sulfuration of the MoCo to become active. The two 35 kDa human mARC enzymes may represent a separate family of molybdoenzymes in that they do not contain an FAD domain and may bind molybdenum in a manner different than either the XO or sulfite oxidase families. However, there is some evidence to suggest that the mARCs are in fact members of the human sulfite oxidase family of molybdoenzymes (Havemeyer *et al.*, 2011). In addition, the mARCs share significant sequence similarity with the C-terminal domain of MOCOS and appear to require cytochrome *b*₅, cytochrome *b*₃ reductase, and NADH for catalytic activity (Wahl *et al.*, 2010). Furthermore, whereas XOR, AO, and SUOX are localized in the cytosol, the 2 mARC proteins appear to be localized to the outer mitochondrial membrane (Havemeyer *et al.*, 2011).

The catalytic cycle for XOR and AO involves an interaction between the molybdenum center with a reducing substrate, which results in the reduction of the MoCo, after which reducing equivalents are transferred intramolecularly to the flavin cofactors (which act as electron sinks), with reoxidation occurring via the flavin moiety by molecular oxygen (in the case of AO and the XO form of XOR) or NAD⁺ (in the case of the XD form of XOR). Electrons are transferred from the MoCo to the flavin cofactor through the intermediacy of the iron–sulfur centers. During substrate oxidation, AO and XOR are reduced and then reoxidized by molecular oxygen; hence, they function as true oxidases. The oxygen incorporated into the xenobiotic is derived from water rather than oxygen, which distinguishes these oxidases from oxygenases. The main functional difference between AO and XOR is the ability of the latter to use both NAD⁺ (in its XD form) and molecular oxygen (in its XO form), as the final acceptors of the reducing equivalents (Garattini and Terao, 2011). Reduction of oxygen by the XO form of XOR leads to the formation of hydrogen peroxide or superoxide anion (in a substrate-dependent manner) as follows:

Additional details of the catalytic cycle are described in the section “Xanthine Oxidoreductase.” XOR and AO catalyze the oxidation of carbon atoms with a low electron density such as the electron-deficient sp²-hybridized carbon atom, double bonded to nitrogen in aromatic azaheterocycles (R₁-CH=N-R₂) or oxygen in various aldehydes (R₁-CH=O). In aromatic azaheterocycles (such as purines, pyrimidines, pteridines, quinolines, iminium ions, and diazanaphthalenes), oxidation by AO (and in most cases by XOR) occurs at the carbon with the lowest electron density, which is typically the α-carbon (next to the nitrogen) but in some cases the γ-carbon (2 carbons removed) (Strolin-Benedetti, 2011). This contrasts with oxidation by CYP, which generally catalyzes the oxidation of carbon atoms with a high electron density. For this reason, xenobiotics that are good substrates for molybdoenzymes

(nucleophilic oxidizing enzymes) tend to be poor substrates for CYP (an electrophilic oxidizing enzyme), and vice versa (Pryde *et al.*, 2010). AO and, to a lesser extent, XOR hydroxylate the carbonyl carbon in certain aldehydes and convert them to carboxylic acids (R-CHO → R-COOH). Both molybdoenzymes hydroxylate the α-carbon in aromatic azaheterocycles (R₁-CH=N-R₂) to form α-hydroxyimines (R₁-COH=N-R₂) that rapidly tautomerize to the corresponding lactam (R₁-CO-NH-R₂) (α-aminoketone). Certain aromatic aldehydes, such as tamoxifen aldehyde and benzaldehyde, are good substrates for AO and XOR, whereas aliphatic aldehydes tend to be poor substrates. Consequently, AO and XOR contribute negligibly to the metabolism of acetaldehyde under normal conditions. Some reactions catalyzed by AO and XOR are shown in Fig. 6-26. It should be noted that although AO and XOR tend to oxidize similar substrates, there are some differences in substrate specificity (eg, vanillin is rapidly oxidized by AO, but there is little contribution of XOR) (Strolin-Benedetti, 2011). An interesting difference between XOR and AO is their regioselective oxidation of the purine prodrug 6-deoxyacyclovir, which is oxidized by XOR in the 6-membered ring to form the active drug acyclovir (discussed below) but is oxidized by AO in the 5-membered ring to form the pharmacologically inactive metabolite 6-deoxy-8-hydroxyacyclovir (Testa and Krämer, 2008, 2010). In the case of nonaromatic azaheterocycles the preferred substrate is the protonated form (–CH=NH⁺) because this form lowers the electron density at the α-carbon. For this same reason, *N*-alkylation of aromatic azaheterocycles to form a quaternary (positively charged) nitrogen next to the α-carbon improves oxidation by AO (more so than by XOR), as in the case of *N*-methylnicotinamide. Under certain conditions, both enzymes can also catalyze the reduction of xenobiotics (Testa and Krämer, 2008, 2010). Examples of reductive reactions catalyzed by AO are shown in Fig. 6-23.

Xanthine Oxidoreductase XD and XO are 2 forms of the same cytosolic enzyme (XOR, gene symbol XDH) that differ in the electron acceptor used in the final step of catalysis. In the case of XD, the final electron acceptor is NAD⁺ (dehydrogenase activity), whereas in the case of XO the final electron acceptor is oxygen (oxidase activity). Although both XOR and AO are expressed in many tissues, the highest XOR expression in humans is found in the proximal intestine, liver, and lactating mammary glands (Strolin-Benedetti, 2011). XD is converted reversibly to XO by oxidation of sulfhydryl groups or irreversibly by proteolytic cleavage (Testa and Krämer, 2008, 2010). In humans, XOR is encoded by a single gene (ie, XDH). Under normal physiological conditions, XD is the predominant form of the enzyme found *in vivo*. However, during tissue processing, the dehydrogenase form tends to be converted to the oxidase form; hence, most *in vitro* studies are conducted with XO or a combination of XO and XD. The induction (upregulation) of XD and/or the conversion of XD to XO *in vivo* is thought to play an important role in ischemia–reperfusion injury, lipopolysaccharide (LPS)–mediated tissue injury, and alcohol-induced hepatotoxicity (Pacher *et al.*, 2006). During ischemia, XO levels increase because hypoxia induces XOR gene transcription, and because XD is converted to XO. During reperfusion, XO contributes to oxidative stress and lipid peroxidation because the oxidase activity of XO involves the reduction of molecular oxygen, which can lead to the formation of ROS of the type shown in Fig. 6-16. Similarly, treatment with LPS, a bacterial endotoxin that triggers an acute inflammatory response, increases XO activity both by inducing XOR transcription and by converting XD to XO. The associated increase in oxidative stress has been implicated in LPS-induced cytotoxicity. Ethanol facilitates the conversion of XD to XO, and the conversion

Figure 6-26. Examples of reactions catalyzed by the molybdoenzymes, xanthine oxidoreductase, and aldehyde oxidase.

of ethanol to acetaldehyde provides a substrate and, hence, a source of electrons for the reduction of oxygen. Hereafter, the 2 forms of the enzyme will be referred to as XOR.

Typical reactions catalyzed by XOR are shown in Fig. 6-26. XOR contributes significantly to the first-pass elimination of several purine derivatives (eg, 6-mercaptopurine and 2,6-dithiopurine), and limits the therapeutic effects of these cancer chemotherapeutic agents. In contrast, certain prodrugs are activated by XOR. For example, the antiviral prodrugs 6-deoxyacyclovir and 2'-fluoroarabino-dideoxypurine, which are relatively well absorbed after oral dosing, are oxidized by XOR to their respective active forms, acyclovir and 2'-fluoroarabino-dideoxyinosine, which are otherwise poorly absorbed (see Fig. 6-26). Furthermore,

XOR has been implicated in the bioactivation of mitomycin C and related antineoplastic drugs, although this bioactivation reaction is thought to be largely catalyzed by NQO1 (DT-diaphorase), as discussed previously in the section "Quinone Reduction—NQO1 and NQO2." Other xenobiotic substrates of XOR include 6-thioxanthine, methotrexate, and the benzylic aldehyde metabolite of tolbutamide (Chladek *et al.*, 1997; Testa and Krämer, 2008, 2010; Kudo *et al.*, 2010).

XOR catalyzes an important physiological reaction, namely, the sequential oxidation of hypoxanthine to xanthine and uric acid, as shown in Fig. 6-26 (Rajagopalan, 1980). By competing with hypoxanthine and xanthine for oxidation by XOR, allopurinol inhibits the formation of uric acid, making allopurinol a useful

Figure 6-27. Catalytic cycle of the molybdoenzyme xanthine oxidoreductase. Xanthine oxidoreductase is a molybdoenzyme with xanthine dehydrogenase (XD) and xanthine oxidase (XO) activities. During the final step of the catalytic cycle, the enzyme is reoxidized by transferring electrons to NAD^+ (in the case of XD) or oxygen (in the case of XO). The same mechanism of catalysis likely applies to aldehyde oxidase, although there is no dehydrogenase form of this molybdoenzyme.

drug in the treatment of gout (a complication of hyperuricemia). Allopurinol can also be used to evaluate the contribution of XOR to xenobiotic biotransformation *in vivo*. Like allopurinol, hydroxylated coumarin derivatives, such as umbelliferone (7-hydroxycoumarin) and esculetin (7,8-dihydroxycoumarin), are potent inhibitors of XOR. Allopurinol and other XOR inhibitors are being evaluated for the treatment of various types of ischemia–reperfusion and vascular injury that appear to be mediated, at least in part, by XOR (Pacher *et al.*, 2006).

Monomethylated xanthines are preferentially oxidized to the corresponding uric acid derivatives by XOR. In contrast, dimethylated and trimethylated xanthines, such as theophylline (1,3-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine), are oxidized to the corresponding uric acid derivatives primarily by CYP. Through 2 sequential *N*-demethylation reactions, CYP converts caffeine to 1-methylxanthine, which is converted by XOR to 1-methyluric acid. The urinary ratio of 1-methylxanthine to 1-methyluric acid provides an *in vivo* marker of XOR activity.

The mechanism of catalysis by molybdoenzymes depicted in Fig. 6-27 is based on studies of XOR by Okamoto *et al.* (2004), Amano *et al.* (2007), and Alfaro and Jones (2008). The molybdopterin active center of the enzyme consists of molybdenum (Mo) bound to the following groups: pterin cofactor, thioxo ($=\text{S}$), oxo ($=\text{O}$), and hydroxyl ($-\text{OH}$). For simplicity, this cofactor will be written as $\text{S}=\text{Mo}-\text{OH}$. The hydroxyl group ($\text{S}=\text{Mo}-\text{OH}$) is activated by a nearby glutamic acid residue in the enzyme to $\text{S}=\text{Mo}-\text{O}^-$, which initiates a concerted nucleophilic attack on the substrate at the electron-deficient carbon atom double bonded to the nitrogen ($\text{H}-\text{CR}_1=\text{N}-\text{R}_2$) with hydride transfer from the α -carbon to the thioxo group to form the intermediate ($\text{HS}-\text{Mo}-\text{O}-\text{CR}_1=\text{N}-\text{R}_2$). The oxygen bound to the α -carbon in the substrate (eg, xanthine) is replaced by oxygen from water to complete formation of product (eg, uric acid). The resting enzyme is restored by the removal of 2 reducing equivalents, which

may be transferred to NAD^+ (in the case of XD) or oxygen (in the case of XO), as shown in Fig. 6-27. In the XO mode, XOR (and AO, which exists only in the XO mode) can transfer both reducing equivalents to a single molecule of oxygen to produce hydrogen peroxide or it can transfer the 2 electrons to 2 molecules of oxygen to produce superoxide anion. In addition to the concerted mechanism described above, a stepwise mechanism involving a tetrahedral intermediate is also possible (Alfaro and Jones, 2008).

Aldehyde Oxidase The term AO is something of a misnomer, in that this enzyme does not solely act on aldehyde-containing substrates (see Table 6-7). AO is the second of 2 molybdoenzymes that play an important role in xenobiotic biotransformation, the other being XOR (discussed in the preceding section). Whereas XOR exists in 2 forms, a dehydrogenase form (XD) that relays electrons to NAD^+ and an oxidase form (XO) that relays electrons to molecular oxygen, AO exists only in the oxidase form because it lacks an NAD^+ binding site (Garattini and Terao, 2011). Another significant difference between these 2 molybdoenzymes is that high levels of XOR appear to be widely distributed throughout the body, whereas high levels of AO (or at least its mRNA) are found in the liver and adrenal gland, with somewhat less expression in the small and large intestines, ovary, prostate, proximal-, distal-, and collecting tubules of the kidney, the epithelia of trachea and bronchium, and the alveolar cells of the lung, with only detectable levels of transcript in the endocrine tissues, esophagus, pancreas, brain, and few other tissues, at least in humans (Pryde *et al.*, 2010; Garattini and Terao, 2011). The human AOX1 gene is complex with 35 exons, and exists as an active homodimer. There is also considerable interindividual variability in the levels of AO in humans, which may be due to genetic (as discussed further below) as well as environmental factors such as age, disease state (eg, cancer, inflammatory conditions leading to altered levels

Table 6-7

Substrates Associated with Oxidation by Aldehyde Oxidase

SUBSTRATE GROUPS	EXAMPLE SUBSTRATES
Aldehydes	Acetaldehyde, benzaldehyde, citalopram aldehyde, phenylacetaldehyde, pyridoxal, retinal, tamoxifen aldehyde, tolbutamide aldehyde, vanillin
Aromatic azaheterocycles	Phthalazines, cinchona alkaloids, quinazolines, carbazeran, chloroquinazolinone, famciclovir, 6-mercaptapurine, <i>N</i> -methyl-nicotinamide, <i>N</i> -methyl-phthalazinium, phenanthridine, 3-descladinosyl-11,12-dideoxy-6-omethyl-3-oxo-12,11-(oxycarbonyl-(1-(1 <i>R</i> -[1,8]naphthyridin-4-yl)-ethyl)azetidid-3-yl) imino)erythromycin A, 2,4-diaminopteridine, <i>N</i> -{ <i>trans</i> -4-[2-(6-cyano-3,4-dihydroisoquinolin-2(1 <i>H</i>)-yl)ethyl]cyclohexyl}quinoline-4-carboxamide (SB-277011), methotrexate, 6-thioxanthine, zebularine, 5-fluoro-pyrimidinone, 5-ethinylpyrimidinone, caffeine, 6-deoxyacyclovir, 8-hydroxy-6-deoxyacyclovir, allopurinol, pyrazinamide, <i>N</i> -[(20-dimethylamino)ethyl]acridine-4-carboxamide (DACA), 2-[4-(7-chloro-2-quinoxalinyloxyphenoxy)-propionic acid (XK-469), dibenzo[<i>b,f</i>]-1,4-oxazepine, briminodine, 3- <i>tert</i> -butyl-7-(5-methylisoxazol-3-yl)-2-(1-methyl-1 <i>H</i> -1,2,4-triazol-5-ylmethoxy)-pyrazolo[1,5- <i>d</i>][1,2,4]triazine (MRK-016), 6-(2,4-difluoro-phenoxy)-2-((<i>R</i>)-2-hydroxy-1-methyl-ethylamino)-8-((<i>S</i>)-2-hydroxy-propyl)-8 <i>H</i> -pyrido[2,3- <i>d</i>]pyrimidin-7-one (RO1), zaleplon
Iminium ions	Nicotine iminium ion, <i>N</i> -methyl-nicotinamide iminium ion, iminium ion of 3-methyl-5-[(2 <i>S</i>)-1-methyl-2-pyrrolidinyl]isoxazole (ABT-418), prolintane iminium ion, azapetine iminium ion

Data from Pryde *et al.* (2010) and Hartmann *et al.* (2012).

of various cytokines), smoking, and drug use (Pryde *et al.*, 2010). Apart from these differences, many of the features of XOR apply to AO, including subcellular location (cytosol), enzyme structure and cofactor composition, typical mechanism of catalysis, preference for oxidizing sp^2 -hybridized carbon atoms adjacent to the nitrogen atoms in nitrogen heterocycles, and its preference for oxidizing aromatic aldehydes over aliphatic aldehydes. Other AO substrate types include nitro- or nitroso-containing compounds as well as aldehyde or iminium ion intermediates formed by CYP, ADHs, or MAOs (Pryde *et al.*, 2010). Furthermore, AO also transfers electrons to molecular oxygen, which can generate ROS (eg, superoxide anion, which dismutates to hydrogen peroxide) and lead to oxidative stress and lipid peroxidation (Garattini and Terao, 2011). However, in contrast to XOR, the physiological functions of AO remain largely unknown, although endogenous compounds such as indole-3-acetate, retinaldehyde, retinoic acid, nicotinamide, and pyridoxal are substrates for AO (Garattini and Terao, 2011).

Many SNPs in the human AOX1 gene have been described in the NCBI dbSNP database (<http://www.ncbi.nlm.nih.gov/projects/SNP>). In a population of 180 Italian individuals, relatively frequent nonsense, synonymous, or missense SNPs in AO have been described, with a total of 51 SNPs identified, with 10 individuals being homozygous for a SNP (Hartmann *et al.*, 2012). Two of the SNPs resulted in a fast metabolizer phenotype (FMs; $N_{1135}S$, frequency = 2.9%, and $H_{1297}R$, frequency = 5.3%) and 1 in a PM phenotype (ie, $R_{921}H$, frequency = 0.3%). In addition, a relatively frequent nonsense mutation in exon 5 (Y_{126} stop, frequency = 0.026) was identified that results in a very short and nonfunctional 126-amino acid protein, but no subjects were homozygous for this loss-of-function mutation. An important point about these polymorphisms described so far is that the effects appear to be somewhat substrate-dependent based on the functional characterization of purified, heterologously expressed variants described above with the AO substrates benzaldehyde, phthalazine, phenanthridine, and chloroquinazolinone (Hartmann *et al.*, 2012).

Substrates for AO do not appear to correlate with any specific area of “chemical space” based on physicochemical properties, which have a wide variety of lipophilicity, polar surface area, polarity, and structure, in contrast to P450 substrates, for which

there is a high correlation between higher log *P* and P450-mediated metabolism as measured by microsomal stability in the presence of NADPH (see Table 6-7 for example substrates) (Pryde *et al.*, 2010). Therefore, although it has been assumed that, in general, xenobiotics that are good substrates for AO are poor substrates for CYP, and vice versa (Rettie and Fisher, 1999), there is some overlap, and structural motifs alone may be a better predictor of AO substrates (Pryde *et al.*, 2010). Naphthalene (with no nitrogen atoms) is oxidized by CYP, but not by AO, whereas the opposite is true of pteridine (1,3,5,8-tetraazaphthalene), which contains 4 nitrogen atoms. The intermediate structure, quinazolinone (1,3-diazaphthalene), is a substrate for both enzymes. This complementarity in substrate specificity reflects the opposing preference of the 2 enzymes for oxidizing carbon atoms; CYP prefers to oxidize carbon atoms with high electron density, whereas AO (and XOR) prefers to oxidize carbon atoms with low electron density. Because of their opposing mechanisms of action (electrophilic for CYP, nucleophilic for AO), the common practice in drug development of adding a fluorine atom to block a site of oxidation by CYP (to improve metabolic stability) can potentially increase the rate of metabolism by AO. In nearly all cases, oxidation of aromatic heterocycles by AO occurs at the α -carbon but occasionally, depending on ring structure, the γ -carbon (or even the β -carbon) has the lowest electron density and is the site of oxidation. Examples of γ -carbon (or β -carbon) oxidation by AO include *N*-methylnicotinamide, quinolone, cinnoline, and *N*-[(2'-dimethylamino)ethyl]acridine-4-carboxamide (DACA) (Schofield *et al.*, 2000; Testa and Krämer, 2008, 2010). In terms of its role in drug metabolism, it is reasonable to conclude that human AO does play—and will continue to play—a significant role in the oxidation of a wide range of structurally diverse nitrogen heterocyclic substrates (Pryde *et al.*, 2010).

As shown in Figs. 6-23 and 6-26, AO can oxidize a number of substituted pyrroles, pyridines, pyrimidines, purines, pteridines, and iminium ions (see Table 6-7 for additional examples) by the mechanism described for XOR in the previous section (Alfaro and Jones, 2008). AO can oxidize aldehydes to their corresponding carboxylic acids, but the enzyme shows a marked preference for aromatic aldehydes (eg, benzaldehyde, tamoxifen aldehyde). Consequently, AO contributes negligibly to the oxidation of aliphatic aldehydes, such

as acetaldehyde. Rodrigues (1994) found that, in a bank of human liver samples, AO activity toward *N*¹-methylnicotinamide varied more than 40-fold, whereas activity toward 6-methylpurine varied less than 3-fold. Although this suggests human liver cytosol contains 2 or more forms of AO, subsequent Southern blot analysis has provided evidence for only a single copy of the AO gene in humans (Terao *et al.*, 1998), although genomic analysis of chromosome 2q has revealed the presence of 2 nearby pseudogenes (Garattini and Terao, 2011). Species differences in the number of functional AOX genes are discussed further below.

The substrate specificity of AO differs among mammalian species, often leading to erroneous conclusions about the potential metabolic stability of certain drugs in humans, as detailed below. AO activity among animal species can vary depending on the particular substrate, but in general it is high in monkeys and humans, low in rats, and essentially absent in dogs (because the latter only express AOX3L1 and AOX4) (Garattini and Terao, 2011). These differences have been ascribed to the size of the active site (Pryde *et al.*, 2010). However, large differences in activity have also been found among individual strains of rats and mice (eg, high activity in Sea:SD rats and low in WKA/Sea rats; large differences between Sprague-Dawley and Wistar as well as between C129/C57 and CB57B1/6J mice) (Pryde *et al.*, 2010). Gender differences between rats and mice due to hormonal regulation further complicate attempts to extrapolate stability of AO substrates from toxicologically relevant species to humans (eg, 2- to 4-fold higher activity in male mice than in female) (Pryde *et al.*, 2010). Finally, whereas humans encode only a single functional AO (namely, AOX1; the others being transcribed pseudogenes, ie, AOX3P and 3L1P), mice and rats possess 4 functional AOX genes (namely, AOX1, 3, 4, and 3L1) (Garattini and Terao, 2011). Rhesus monkeys possess 2 functional AO (AOX3 and AOX3L1). In the mouse and monkey, AOX3L1 is expressed only in nasal mucosa (Garattini and Terao, 2011). A further complication is the observation of species differences in the relative roles of AO and XOR in xenobiotic biotransformation. For example, the 6-oxidation of antiviral deoxyguanine prodrugs is catalyzed exclusively in rats by XOR, but by AO in humans (Rettie and Fisher, 1999). Similarly, only human AO catalyzes the oxidation of 6-deoxypenciclovir to penciclovir (Strolin-Benedetti, 2011).

AO in human liver has proven to be rather unstable, which complicates an *in vitro* assessment of species differences in AO activity in frozen stocks of human liver cytosol (Rodrigues, 1994; Rettie and Fisher, 1999; Garattini and Terao, 2011). In addition, few human cell lines express functional AO (eg, HepG2 cells express the AOX1 transcript, but lack the functional enzyme) (Garattini and Terao, 2011). Fresh or cryopreserved human hepatocytes are therefore most likely to have relevant levels of AO activity.

AO is the second of 2 enzymes involved in the formation of cotinine, a major metabolite of nicotine excreted in the urine of cigarette smokers. The initial step in this reaction is the formation of a double bond (C=N) in the pyrrole ring, which produces nicotine $\Delta^{1,5}$ -iminium ion. Like nicotine, several other drugs are oxidized either sequentially or concomitantly by CYP and AO, including quinidine, azapetine, cyclophosphamide, carbazeran, and prolintane. Other drugs that are oxidized by AO include bromonidine, citalopram, proprionaldehyde, *O*⁶-benzylguanine, 6-mercaptopurine, metyrapone, quinine, pyrazinamide, methotrexate, vanillin, isovanillin, zaleplon, and famciclovir (an antiviral prodrug that is converted by AO to penciclovir) (for additional examples, see Table 6-7). Several pyrimidine derivatives are oxidized by AO, including 5-ethyl-2(1*H*)-pyrimidine, which is converted by AO to 5-ethinyluracil. Like sorivudine, 5-ethinyluracil is a metabolism-dependent (suicide) inactivator of DPD (see Fig. 6-17).

Raloxifene is an extraordinarily potent inhibitor of human AO (K_i values as low as 0.9 nM), whereas it is at least 3 orders of magnitude less potent in other species (Obach, 2004; Pryde *et al.*, 2010). Perphenazine and menadione are also potent inhibitors of AO (IC_{50} ~0.03 and ~0.2 μ M) and are often used together with allopurinol to discriminate between AO- and XOR-catalyzed reactions. The ability of proadifen to inhibit AO is noteworthy because this methadone analog, commonly known as SKF 525A, is widely used as a CYP inhibitor. Hydralazine is an irreversible (time-dependent) inhibitor of AO. Nitroso-imidacloprid has been characterized as a mechanism-based inhibitor of rabbit AO with a K_i value of 1.3 mM and k_{inact} of 0.35/min (Dick *et al.*, 2007). Several other inhibitors of AO have also been described, but raloxifene is probably the most useful for *in vitro* studies to evaluate the contribution of AO to the metabolism of a substrate (Pryde *et al.*, 2010). For instance, if a substrate that undergoes oxidative metabolism is found (1) to have higher *in vitro* turnover in human hepatocytes than in human liver microsomes, (2) is oxidized in human liver S9 or cytosol in the absence of NADPH, and (3) contains a structure amenable to oxidation by aldehyde oxidase, then raloxifene can be used to confirm involvement of aldehyde oxidase in the metabolism of the substrate (Pryde *et al.*, 2010).

Under certain conditions, AO and XOR can also catalyze the reduction of xenobiotics, including azo-reduction (eg, 4-dimethylaminoazobenzene), nitro-reduction (eg, 1-nitropyrene, imidacloprid and other nitroguanidines, nitromethylenes), *N*-oxide reduction (eg, *S*-(-)-nicotine-1'-*N*-oxide, imipramine *N*-oxide, and cyclobenzaprine *N*-oxide), nitrosamine reduction (eg, *N*-nitrosodiphenylamine), hydroxamic acid reduction (eg, *N*-hydroxy-2-acetylaminofluorene [NOH-AAF]), sulfoxide reduction (eg, sulindac; see Fig. 6-15, fenthion sulfoxide), quinone reduction (eg, diethylstilbestrol quinone), epoxide reduction (eg, B[a]P, 4,5-oxide), and heterocycle reduction (eg, ziprasidone and zonisamide) (Testa and Krämer, 2008, 2010; Pryde *et al.*, 2010). Oximes (C=NOH) can also be reduced by AO to the corresponding ketimines (C=NH), which may react nonenzymatically with water to produce the corresponding ketone or aldehyde (C=O) and ammonia (Testa and Krämer, 2008, 2010). The reduction of ziprasidone by AO is shown in Fig. 6-4, and examples of other reductive reactions catalyzed by AO are shown in Fig. 6-23. Xenobiotic reduction by AO *in vitro* requires anaerobic conditions or the presence of a reducing substrate, such as *N*¹-methylnicotinamide, 2-hydroxypyrimidine, or benzaldehyde. These "cosubstrates" reduce the enzyme, which in turn catalyzes azo-reduction, nitro-reduction, etc, by relaying electrons to xenobiotics (rather than molecular oxygen). These unusual requirements make it difficult to assess the degree to which AO functions as a reductive enzyme *in vivo*.

Amine Oxidases Human amine oxidases can be divided into 2 classes: (I) the familiar FAD-containing mitochondrial MAOs, MAO-A and -B (gene symbols MAOA and MAOB), as well as polyamine oxidase (PAO; gene symbol PAOX) and spermine oxidase (gene symbol SMOX); and (II) the copper-containing amine oxidases (CuAOs) that contain a tightly bound Cu^{II} and a quinone residue (typically 2,4,5-trihydroxyphenylalanine quinone [TPQ]) as the redox cofactor (Lageron, 2011). The latter class of human amine oxidases belongs to the larger class of so-called quinoproteins class, which are present in plants, animals, fungi, yeast, and bacteria. In humans the CuAOs include (1) the intracellular lysyl oxidase (gene symbol LOX), (2) diamine oxidase (DAO; also known as AOC1 [from "amine-oxidase, copper-containing"] and DAO [gene symbol ABP1, from "amiloride binding protein"]), and (3) the 2 known

so-called semicarbazide-sensitive copper-containing amine oxidases (or SSAOs), which are located in plasma and the plasma membranes of various tissues (gene symbols AOC2 for the retina-specific amine oxidase and AOC3 for the gene encoding what is probably the originally identified SSAO, which is the same as vascular adhesion protein [VAP1]) (Largeron, 2011).

Class I amine oxidases differ markedly from class II amine oxidases in their substrate specificity, but there is some overlap. For instance, dopamine and tyramine are good substrates for MAOs, SSAOs, and DAO, whereas benzylamine is a good substrate for both MAOs and the CuAOs (Largeron, 2011). Features of some of these enzymes will be discussed below, with examples of reactions catalyzed by MAO, DAO, and PAO shown in Fig. 6-28.

Class I Amine Oxidases: MAO-A and B, PAO, and SMOX MAO (gene symbols MAOA and MAOB), spermine oxidase (gene symbol SMOX), and PAO (gene symbol PAOX) are involved in the oxidative deamination of primary, secondary, and tertiary amines (Benedetti, 2001; Agostinelli *et al.*, 2004; Edmondson *et al.*, 2004). Substrates for these enzymes include several naturally occurring amines, such as the monoamine serotonin (5-hydroxytryptamine), and monoacetylated derivatives of the polyamines spermine and spermidine. A number of xenobiotics are substrates for these enzymes, particularly MAOs. Oxidative deamination of a primary amine produces ammonia and an aldehyde, whereas oxidative deamination of a secondary amine produces a primary amine and an aldehyde. (The products of the former reaction—that is, an aldehyde and ammonia—are those produced during the reductive biotransformation of certain oximes by AO, as described in the section “Aldehyde Oxidase.”) The aldehydes formed by MAO are usually oxidized further by other enzymes to the corresponding carboxylic acids, although in some cases they are reduced to alcohols.

MAO is located throughout the brain, and is present at high levels in the liver, kidney, intestine, heart, blood platelets, and blood vessels (but absent from erythrocytes) in the outer membrane of mitochondria (although some activity has been found in other cellular compartments, possibly because human liver microsomes prepared from frozen tissue are contaminated with the outer mitochondrial membrane) (Pearce *et al.*, 1996a; Testa and Krämer, 2008, 2010). Although MAOs are expressed in most tissues, there are some that express predominantly one form over the other. For example, MAO-A is the predominant form in human placenta, whereas MAO-B is the predominant form in human platelets, lymphocytes, and chromaffin cells (Strolin Benedetti *et al.*, 2007). MAO substrates include milacemide (Fig. 6-28), a dealkylated metabolite of propranolol (Fig. 6-28), primaquine, haloperidol, citalopram, sertraline, doxylamine, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP), β -phenylethylamine, tyramine, catecholamines (eg, dopamine, norepinephrine, epinephrine), tryptophan derivatives (tryptamine, serotonin), and tryptophan analogs known as triptans, which include the antimigraine drugs almotriptan, sumatriptan, zolmitriptan, and rizatriptan (Strolin Benedetti *et al.*, 2007; Testa and Krämer, 2008, 2010). In the case of the triptans, when a nitrogen exists in either a pyrrolidine or a piperidine ring, MAOs are not involved in their metabolism. Also, as a general rule, the introduction of a methyl group in the α -position relative to the nitrogen atom in what would otherwise be an MAO substrate renders it resistant to oxidative deamination by MAO (Strolin Benedetti *et al.*, 2007).

MAO-A preferentially oxidizes serotonin (5-hydroxytryptamine), norepinephrine, and the dealkylated metabolite of propranolol, and is preferentially inhibited by clorgyline, whereas MAO-B preferentially oxidizes β -phenylethylamine, benzylamine, and

citalopram, and is preferentially inhibited by L-deprenyl (selegiline) (Strolin Benedetti *et al.*, 2007). Species differences in the substrate specificity of MAO have been documented. For example, dopamine is oxidized by MAO-B in humans, but by MAO-A in rats, and by both enzymes in several other mammalian species. The distribution of MAO in the brain shows little species variation, with the highest concentration of MAO-A in the locus coeruleus, and the highest concentration of MAO-B in the raphe nuclei. MAO-A is expressed predominantly in catecholaminergic neurons, whereas MAO-B is expressed largely in serotonergic and histaminergic neurons and glial cells. The distribution of MAO throughout the brain does not always parallel that of its substrates. For example, serotonin is preferentially oxidized by MAO-A, but MAO-A is not found in serotonergic neurons.

The mechanism of catalysis by MAO is illustrated as follows:

The substrate is oxidized by the enzyme, which itself is reduced ($\text{FAD} \rightarrow \text{FADH}_2$). The oxygen incorporated into the substrate is derived from water, not molecular oxygen; hence, the enzyme functions as a true oxidase. The catalytic cycle is completed by reoxidation of the reduced enzyme ($\text{FADH}_2 \rightarrow \text{FAD}$) by oxygen, which generates hydrogen peroxide (which may be a cause of oxidative stress). The initial step in the catalytic cycle is abstraction of hydrogen from the α -carbon adjacent to the nitrogen atom; hence, the oxidative deamination of xenobiotics by MAO is generally blocked by substitution of the α -carbon. For example, amphetamine and other phenylethylamine derivatives carrying a methyl group on the α -carbon atom are not oxidized well by MAO. (Amphetamines can undergo oxidative deamination, but the reaction is catalyzed by CYP.) The abstraction of hydrogen from the α -carbon adjacent to the nitrogen atom can occur stereospecifically; therefore, only one enantiomer of an α -substituted compound may be oxidized by MAO. For example, whereas MAO-B catalyzes the oxidative deamination of both *R*- and *S*- β -phenylethylamine, only the *R*-enantiomer is a substrate for MAO-A. The oxidative deamination of the dealkylated metabolite of propranolol is catalyzed stereoselectively by MAO-A, although in this case the preferred substrate is the *S*-enantiomer (which has the same absolute configuration as the *R*-enantiomer of β -phenylethylamine) (Benedetti and Dostert, 1994).

Clorgyline and L-deprenyl (selegiline) are metabolism-dependent inhibitors (ie, mechanism-based or suicide inactivators) of MAO-A and MAO-B, respectively. Both enzymes are irreversibly inhibited by phenelzine, a hydrazine that can be oxidized either by abstraction of hydrogen from the α -carbon atom, which leads to oxidative deamination with formation of benzaldehyde and benzoic acid, or by abstraction of hydrogen from the terminal nitrogen atom, which leads to formation of phenylethyldiazene and covalent modification of the enzyme, as shown in Fig. 6-28.

MAO has received considerable attention for its role in the activation of MPTP to a neurotoxin that causes symptoms characteristic of Parkinson disease in humans and monkeys but not rodents (Gerlach *et al.*, 1991). In 1983, Parkinsonism was observed in young individuals who, in attempting to synthesize and use a narcotic drug related to meperidine (Demerol®), instead synthesized and self-administered MPTP, which causes selective destruction of dopaminergic neurons in the substantia nigra. MPTP crosses the blood-brain barrier, where it is oxidized by MAO in the astrocytes (a type of glial cell) to 1-methyl-4-phenyl-2,3-dihydropyridine

Figure 6-28. Examples of reactions catalyzed by selected amine oxidases. Note that phenelzine is a metabolism-dependent (mechanism-based) inhibitor of MAO-A and MAO-B.

Figure 6-29. Activation of 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) to the neurotoxic metabolite, 1-methyl-4-phenylpyridine (MPP⁺), by monoamine oxidase B. The toxic pyridinium metabolite, MPP⁺, is structurally similar to the herbicide paraquat MPDP⁺, 1-methyl-4-phenyl-2,3-dihydropyridine.

(MPDP⁺), which in turn autoxidizes to the neurotoxic metabolite, 1-methyl-4-phenylpyridine (MPP⁺), as shown in Fig. 6-29. Because it is transported by the dopamine transporter, MPP⁺ concentrates in dopaminergic neurons, where it impairs mitochondrial respiration. The neurotoxic effects of MPTP can be blocked with pargyline (an inhibitor of both MAO-A and MAO-B) and by L-deprenyl (a selective inhibitor of MAO-B) but not by clorgyline (a selective inhibitor of MAO-A). This suggests that the activation of MPTP to its neurotoxic metabolite is catalyzed predominantly by MAO-B. This interpretation is consistent with the finding that MAO-B knockout mice (ie, transgenic mice that lack MAO-B) do not sustain damage to the dopaminergic terminals of nigrostriatal neurons after MPTP treatment (Shih *et al.*, 1999; Quinn *et al.*, 2007).

Both genetic and environmental factors appear to play important roles in the etiology of Parkinson disease. Apart from MPTP, Parkinsonogenic neurotoxins to which humans are exposed have not been identified unequivocally; hence, the environmental factors that cause Parkinson disease remain to be identified. It is interesting that the bipyridyl herbicide, paraquat, is similar in structure to the toxic metabolite of MPTP, as shown in Fig. 6-29. Some epidemiological studies have shown a positive correlation between herbicide exposure and the incidence of Parkinsonism in some but not all rural communities. Haloperidol can also be converted to a potentially neurotoxic pyridinium metabolite (Subramanyam *et al.*, 1991).

MAO-B may be among the genetic factors that affect susceptibility to Parkinson disease. MAO-B activity in the human brain increases with aging, perhaps due to a proliferation of glial cells. It has been proposed that increased oxidation of dopamine by MAO-B in the elderly may lead to a loss of dopaminergic neurons in the substantia nigra, which underlies Parkinson disease. Such damage may be caused by the oxidative stress associated with the oxidative deamination of dopamine by MAO-B. In support of this proposal, patients with Parkinson disease have elevated MAO-B activity in the substantia nigra, and the MAO-B inhibitors L-deprenyl (selegiline), lazabemide, and rasagiline provide some symptomatic relief and can delay the progression of symptoms and need for levodopa (Sano *et al.*, 1997; Löhle and Reichmann, 2011). Furthermore, there are allelic variants of MAO-B, some of

which (such as alleles 1, A, B4, and G) appear to be associated with an increased risk of developing Parkinson disease, especially in women (Shih *et al.*, 1999; Kang *et al.*, 2006). No such association has been found between Parkinson disease and MAO-A gene polymorphisms (Williams-Gray *et al.*, 2009). Cigarette smoking, which carries a number of health risks, nevertheless provides some protection against Parkinson disease (Gorell *et al.*, 1999; Gu *et al.*, 2010). Although the mechanism of protection remains to be determined, it is interesting to note that cigarette smokers are known to have decreased levels of MAO-B (and MAO-A) (Shih *et al.*, 1999), the degree of which is proportional to cigarette usage (ie, it is dose related) (Whitfield *et al.*, 2000).

MAO-A knockout mice have elevated brain levels of serotonin and a distinct behavioral syndrome, including enhanced aggression in adult males. The enhanced aggressive behavior exhibited by MAO-A knockout mice is consistent with the abnormal aggressive behavior in individuals who lack MAO-A activity due to a point mutation in the MAO-A gene (Shih *et al.*, 1999). Other polymorphisms in the MAO-A gene appear to be risk factors for alcoholism among Euro-Americans and Han Chinese (Shih *et al.*, 1999). MAO-B may also be a factor in alcoholism inasmuch as alcoholics (especially male Type 2 alcoholics) tend to have lower MAO activity in platelets, which only contain MAO-B. However, MAO-B activity is not lower in alcoholics when cigarette smoking status is taken into account, which suggests that MAO-B activity tends to be lower in alcoholics because smoking and alcohol dependence are strongly associated with each other (Whitfield *et al.*, 2000).

Although not present in mitochondria, the PAO, PAOX (approved name: "polyamine oxidase [exo-N4-amino]"), and SMOX (approved name: "spermine oxidase") resemble MAO in their cofactor requirement and basic mechanism of action. These enzymes use oxygen as an electron acceptor, which results in the production of hydrogen peroxide. However, spermine and spermidine are first acetylated by spermidine/spermine N¹-acetyltransferases (gene symbols SAT1 and 2), and subsequently oxidized by PAOX, which produces not only hydrogen peroxide but also 3-acetamidopropanal (Hakkinen *et al.*, 2010). SMOX has very different substrate specificity, preferring nonacetylated polyamines (but

not spermidine). The polyamines, spermine, spermidine, and the diamine precursor, putrescine (discussed below), are ubiquitous in mammalian cells. The intracellular levels of these amines are strictly controlled by several enzymes (including PAOX and SMOX) as well as various transporters (Hakkinen *et al.*, 2010). Dysregulation of polyamine metabolism is associated with cancer and other diseases. Because of differences in polyamine regulation in various parasites, several xenobiotic polyamine synthesis inhibitors or substrates have been investigated as antiparasitic, chemopreventive, or chemotherapeutic drugs, including *N*-alkylated polyamine analogs such as diethylnorspermine, as well as some *N*-benzyl-substituted polyamines (Hakkinen *et al.*, 2010).

The MAO inhibitor pargyline also inhibits PAOX. The anti-convulsant milacemide is one of the few xenobiotic substrates for PAOX (the structure of which is unrelated to polyamines), although it is also a substrate for MAO (Fig. 6-28) (Strolin Benedetti *et al.*, 1992). By converting milacemide to glycine (via glycinamide), MAO plays an important role in the anticonvulsant therapy with milacemide (Benedetti and Dostert, 1994).

Class II Amine Oxidases (CuAOs): SSAOs, DAO, and LOX The term SSAO is confusing because the term has been previously used to refer only to amine oxidases that are active only toward primary amines, although this has not been proven, and several publications that mention SSAOs actually describe DAO. There are at least 3 types of SSAOs (Largergeron, 2011). The first (which probably includes the original SSAO) has the recommended name PrAOs, for “primary amine oxidases,” and includes gene symbols AOC2 and AOC3, the latter of which is probably the originally identified SSAO. The second SSAO is DAO (represented by AOC1; gene symbol ABP1, for “amiloride-binding protein”). A third type of SSAO is lysyl oxidase (LOX) (Largergeron, 2011). All of these enzymes are CuAOs. In general, the SSAOs (ie, PrAOs) do oxidize primary monoamines and have little or no activity toward diamines. DAO (ABP1) oxidizes both diamines such as histamine and some primary amines. Neither DAO nor SSAOs have activity toward secondary and tertiary amines (Largergeron, 2011). These PrAOs can be either soluble or membrane associated and are expressed in the liver, lung, lymph nodes, small intestine, and blood plasma (Testa and Krämer, 2008, 2010). The PrAO/SSAO known as AOC3 is a 180 kDa dimeric endothelial transmembrane glycoprotein that mediates leukocyte extravasation, for which reason it is widely known as the “vascular adhesion protein 1” [VAP1] (Kaitaniemi *et al.*, 2009).

SSAOs/PrAOs catalyze fundamentally the same reaction catalyzed by MAO (Kaitaniemi *et al.*, 2009):

The endogenous roles of the CuAOs include regulating levels of endogenous and exogenous levels of primary monoamines and polyamines by catalyzing their oxidative deamination (eg, methylamine, putrescine, and cadaverine [and specific lysine residues of extracellular matrix proteins in the case of LOX]), which produces an aldehyde, hydrogen peroxide, and ammonia (Yraola *et al.*, 2009; Largergeron, 2011). Because all of the latter species are potentially cytotoxic, these metabolic pathways can activate endobiotics and xenobiotics. The activity of plasma CuAOs is generally increased in various disease states, including Alzheimer disease, congestive heart failure, cirrhosis, Type 1 and 2 diabetes, atherosclerosis, and other inflammatory conditions, which leads to the overproduction of toxic species, especially aldehydes and hydrogen peroxide, and may further contribute to the disease process (Largergeron, 2011).

Although CuAOs do not play a large role in xenobiotic oxidation, there is some evidence for the involvement of SSAOs

in the oxidative deamination of a few xenobiotics, including allylamine, primaquine, mescaline, amlodipine, and amifostine (Testa and Krämer, 2008, 2010; Largergeron, 2011). The calcium channel blocker amlodipine is first oxidized (mainly by CYP3A4) to dehydroamlodipine, with subsequent deamination to an aldehyde (consistent with the action of an SSAO) and finally oxidation to the corresponding carboxylic acid by an ALDH and/or AO (Largergeron, 2011). Amifostine is a thiophosphate prodrug used as a cytoprotective adjuvant used in cancer chemotherapy and radiotherapy; it is rapidly converted to 2-[3-aminopropylamino] ethanethiol by alkaline phosphatase followed by oxidative deamination catalyzed by one or more CuAOs to an aldehyde that spontaneously decomposes to acrolein and cysteamine (Largergeron, 2011). Benzylamine (and several analogs) may be used in vitro as a substrate for SSAOs (Yraola *et al.*, 2009). MAO-B can also catalyze the deamination of benzylamine, but MAO-B acts by removal of the *pro-R* H-atom, whereas SSAOs act by removal of the *pro-S* H-atom (Testa and Krämer, 2008, 2010). There also appear to be some substrate selectivity between the individual SSAOs, AOC2 and 3, in that the preferred in vitro substrates of AOC2 (highly expressed in the retina) include 2-phenylethylamine, tryptamine, and tyramine, rather than the benzylamines and methylamine, which appear to be the preferred substrates for AOC3 (Kaitaniemi *et al.*, 2009).

DAO is a cytosolic, copper-containing, pyridoxal phosphate-dependent enzyme that is highly expressed in lung, liver, kidney, intestine, and placenta, among other tissues, for which 2 crystal structures have been described (McGrath *et al.*, 2010). It is located in the extracellular space (secreted form) or in the endoplasmic reticulum (Testa and Krämer, 2008, 2010). Its preferred substrates include histamine and simple alkyl diamines with a 4- or 5-carbon chain length such as putrescine (1,4-diaminobutane) and cadaverine (1,5-diaminopentane) (McGrath *et al.*, 2010). Diamines with carbon chains longer than 9 are not substrates for DAO, although they can be oxidized by MAO. DAO or a similar enzyme is present in cardiovascular tissue and appears to be responsible for the cardiotoxic effects of allylamine, which is converted by oxidative deamination to acrolein. Although histamine is a substrate for DAO (which catalyzes oxidative deamination of the primary amine to imidazole acetaldehyde by the secreted DAO) (McGrath *et al.*, 2010), there is little DAO in brain (nor is there a receptor-mediated uptake system for histamine, in contrast to other neurotransmitters). For this reason, the major pathway of histamine metabolism in the brain is by methylation (see the section “Methylation”).

Aromatization The conversion of MPTP to MPP⁺ (Fig. 6-29) is an example of a xenobiotic whose oxidation involves the introduction of multiple double bonds to achieve some semblance of aromaticity (in this case, formation of a pyridinium ion). Aromatization of xenobiotics is an unusual reaction, but some examples have been documented. A mitochondrial enzyme in guinea pig and rabbit liver can oxidize several cyclohexane derivatives to the corresponding aromatic hydrocarbon, as shown in Fig. 6-30 for the aromatization of cyclohexane carboxylic acid (hexahydrobenzoic acid) to benzoic acid. Mitochondria from rat liver are less active, and those from cat, mouse, dog, monkey, and human are inactive (Mitoma *et al.*, 1958). The reaction requires magnesium, CoA, oxygen, and ATP. The first step is the formation of hexahydrobenzoyl-CoA, which is then dehydrogenated to the aromatic product. Glycine stimulates the reaction, probably by removing benzoic acid through conjugation to form hippuric acid. The conversion of androgens to estrogens involves aromatization of the A-ring of the steroid nucleus. This reaction is catalyzed by CYP19A1, one of the CYP enzymes involved in steroidogenesis. The major substrate of CYP19A1 is

Figure 6-30. Aromatization of cyclohexane carboxylic acid, a reaction catalyzed by rabbit and guinea pig liver mitochondria.

androstenedione, which is converted to estrone by 3 successive oxidation steps (Kuhl and Wiegratz, 2007). Gut microflora can catalyze aromatization reactions, as shown in Fig. 6-1 for the conversion of quinic acid to benzoic acid.

Evidence for the apparent aromatization of a few xenobiotics by other P450 enzyme has also been described. For instance, 19-nortestosterone derivatives can be converted to aromatic metabolites, namely, ethinylestradiol (from norethisterone and norethynodrel) and 7 α -methyl ethinylestradiol (from tibolone) (Kuhl and Wiegratz, 2007). Formation of these A-ring aromatized steroids occurs in the liver, which does not express the steroidogenic enzyme CYP19A1 (aromatase). In addition, indoline (and some derivatives) is aromatized to indole in human liver microsomes, and mainly by recombinant human CYP3A4 (as well as CYP1A2, 2B6, 2C19, 2D6, and 2E1) by a dehydrogenation pathway (Sun *et al.*, 2007). The aromatization mechanism involves two one-electron oxidations, which is different from that catalyzed by CYP19A1, which catalyzes 2 sequential carbon oxidations followed by cleavage of a carbon-carbon bond (Sun *et al.*, 2007). The indoline-containing diuretic, indapamide, is also dehydrogenated to the aromatic indole by CYP3A4 (Sun *et al.*, 2009). This type of dehydrogenation can lead to P450 inactivation, as exemplified by the mechanism-based inhibition of CYP3A4 by the 3-alkylindole-containing TNF α inhibitor, SPD-304, which forms an electrophilic 3-methylenindolenine (Sun and Yost, 2008).

Peroxidase-Dependent Cooxidation The oxidative biotransformation of xenobiotics generally requires the reduced pyridine nucleotide cofactors, NADPH and NADH, although oxidation by AO and MAO is a notable exception. Another exception

is xenobiotic biotransformation by peroxidases, which are heme-containing enzymes that couple the reduction of hydrogen peroxide (or a lipid hydroperoxide) to the one-electron oxidation of other substrates (O'Brien, 2000; Tafazoli and O'Brien, 2005). Several different peroxidases catalyze the biotransformation of xenobiotics (in addition to performing important physiological functions), and these enzymes occur in a variety of tissues and cell types. Peroxidases do not play an important role in the first-pass metabolism or clearance of drugs and most other xenobiotics because their contribution is usually negligible compared with CYP and other oxidative enzymes. However, peroxidases do play an important role in xenobiotic toxicity, especially the activation of drugs associated with idiosyncratic hepatotoxicity, blood dyscrasias (eg, agranulocytosis, neutropenia, aplastic anemia, and thrombocytopenia), and skin rashes, and the activation of xenobiotics (including the activation of proximate carcinogens to ultimate carcinogens) in skin, bladder, bone marrow, and various other extrahepatic tissues. As shown in Fig. 6-2, peroxidases form reactive intermediates by converting nitrogen- and sulfur-containing xenobiotics to heteroatom-centered radicals (Tang and Lu, 2010; Walsh and Miwa, 2011).

In humans, the family of peroxidases includes myeloperoxidase (gene symbol MPO), eosinophil peroxidase (EPO; gene symbol EPX), lactoperoxidase (gene symbol LPO), thyroid peroxidase (gene symbol TPO), catalase, 2 forms of prostaglandin H synthase (also known as PHS1 and 2 or cyclooxygenase-1 [COX-1] and COX-2; gene symbols PTGS1 and 2), as well as the selenium-containing glutathione peroxidases (gene symbols GPX1-8). Some basic features of these peroxidases are summarized in Table 6-8.

Table 6-8

Characteristics of Some Human Peroxidases

PEROXIDASES	CELLULAR LOCATION	SUBCELLULAR LOCATION	HOMOLOGY WITH MPO
Myeloperoxidase (MPO)	Neutrophils, leukocytes	Lysosomes (human milk)	100%
Eosinophil peroxidase (EPO)	Eosinophils	Lysosomes	70%
Lactoperoxidase (LPO)	Mammary duct epithelial cells	Saliva, tears (bovine milk)	61%
Thyroid peroxidase (TPO)	Thyroid follicular cells	Microsomes, Golgi	47%
Prostaglandin-H synthase			
PHS1 (COX-1)*	Numerous extrahepatic tissues	Microsomes	
PHS2 (COX-2)*	Inflammatory cells	Microsomes	

Data from O'Brien (2000).

*There are 2 forms of prostaglandin H synthase, PHS1 and PHS2; they are the peroxidase component of the bifunctional enzymes known as COX-1 and COX-2 (gene symbols PTGS1 and PTGS2), respectively.

These peroxidases all have physiological functions: MPO, EPO, and LPO are lysosomal enzymes present in neutrophils, eosinophils, and secretory cells of exocrine glands, respectively. During infection, MPO and EPO are released into phagocytic vacuoles (granules) and into the plasma, whereas LPO is released into saliva and tears, where they kill microorganisms and thereby provide protection against infectious agents such as bacteria and parasites. (Peroxidases are also present in milk: LPO is the predominant peroxidase in cow's milk, whereas MPO is the predominant peroxidase in human milk.) The hydrogen peroxide required by MPO and EPO is produced by a membrane-bound NADPH oxidase that is activated by the presence of infectious agents. Unlike MPO, EPO, and LPO, which are soluble enzymes, TPO is a membrane-bound peroxidase located on the apical membrane of thyroid follicular cells; it catalyzes the iodination of tyrosine residues and the oxidative coupling of di-iodinated and monoiodinated tyrosine residues in thyroglobulin to form T3- and thyroxine (T4)-bound thyroglobulin, from which thyroid hormones are released. An NAD(P)H-oxidase known as p138 TOX (gene symbol DUOX2), which is also localized on the apical plasma membrane, produces the hydrogen peroxide required by TPO to synthesize thyroid hormones. PHS1 and PHS2 are the peroxidase component of COX-1 and COX-2; they are enzymes that convert arachidonic acid (and closely related fatty acids) to a variety of eicosanoids (prostaglandins, leukotrienes, thromboxane, and prostacyclin). In contrast to the other peroxidases, PHS1 and PHS2 do not require a source of hydrogen peroxide (although they can use it); hence, their activity is not dependent on an H_2O_2 -generating NAD(P)H-oxidase. Catalase is also a peroxidase. This peroxisomal enzyme catalyzes the disproportionation of hydrogen peroxide to water and oxygen ($2H_2O_2 \rightarrow 2H_2O + O_2$). At low concentrations of hydrogen peroxide, catalase can catalyze the oxidation of ethanol (see Fig. 6-25) and various other small molecules. GPXs are a family of selenium-containing enzymes that also detoxify hydrogen peroxide (and lipid hydroperoxides) by reducing it to water, which is associated with the formation of oxidized GSH as follows:

In mammalian peroxidases (in contrast to plant peroxidases), the heme prosthetic group is covalently attached to the enzyme. Iron is bound to 4 pyrrole nitrogen atoms with the nitrogen on the imidazole ring of histidine serving as the usual fifth ligand. The sixth coordination position is vacant so that peroxidases can interact with hydrogen peroxide (or other hydroperoxides), just as the sixth coordinate position of hemoglobin and myoglobin (both of which have low peroxidase activity) is available to bind molecular oxygen (Tafazoli and O'Brien, 2005). The oxidation of a xenobiotic ($X \rightarrow \text{XO}$ or $2\text{XH} \rightarrow 2\text{X}^{\bullet} + \text{H}_2\text{O}$) by peroxidase involves the conversion of hydrogen peroxide to water or the conversion of a hydroperoxide to the corresponding alcohol ($\text{ROOH} \rightarrow \text{ROH}$), during which the peroxidase (Fe^{III}) is converted to spectrophotometrically distinct states known as compound I and compound II, shown as follows for the conversion of a xenobiotic phenol (XOH) to the corresponding phenoxyl radical (XO^{\bullet}) (Tafazoli and O'Brien, 2005):

In this example, the hydroperoxide is converted to the corresponding alcohol ($\text{ROOH} \rightarrow \text{ROH}$), and the peroxy oxygen atom is reduced to water (H_2O) by the one-electron oxidation of 2 molecules of xenobiotic (XOH) to produce 2 xenobiotic radicals (XO^{\bullet}). In some cases, the oxygen from the hydroperoxide is incorporated

into the xenobiotic itself ($\text{XH} \rightarrow \text{XOH}$). Examples of each reaction are given later in this section. The conversion of ROOH to ROH involves the release of an oxygen atom that coordinates with the heme iron (initially in the ferric or Fe^{III} state). This iron-bound oxygen formally contains only 6 (instead of 8) valence electrons, making it a powerful oxidizing species. One electron is removed from the iron to produce $\text{Fe}^{\text{IV}}=\text{O}$, and a second electron is removed from the tetrapyrrole ring to produce a π -porphyrin cation radical ($\text{Por}^{\bullet+}$), which corresponds to compound I ($\text{Fe}^{\text{IV}}=\text{O}-\text{Por}^{\bullet+}$). The transfer of an electron from a xenobiotic ($\text{XOH} \rightarrow \text{XO}^{\bullet} + \text{H}^{\dagger}$) to the porphyrin cation radical produces compound II ($\text{Fe}^{\text{IV}}=\text{O}-\text{Por}$). In some cases, such as PHS, the electron donated to the initial $\text{Fe}=\text{O}$ complex comes directly or indirectly from an amino acid rather than the tetrapyrrole ring, and this accounts in part for some of the differences among the various peroxidases (such as the ability of TPO to catalyze the iodination of tyrosine residues and the subsequent formation of thyroid hormones).

Although peroxidases are renowned for catalyzing one-electron oxidation reactions, they can catalyze the 2-electron oxidation of iodide (I^-) to hypoiodous acid (HOI) and iodine which, in the case of TPO, is important for the synthesis of thyroid hormones:

MPO, EPO, and LPO can all oxidize the pseudohalide thiocyanate (SCN^-) faster than iodide, which in turn is oxidized faster than bromide, which is oxidized much faster than chloride. In fact, MPO is the only peroxidase with appreciable ability to oxidize chloride to hypochlorous acid (HOCl). There is an inverse relationship between the rate of conversion of halides to hypohalous acids and their physiological plasma concentrations: chloride = 100 to 140 mM, bromide = 20 to 100 μM , and iodide = 0.1 to 0.5 μM . Consequently, the relatively low rate of chloride oxidation is offset by the high levels of chloride such that about half (20%–70%) of the hydrogen peroxide produced by activated neutrophils is converted to HOCl, which reacts with GSH, proteins, thiols, amines, unsaturated fatty acids, and cholesterol, all of which disrupt cell membranes and lead to cell lysis and death (of both infectious organisms and host cells). Formation of HOCl by MPO is important not only from a physiological perspective but also from a drug metabolism and toxicity perspective, as discussed later in this section. The preferred "halide" substrate for MPO is thiocyanate, which is present in plasma at concentrations ranging from 20 to 120 μM , which is sufficiently high that oxidation of thiocyanate consumes the other half of the hydrogen peroxide produced by activated neutrophils. Whereas MPO oxidizes chloride to HOCl, which is cytotoxic, it oxidizes thiocyanate to thiocyanogen (SCN_2), which rapidly hydrolyzes to hypothiocyanic acid (HOSCN). HOSCN is much less reactive and cytotoxic than HOCl, such that the oxidation of thiocyanate by peroxidases is a mechanism to remove hydrogen peroxide without forming HOCl. This represents an important mechanism of hydrogen peroxide detoxication in saliva, which contains low levels of catalase but high levels (1–5 mM) of thiocyanate, and in the stomach, where the levels of thiocyanate in parietal cells are 3 times greater than plasma levels, which allows gastric peroxidase to inactivate hydrogen peroxide that otherwise stimulates gastric acid secretion by stimulating histamine release from mast cells. Inactivation of gastric peroxidase by aspirin, dexamethasone, indomethacin, or methimazole can result in gastric ulceration due to impaired detoxication of hydrogen peroxide and impaired synthesis of cytoprotective prostaglandins (O'Brien, 2000).

MPO and EPO can be distinguished by (1) their cellular distribution (neutrophils/leukocytes vs eosinophils); (2) their ability to oxidize halides (MPO is better than EPO at converting chloride to HOCl, whereas EPO is better than MPO at converting bromide to hypobromous acid), and (3) their sensitivity to inhibitors (MPO is more sensitive to the inhibitory effect of cyanide over azide, whereas the opposite is true of EPO).

The level of EPO (or a related peroxidase) in uterine epithelial cells is regulated by estrogen; uterine peroxidase activity is inducible several hundred-fold by estrogenic steroids, including the synthetic estrogens diethylstilbestrol and tamoxifen. The level of TPO in thyroid follicular cells is regulated by TSH. The enzyme is inactivated by a variety of ethylenethiourea drugs, such as propylthiouracil and methimazole (which is used as an antithyroid drug in patients with Graves disease), as well as a number of naturally occurring flavonoid/resorcinol compounds that also have antithyroid effects. By inactivating TPO and impairing thyroid hormone synthesis, these chemicals trigger a large and prolonged increase in TSH that in rodents (but apparently not in humans) can result in thyroid follicular cell tumor formation.

MPO is an abundant enzyme in granulocytes, where it accounts for 5% of the dry weight. It can be used as a diagnostic marker to differentiate myeloid leukemia from lymphoid leukemia. MPO is one of the peroxidases implicated in the formation of reactive metabolites of drugs that cause idiosyncratic agranulocytosis (or other blood dyscrasias), including clozapine, aminopyrine, vesnarinone, propylthiouracil, dapsone, remoxipride, sulfonamides, procainamide, amodiaquine, and ticlopidine (Liu and Utrecht, 2000; O'Brien, 2000; Tafazoli and O'Brien, 2005; Testa and Krämer, 2008, 2010). The nitro-reduced metabolite of tolcapone can be converted to a reactive *ortho*-quinoneimine by MPO and potentially lead to hepatotoxicity (Testa and Krämer, 2008, 2010). Many of these drugs are aromatic amines, and both MPO and PHS have also been implicated in the activation of several carcinogenic aromatic amines, such as benzidine, methylaminoazobenzene, and aminofluorene. Furthermore, inactivating polymorphisms in MPO (such as MPO-463A) appear to afford protection against both the activation of aromatic amines and PAH in tobacco smoke and the tumor-promoting effects of hydrogen peroxide formed by tobacco smoke-activated neutrophils (O'Brien, 2000).

In the presence of hydrogen peroxide and chloride (which are converted to HOCl by MPO), activated neutrophils and monocytes (including Kupffer cells) oxidize the aforementioned drugs to reactive intermediates (such as nitrogen-centered radicals, hydroxylamines, *N*-chloramines, and, in the case of aromatic amines with a hydroxyl group in the *para*-position, quinoneimines or the corresponding semiquinoneimine radicals). In the case of ticlopidine, MPO converts the thiophene ring of this antiplatelet drug to a thiophene-*S*-chloride, a reactive metabolite that rearranges to 2-chloroticlopidine (minor) and dehydro-ticlopidine (major), or reacts with GSH, as shown in Fig. 6-31. When catalyzed by activated neutrophils, ticlopidine oxidation is inhibited by low concentrations of azide and catalase. When catalyzed by purified myeloperoxidase, ticlopidine oxidation requires hydrogen peroxide and chloride, although all components of this purified system can be replaced with HOCl. It is not known whether drugs that cause agranulocytosis are activated in the bone marrow by neutrophils or their precursors that contain myeloperoxidase, or are activated in neutrophils in the general circulation. In the latter case, agranulocytosis would presumably involve an immune response triggered by neoantigens formed in neutrophils by the covalent modification of cellular component by one or more of the reactive metabolites formed by MPO. MPO is also present in Kupffer cells, which

release the enzyme in the liver upon activation by hydrogen peroxide. It is possible to increase the toxicity of hydralazine (which is associated with the development of hepatitis and centrilobular necrosis) toward cultured hepatocytes by the inclusion of a hydrogen peroxide-generating system (Tafazoli and O'Brien, 2008).

MPO has also been implicated in the formation of pro-oxidant phenoxyl radicals of etoposide, a topoisomerase inhibitor that can cause myelogenous leukemia, and both MPO and PHS have been implicated in the formation of phenoxyl radicals of benzene, an industrial solvent linked to bone marrow suppression and leukemia. MPO and PHS cannot oxidize benzene itself. Liver CYP converts benzene to phenol, which in turn is oxidized to hydroquinone, which can be converted to DNA-reactive metabolites by MPO in bone marrow leukocytes and by PHS in bone marrow. The myelosuppressive effect of benzene can be blocked by the PHS inhibitor, indomethacin, which suggests an important role for PHS-dependent activation in the myelotoxicity of benzene. The formation of phenol and hydroquinone in the liver is also important for myelosuppression by benzene. However, such bone marrow suppression cannot be achieved simply by administering phenol or hydroquinone to mice, although it can be achieved by coadministering hydroquinone with phenol. Phenol stimulates the MPO- and PHS-dependent activation of hydroquinone. Therefore, bone marrow suppression by benzene involves the CYP-dependent oxidation of benzene to phenol and hydroquinone in the liver, followed by the phenol-enhanced, MPO- and PHS-catalyzed peroxidative oxidation of hydroquinone to reactive intermediates that bind to protein and DNA in the bone marrow (Fig. 6-32). It is noteworthy that the CYP enzyme responsible for hydroxylating benzene has been identified as CYP2E1 (see the section "Cytochrome P450"). Although CYP2E1 was first identified in liver, this same enzyme has been identified in bone marrow where it can presumably convert benzene to phenol and possibly hydroquinone. The importance of CYP2E1 in the metabolic activation of benzene was confirmed by the demonstration that CYP2E1 knockout mice are relatively resistant to the myelosuppressive effects of benzene (Gonzalez, 2003; Gonzalez and Yu, 2006). MPO has also been shown to convert phenol to diols. Benzene-diols are good substrates of EPO, LPO, and MPO and their oxidation by peroxidases leads to oxidative stress (Testa and Krämer, 2008, 2010).

Prostaglandin H synthase (formally known as prostaglandin-endoperoxide synthase 1 and 2, and also widely known as cyclooxygenase 1 and 2; gene symbols PTGS1 and 2 and collectively referred to below as "PHS") is one of the most extensively studied peroxidases involved in xenobiotic biotransformation. As shown in Fig. 6-33, PHS is a dual-function enzyme composed of a *cyclooxygenase*, which converts arachidonic acid to PGG₂, a 15-hydroperoxide-endoperoxide (which involves the addition of 2 molecules of oxygen to each molecule of arachidonic acid), and a *peroxidase* that converts the 15-hydroperoxide to the corresponding 15-alcohol PGH₂, which can be accompanied by the oxidation of xenobiotics (a "cosubstrate") and formation of ROS (Ramkissoon and Wells, 2011). PHS1 is localized in the endoplasmic reticulum and nuclear envelope and is constitutively expressed in a wide variety of tissues that synthesize and release eicosanoids (prostaglandins, leukotrienes, thromboxane, prostacyclin), which generally bind to G-coupled cell surface receptors and regulate cellular function, largely in a paracrine (local) fashion (Ramkissoon and Wells, 2011). In contrast, PHS2 is expressed in cells that respond to inflammatory cytokines, mitogens, tumor promoters, and AhR agonists (ie, agents such as TNF α , LPS, phorbol esters, TPA, TCDD) such as the macula densa of the kidney, the vas deferens, and certain regions of the brain (Ramkissoon and Wells, 2011). PGH₂ produces prostaglandins that activate receptors on the

Figure 6-31. Activation of ticlopidine to a reactive thiophene-S-chloride by myeloperoxidase.

nuclear membrane, and high levels of the enzyme are expressed in colorectal and other tumors, which appear to be important for tumor promotion and angiogenesis (the process of stimulating the blood vessel supply). Both enzymes play an important role in the activation of xenobiotics to toxic or tumorigenic metabolites, particularly in extrahepatic tissues that contain low levels of CYP. PHS2 (COX-2) also plays an important role in the subsequent response of tissues to cell damage and tumor initiation, and is a possible target for the treatment or prevention of certain types of cancer. Increasing evidence suggests that inhibition of COX-2 by NSAIDs may be part of the mechanism whereby these drugs protect against colon and other gastrointestinal cancers (Dubé *et al.*, 2007; Wu *et al.*, 2010). PHS has been evaluated for its contribution to the activation of phenytoin and other antiepileptic drugs, B[a]P, thalidomide, methamphetamine, and 3,4-methylenedioxymethamphetamine (Ramkissoon and Wells, 2011).

In certain cases, the oxidation of xenobiotics by peroxidases involves direct transfer of the peroxide oxygen to the xenobiotic, as

shown in Fig. 6-33 for the conversion of substrate X to product XO. An example of this type of reaction is the PHS-catalyzed epoxidation of B[a]P 7,8-dihydrodiol to the corresponding 9,10-epoxide (see Fig. 6-10). Although PHS can catalyze the final step (i.e., 9,10-epoxidation) in the formation of this tumorigenic metabolite of B[a]P, it cannot catalyze the initial step (i.e., 7,8-epoxidation), which is catalyzed by CYP. Several lines of evidence suggest that both PHS1 and PHS2 play an important role in PAH-induced skin carcinogenesis. First, both PHS1 knockout and PHS2 knockout mice are resistant to PAH-induced skin cancer. (It is noteworthy that PHS1 knockout mice appear normal despite having only 1% of the prostaglandin levels of wild-type mice, whereas only 60% of PHS2 knockout mice survive until weaning, and the 40% that survive past weaning usually die within a year of kidney disease.) Both resveratrol (an inhibitor of PHS1 and CYP1A1) and SC-58125 (an inhibitor of PHS2) block PAH-induced skin cancer in mice.

PHS can also catalyze the 8,9-epoxidation of aflatoxin B₁, which is one of the most potent hepatotumorigens known.

Figure 6-32. Role of cytochrome P450 and peroxidases in the activation of benzene to myelotoxic metabolites.

Epoxidation by CYP is thought to be primarily responsible for the hepatotumorigenic effects of aflatoxin B₁. However, aflatoxin B₁ also causes neoplasia of rat renal papilla. This tissue has very low levels of CYP, but contains relatively high levels of PHS, which is suspected, therefore, of mediating the nephrotumorigenic effects of aflatoxin (Fig. 6-34).

The direct transfer of the peroxide oxygen from a hydroperoxide to a xenobiotic is neither the only mechanism of xenobiotic oxidation by peroxidases nor the most common. Xenobiotics that can serve as electron donors, such as amines and phenols, can be oxidized to free radicals during the reduction of a hydroperoxide. In this case, the hydroperoxide is still converted to the corresponding alcohol, but the peroxide oxygen is reduced to water instead of being incorporated into the xenobiotic. For each molecule of hydroperoxide reduced (which is a 2-electron process), 2 molecules of xenobiotic can be oxidized (each by a one-electron process). Important classes of compounds that undergo one-electron oxidation reactions by peroxidase include aromatic amines, phenols, hydroquinones, and polycyclic hydrocarbons. Many of the metabolites produced are reactive electrophiles. For example, PAHs, phenols, and hydroquinones are oxidized to electrophilic quinones. Acetaminophen is similarly converted to a quinoneimine, namely, *N*-acetyl-benzoquinoneimine, a cytotoxic electrophile that binds to cellular proteins, as shown in Fig. 6-35. The formation of this toxic metabolite by CYP causes centrilobular necrosis of the liver. However, acetaminophen can also damage the kidney medulla, which contains low levels of CYP but relatively high levels of PHS; hence, PHS may play a significant role in the nephrotoxicity of acetaminophen. The 2-electron oxidation of acetaminophen to *N*-acetyl-benzoquinoneimine by PHS likely involves the formation of a one-electron oxidation product, namely, *N*-acetyl-benzosemiquinoneimine radical. Formation of this semiquinoneimine radical by PHS likely contributes to the nephrotoxicity of acetaminophen and related compounds, such as phenacetin and 4-aminophenol. Metabolites of the NSAID diclofenac (namely, 4'-hydroxydiclofenac and 5-hydroxydiclofenac) can also be converted to benzquinoneimines by peroxidases (Testa and Krämer, 2008, 2010).

Like the kidney medulla, urinary bladder epithelium also contains low levels of CYP but relatively high levels of PHS. Just as

PHS in kidney medulla can ostensibly activate aflatoxin and acetaminophen to nephrotoxic metabolites, so PHS in urinary bladder epithelium can potentially activate certain aromatic amines, such as benzidine, 4-aminobiphenyl, and 2-aminonaphthalene, to DNA-reactive metabolites that cause bladder cancer in certain species, including humans and dogs. PHS can convert aromatic amines to reactive radicals, which can undergo nitrogen–nitrogen or nitrogen–carbon coupling reactions, or they can undergo a second one-electron oxidation to reactive diimines. Binding of these reactive metabolites to DNA is presumed to be one of the underlying mechanisms by which several aromatic amines cause bladder cancer in humans and dogs. In some cases the one-electron oxidation of an amine leads to *N*-dealkylation. For example, PHS catalyzes the *N*-demethylation of aminopyrine, although in vivo this reaction is mainly catalyzed by CYP. In contrast to CYP, PHS does not appear to catalyze the *N*-hydroxylation of carcinogenic aromatic amines (an important step in their metabolic activation), although MPO and LPO have been shown to catalyze this reaction. In liver, activation of aromatic amines by *N*-hydroxylation is catalyzed predominantly by CYP1A2, whereas this same reaction in the bladder epithelium appears to be catalyzed by another enzyme, possibly a CYP enzyme other than CYP1A2, such as CYP2A13, CYP4B1, or CYP2S1 (Nakajima *et al.*, 2006), or a peroxidase other than PHS.

Many of the aromatic amines known or suspected of causing bladder cancer in humans have been shown to cause bladder tumors in dogs. In rats, however, aromatic amines cause liver tumors by a process that is thought to involve *N*-hydroxylation by CYP, followed by conjugation with acetate or sulfonate, as shown in Fig. 6-12. This species difference has complicated an assessment of the role of PHS in aromatic amine–induced bladder cancer, because such experiments must be carried out in dogs. However, another class of compounds, the 5-nitrofurans, such as *N*-[4-(5-nitro-2-furyl)-2-thiazole]formamide (FANFT) and its deformed analog 2-amino-4-(5-nitro-2-furyl)thiazole (ANFT), are substrates for PHS and are potent bladder tumorigens in rats. The tumorigenicity of FANFT is thought to involve deformylation to ANFT, which is oxidized to DNA-reactive metabolites by PHS. The ability of FANFT to cause bladder tumors in rats is blocked by the COX inhibitor, aspirin, which suggests that PHS plays an important role in the metabolic

Figure 6-33. Cooxidation of xenobiotics (X) during the conversion of arachidonic acid to PGH₂ by prostaglandin H synthase.

activation and tumorigenicity of this nitrofuran. Unexpectedly, combined treatment of rats with FANFT and aspirin causes forestomach tumors, which are not observed when either compound is administered alone.

Increased expression of PHS2 (COX-2) has been documented in a number of tumors, including human colorectal, gastric, esophageal, pulmonary, and pancreatic carcinomas (Gupta and DuBois, 1998; Molina *et al.*, 1999; Dubé *et al.*, 2007; Wu *et al.*, 2010). Aspirin and other NSAIDs block the formation of colon cancer in experimental animals, and there is epidemiological evidence that long-term use of certain NSAIDs (aspirin and sulindac), but not acetaminophen (which does not inhibit COX-2), decreases the incidence of colorectal polyps and cancer in humans, and also decreases the number of deaths from esophageal, gastric, and rectal cancers. The incidence of intestinal neoplasms in Apc^{Δ716} knockout mice is dramatically suppressed by crossing these transgenic animals with PHS2 (COX-2) knockout mice (Oshima *et al.*, 1996). From these few examples it is apparent that PHS2 may play at least 2 distinct roles in tumor formation; it may convert certain xenobiotics to

Figure 6-34. Activation of aflatoxin B₁ by cytochrome P450, leading to liver tumor formation, and by peroxidases, leading to renal papilla neoplasia.

DNA-reactive metabolites (and thereby initiate tumor formation), and it may promote subsequent tumor growth, perhaps through formation of growth-promoting eicosanoids, such as PGE₂, which can activate EGFR, ERKs, etc (Wu *et al.*, 2010).

Many phenolic compounds can serve as reducing substrates for PHS peroxidase. The phenoxy radicals produced by one-electron oxidation reactions can undergo a variety of reactions, including binding to critical nucleophiles, such as protein and DNA, reduction by antioxidants such as GSH, and self-coupling. The reactions of phenoxy radicals are analogous to those of the nitrogen-centered free radicals produced during the one-electron oxidation of aromatic amines by PHS.

It was previously mentioned in this section that phenol can enhance the peroxidative metabolism of hydroquinone, which is an important component to benzene myelotoxicity. An analogous interaction has been described between the phenolic antioxidants, BHT, and BHA. In mice, the pulmonary toxicity of BHT, which is a relatively poor substrate for PHS, is enhanced by BHA, which is a relatively good substrate for PHS. The mechanism by which BHA enhances the pulmonary toxicity of BHT involves the peroxidase-dependent conversion of BHA to a phenoxy radical that interacts with BHT, converting it to a phenoxy radical (by one-electron

Figure 6-35. Activation of acetaminophen by cytochrome P450, leading to hepatotoxicity, and by prostaglandin H synthase (PHS), leading to nephrotoxicity. Conjugation with sulfonate, glucuronic acid, or glutathione represents detoxication reactions.

oxidation) or a quinone methide (by 2-electron oxidation), as shown in Fig. 6-36. Formation of the toxic quinone methide of BHT can also be catalyzed by CYP, which is largely responsible for activating BHT in the absence of BHA. A similar outcome occurs with quercetin, which is oxidized to a quinonemethide in the presence of peroxidases (Testa and Krämer, 2008, 2010).

Several reducing substrates, such as phenylbutazone, retinoic acid, 3-methylindole, sulfite, and bisulfite, are oxidized by PHS to carbon- or sulfur-centered free radicals that can trap oxygen to form a peroxy radical, as shown in Fig. 6-37 for phenylbutazone. The peroxy radical can oxidize xenobiotics in a peroxidative manner. For example, the peroxy radical of phenylbutazone can convert B[a]P 7,8-dihydrodiol to the corresponding 9,10-epoxide.

PHS is unique among peroxidases because it can both generate hydroperoxides and catalyze peroxidase-dependent reactions, as shown in Fig. 6-33. Xenobiotic biotransformation by PHS is controlled by the availability of arachidonic acid. The biotransformation of xenobiotics by other peroxidases is controlled by the availability of hydroperoxide substrates. Hydrogen peroxide is a

normal product of cellular respiration, and lipid peroxides can form during lipid peroxidation. The level of these peroxides and their availability for peroxidase reactions depends on the efficiency of hydroperoxide scavenging by GPX and catalase.

Flavin Monooxygenases Liver, kidney, intestine, brain, and lung (among other tissues) contain one or more FAD-containing monooxygenases (FMO) that oxidize soft nucleophilic nitrogen, sulfur, selenium, phosphorus, and rarely—iodine, carbon, and boron—atoms of xenobiotics (Ziegler, 1993; Lawton *et al.*, 1994; Cashman, 1995, 1999, 2008; Rettie and Fisher, 1999; Cashman and Zhang, 2006; Mitchell, 2008; Testa and Krämer, 2008, 2010). Among these types of substrates, the best tend to be those with lone pairs of electrons available to form a polar, coordinate covalent (dative) bond (eg, hydroxylamines and piperidines) (Cashman, 2008; Testa and Krämer, 2008, 2010). The mammalian FMO gene family comprises 5 enzymes (designated FMO1-FMO5) that contain 532 to 558 amino acid residues each and are 48% to 60% identical in amino acid sequence within a species, whereas orthologous

Figure 6-36. Metabolite interaction between the phenolic antioxidants, butylated hydroxytoluene (BHT), and butylated hydroxyanisole (BHA). Note that activation of BHT to a toxic quinone methide can be catalyzed by cytochrome P450 or, in the presence of BHA, by prostaglandin H synthase (PHS).

forms are 82% to 86% identical across species (Hines *et al.*, 2002). The human enzymes range in apparent molecular weight from 52 to 64 kDa (Testa and Krämer, 2008, 2010). Up to 6 human FMO pseudogenes have also been observed, including one that shares 71% sequence identity with FMO3, namely, FMO6, for which 9 distinct transcripts were identified in liver, but not kidney. All of these variant FMO6 transcripts arise by alternative splicing and lead to truncated, and therefore nonfunctional, enzymes. The possibility remains that rare SNPs in the FMO6 pseudogene could lead to normal expression of FMO6 in some individuals, but this has not yet been documented (Hines *et al.*, 2002). Each FMO enzyme contains a highly conserved glycine-rich region (residues 4-32) that binds 1 mol of FAD (noncovalently) near the active site, which is adjacent to a second highly conserved glycine-rich region (residues 186-213) that binds NADPH (or NADH). Other structural motifs have been reviewed in detail by Ziegler (2002).

Like CYP, the FMOs are microsomal enzymes that require O_2 and NADPH (or NADH in some cases) (Lai *et al.*, 2011), and many of the reactions catalyzed by FMO also can be catalyzed by CYP. However, whereas CYP catalyzes 2 sequential one-electron oxidations, FMO catalyzes a single 2-electron oxidation (Cashman, 2008). In contrast to CYP enzymes, FMOs are not readily induced or inhibited, such that metabolism of a drug by FMO tends to decrease its victim potential (ie, its potential to be the object of drug-drug interactions) (Cashman, 2008). However, basal expression levels appear to vary as much as 20-fold between individuals, with the differences appearing to be caused by mutations in the promoter regions of at least FMO1 and 3 (Testa and Krämer, 2008, 2010). Consequently, the disposition of a drug primarily metabolized by

FMO would likely show considerable interindividual variation and, for reasons outlined later in this section, infants and young children would likely be PMs.

Several *in vitro* techniques have been developed to distinguish reactions catalyzed by FMO from those catalyzed by CYP. In general, and in contrast to CYP, FMO is heat labile and can be inactivated in the absence of NADPH by warming microsomes to 50°C for one minute (Ogilvie *et al.*, 2008). However, even the often-used procedure of preincubating human liver microsomes at 37°C prior to addition of NADPH can cause significant inactivation of FMO, possibly leading to an underestimation of the role of FMO in the metabolism of xenobiotics (Cashman, 2008). By comparison, CYP can be inactivated with nonionic detergent, such as 1% Emulgen 911, which has a minimal effect on FMO activity. The pH optimum for FMO-catalyzed reactions (pH 8-10) tends to be higher than that for most (but not all) CYP reactions (pH 7-8). Based on the latter approach, a higher rate of formation of *N*-oxides from tertiary amines in microsomal incubations at pH 10 relative to pH 7.4 provides strong evidence for the role of FMO in *N*-oxide formation (Cashman, 2008). Antibodies raised against purified CYP enzymes can be used not only to establish the role of CYP in a microsomal reaction but also to identify which particular CYP enzyme catalyzes the reaction. In contrast, antibodies raised against purified FMO do not inhibit the enzyme. The use of chemical inhibitors to ascertain the relative contribution of FMO and CYP to microsomal reactions is often complicated by a lack of specificity. For example, both cimetidine and SKF 525A, which are well-recognized CYP inhibitors, are substrates for FMO. Conversely, the FMO inhibitor methimazole is known to cause direct inhibition of CYP2B6 and

Figure 6-37. Oxidation of phenylbutazone by prostaglandin H synthase (PHS) to a carbon-centered radical and peroxy radical. Note that the peroxy radical can oxidize xenobiotics (X) in a peroxidative manner.

CYP2C9, and MDI of CYP3A4 (Parkinson *et al.*, 2011). Excellent FMO substrates, such as the strong nucleophile mercaptoimidazole, can potentially be used as competitive inhibitors of FMO-mediated *N*-oxidation of tertiary amines (Cashman, 2008). Zwitterions, positively multiple charged compounds, and diamines such as cadaverine are generally not FMO substrates (Krueger *et al.*, 2006). The situation is further complicated by the observation that the various forms of FMO differ in their thermal stability and sensitivity to detergents and other chemical modulators (examples of which are described later in this section).

FMO catalyzes the oxidation of nucleophilic tertiary amines to *N*-oxides, secondary amines to hydroxylamines and nitrones, and primary amines to hydroxylamines and oximes. Amphetamine, benzydamine, chlorpromazine, clozapine, guanethidine, imipramine, methamphetamine, olanzapine, and tamoxifen are examples of nitrogen-containing drugs that are *N*-oxygenated by FMO (and by CYP in most cases). Only sp^3 -hybridized electron-rich (nucleophilic) nitrogen atoms—those with pK_a values 5 to 10—are substrates for *N*-oxygenation by FMO, hence the preference of FMO for tertiary and cyclic amines. Therefore, in general, FMO *N*-oxygenates tertiary aliphatic amines and aliphatic cyclic amines (CYP can also) but FMO does not usually *N*-oxygenate aromatic amines (pyridines and anilines such as clozapine) (Testa and Krämer, 2008, 2010). Heteroaromatics (with an sp^2 -hybridized

nitrogen) and amides (which have low basicity [low pK_a]) are not *N*-oxygenated by FMO but they may be *N*-oxygenated by CYP. Thus, CYP can *N*-oxygenate both tertiary/cyclic amines and pyridines. In the case of anilines (arylamines), however, CYP (as will peroxidases, but rarely FMO) will *N*-hydroxylate them (Testa and Krämer, 2008, 2010). The *N*-oxygenation of primary and secondary aliphatic amines by FMO is more complex. For instance, the aliphatic *secondary* amine, methamphetamine ($R-NH-CH_3$), is *N*-oxygenated by FMO3 first to a hydroxylamine ($R-NOH-CH_3$) and then to a dihydroxylated intermediate ($R-N^+(OH)_2-CH_3$) that loses water to form a nitron ($R-N^+O-CH_3$). The resulting nitron can spontaneously hydrolyze to a ketone (phenylacetone in this case), such that this overall reaction represents an alternative deamination pathway (Testa and Krämer, 2008, 2010). In the case of the aliphatic *primary* amine, amphetamine ($R-CH_2-NH_2$), FMO again catalyzes 2 sequential *N*-hydroxylation reactions but in this case the *N*-dihydroxylated metabolite $R-CH_2-N(OH)_2$ loses water to form an oxime ($R-CH=NOH$). Primary aliphatic amines tend to be poor substrates for CYP; in fact, primary alkylamines, such as the *N*-demethylated metabolite of fluoxetine, are metabolically stable and potent inhibitors of CYP (discussed later in the section “Inhibition of Cytochrome P450”).

FMO also oxygenates several sulfur-containing xenobiotics (such as thiols, thioethers, thiones, and thiocarbamates) and

phosphines to *S*- and *P*-oxides, respectively. Cimetidine and sulindac sulfide are examples of sulfur-containing drugs that are converted to sulfoxides by FMO. As in the case of *N*-oxygenation, *S*-oxygenation requires a soft nucleophilic heteroatom, such as that found in thioethers. Both FMO and CYP can convert thioethers to sulfoxides ($R_1-S-R_2 \rightarrow R_1-SO-R_2$) but only CYP can convert sulfoxides to sulfones ($R_1-SO-R_2 \rightarrow R_1-SO_2-R_2$). Electron-withdrawing groups next to the sulfur (as in the case of sulfoxides and many heteroaromatics) decrease the nucleophilicity of the sulfur atom and decrease or abolish its oxygenation by FMO, whereas electron-donating groups have the opposite effect, which is why thioamides are excellent substrates for *S*-oxygenation by FMO. Fig. 6-15 shows how sulindac, a sulfoxide, is reduced to sulindac sulfide, only to be oxidized by FMO back to the parent drug in what is often called a futile cycle as discussed further below in this section. Hydrazines, iodides, selenides, and boron-containing compounds are also substrates for FMO. Examples of FMO-catalyzed reactions are shown in Fig. 6-38A and B. One of the more unusual reactions catalyzed by FMO1 is the oxidative defluorination of 4-fluoro-*N*-methylaniline to 4-hydroxy-*N*-methylaniline (ie, 4-*N*-methylanilino-phenol) through the intermediacy of a reactive quinoneimine (Driscoll *et al.*, 2010). In the case of 4-fluoro-*N*-methylaniline, this oxidative defluorination reaction is facilitated by delocalization of the lone pair of electrons on the aniline nitrogen.

In general, the metabolites produced by FMO are the products of a chemical reaction between a xenobiotic and a peracid or peroxide, which is consistent with the mechanism of catalysis of FMO (discussed later in this section). The reactions catalyzed by FMO are generally detoxication reactions, although there are exceptions to this rule, which are described below (this section). Inasmuch as FMO attacks nucleophilic heteroatoms, it might be assumed that substrates for FMO could be predicted from their pK_a values (ie, from a measure of their basicity). Although there is some truth to this—for example, xenobiotics containing an sp^3 -hybridized nitrogen atom with a pK_a of 5 to 10 are generally good substrates for FMO—predictions of substrate specificity based on pK_a values alone are not very reliable presumably because steric effects influence access of substrates to the FMO active site, which is consistent with the reported lack of rabbit FMO2 activity toward imipramine and chlorpromazine (Rettie and Fisher, 1999; Krueger *et al.*, 2006).

The mechanism of catalysis by FMO is depicted in Fig. 6-39. After the FAD moiety is reduced to $FADH_2$ by NADPH, the oxidized cofactor, $NADP^+$, remains bound to the enzyme. $FADH_2$ then binds oxygen to produce a peroxide (ie, the C(4a)-hydroperoxyflavin of FAD). The FAD-hydroperoxide is relatively stable, probably because the active site of FMO comprises non-nucleophilic, lipophilic amino acid residues, and this is thought to be the enzyme's resting state (ie, the FAD-hydroperoxide is the form in which FMO exists prior to substrate binding). During the oxygenation of xenobiotics (depicted as $X \rightarrow XO$ in Fig. 6-39), the nucleophilic heteroatom (N or S) attacks the terminal oxygen of the C(4a)-hydroperoxyflavin resulting in oxygen transfer to the xenobiotic (to form an *N*-oxide or sulfoxide) and formation of C(4a)-hydroxyflavin. From the latter step, it is understandable why the metabolites produced by FMO are generally the products of a chemical reaction between a xenobiotic and a peroxide or peracid. The final step in the catalytic cycle involves dehydration of C(4a)-hydroxyflavin (which restores FAD to the ground state) and release of $NADP^+$. This final step is important because it is rate-limiting, and it occurs after substrate oxygenation. Consequently, this step determines the upper limit of the rate of substrate oxidation. Therefore, all good substrates for FMO are converted to products at roughly the same maximum rate (ie, V_{max} is determined

by the final step in the catalytic cycle). Binding of $NADP^+$ to FMO during catalysis is important because it prevents the reduction of oxygen to H_2O_2 . In the absence of bound $NADP^+$, FMO would function as an NADPH-oxidase that would consume NADPH and cause oxidative stress through excessive production of H_2O_2 . In some cases the reactive C(4a)-hydroperoxyflavin can function as an "enzymatic peroxide" to catalyze a Baeyer–Villiger oxidation, which involves the insertion of an oxygen atom into a carbon-carbon bond next to a carbonyl group (eg, aldehyde or ketone), to form an ester (eg, oxidation of salicylaldehyde by pig FMO1) (Lai *et al.*, 2011). However, this reaction has not been described in humans with the notable exception of FMO5 (and only FMO5), which mediates the Baeyer–Villiger lactonization of ER-879819, the ketone metabolite of the poly(ADP-ribose) polymerase inhibitor, E7016 (Lai *et al.*, 2011).

The oxygenation of substrates by FMO does not lead to inactivation of the enzyme, even though some of the products are strong electrophiles capable of binding covalently to critical and non-critical nucleophiles such as protein and GSH, respectively. The products of the oxygenation reactions catalyzed by FMO and/or the oxygenation of the same substrates by CYP can inactivate CYP. For example, the FMO-dependent *S*-oxygenation of spironolactone thiol (which is formed by the deacetylation of spironolactone by carboxylesterases, as shown in Fig. 6-5) leads to the formation of an electrophilic sulfenic acid ($R-SH \rightarrow R-SOH$) that can undergo redox cycling, or be further converted to the reactive sulfinic acid ($R-SO_2H$) or sulfanyl radical (HS^*) that inactivates CYP and binds covalently to other proteins (Decker *et al.*, 1991; Krueger *et al.*, 2006; Testa and Krämer, 2008, 2010).

In humans, FMO plays a role in the biotransformation of several drugs (eg, albendazole, amphetamine, benzydramine, chlorpheniramine, cimetidine, clindamycin, clozapine, codeine, dasatinib, deprenyl, ethionamide, fenbendazole, guanethidine, itopride, methimazole, olanzapine, olopatadine, pargyline, ranitidine, sulindac sulfide, tamoxifen, tazarotene, thiacetazone, thioridazine, tozasertib, vandetanib, voriconazole, xanomeline, zimeldine, hydrazines such as procarbazine, and various dimethylaminoalkyl phenothiazine derivatives such as chlorpromazine and imipramine) and other xenobiotics (eg, aldicarb, cocaine, diallyl disulfide, *N,N*-dimethylaniline, disulfoton, fenthion, methyl-*p*-tolyl sulfide, methamphetamine, nicotine, phorate, thioacetamide, thiobenzamide, and tyramine), and in the activation of 3,3'-iminodipropionitrile to the neurotoxic *N*-hydroxy-3,3'-iminodipropionitrile (Ballard *et al.*, 2007; Testa and Krämer, 2008, 2010; Wang *et al.*, 2008; Francois *et al.*, 2009; Weil *et al.*, 2010; Strolin-Benedetti, 2011). As discussed later in this section, FMO also plays a role in the metabolism of some endogenous substrates such as TMA, cysteamine, cysteine conjugates, methionine, and lipoic acid (6,8-dithiooctanoic acid).

The major flavin monooxygenase in human liver microsomes, FMO3, is predominantly if not solely responsible for converting (*S*)-nicotine to (*S*)-nicotine *N*-1'-oxide (which is one of the reactions shown in Fig. 6-38A). The reaction proceeds stereospecifically; only the *trans* isomer is produced by FMO3, and this is the only isomer of (*S*)-nicotine *N*-1'-oxide excreted in the urine of cigarette smokers or individuals wearing a nicotine patch (Cashman and Zhang, 2006). Therefore, the urinary excretion of *trans*-(*S*)-nicotine *N*-1'-oxide can be used as an *in vivo* probe of FMO3 activity in humans. However, common polymorphisms in FMO1 (eg, FMO1*6) have been shown to be associated with nicotine dependence in European patients (Hinrichs *et al.*, 2011). Furthermore, recombinant human FMO1 catalyzes the *N*-oxidation of (*S*)-nicotine approximately 4-fold more efficiently than recombinant human FMO3, and does so nonstereospecifically (ie, 55:45 *cis:trans* ratio of (*S*)-nicotine

Figure 6-38. Examples of reactions catalyzed by flavin monooxygenases (FMO). (A) Nitrogen-containing xenobiotics.

N-1'-oxide, similar to the situation with pig, rat, and rabbit FMO1), whereas FMO3 forms predominantly the *trans*-(*S*)-nicotine *N*-1'-oxide (as described above) (Hinrichs *et al.*, 2011). FMO1 is extrahepatic, with high expression levels in the kidney, and some expression in the intestine and brain. If FMO1 contributes significantly to the metabolism of nicotine in the brains of smokers, it is possible that the *N*-oxide formed by FMO1 could be reduced back to nicotine in the brain by AO, a process known as retro-reduction or futile cycling (Hinrichs *et al.*, 2011).

FMO3 is also the principal enzyme involved in the *S*-oxygenation of cimetidine, an H_2 -antagonist that was once widely used in the treatment of gastric ulcers and other acid-related disorders (this reaction is shown in Fig. 6-38B). Cimetidine is stereoselectively sulfoxidated by FMO3 to an 84:16 mixture of (+) and (–) enantiomers, which closely matches the 75:25 enantiomeric composition of cimetidine *S*-oxide in human urine. Therefore, the urinary excretion of cimetidine *S*-oxide, like that of (*S*)-nicotine *N*-1'-oxide, is an *in vivo* indicator of FMO3 activity in humans.

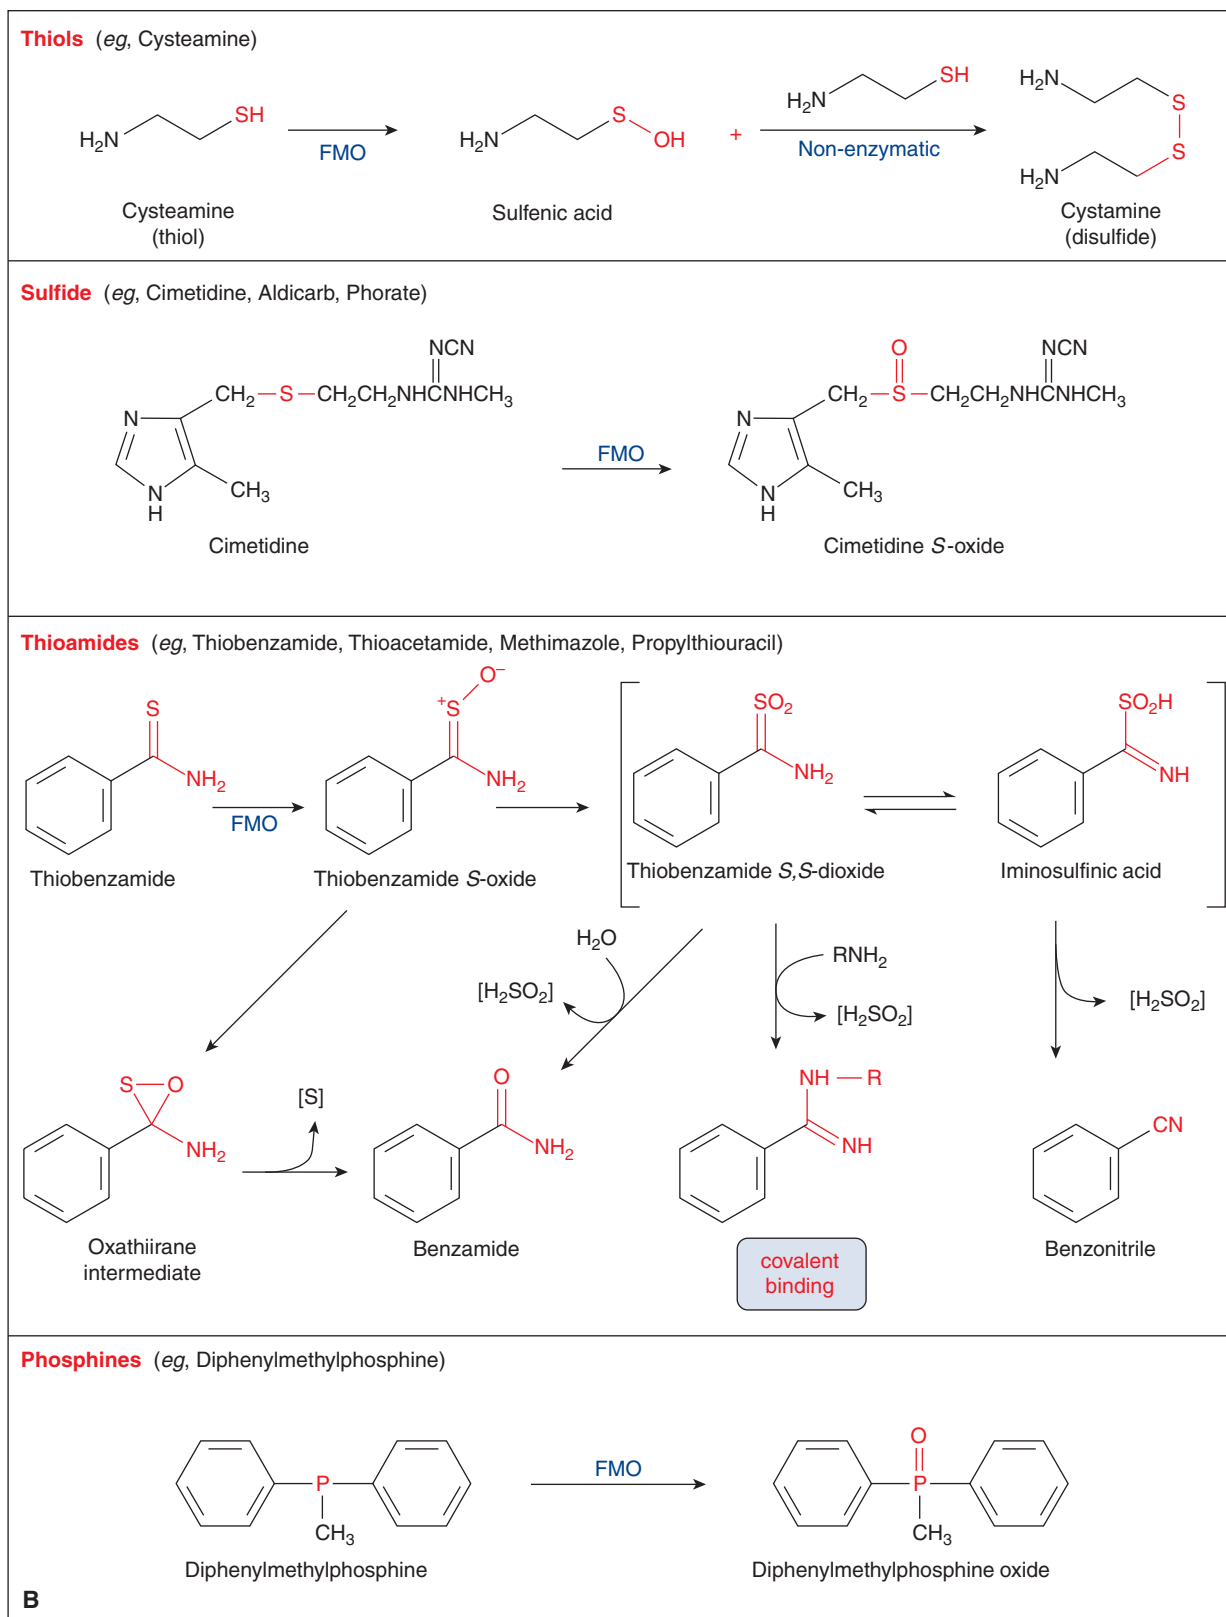

Figure 6-38. (Continued) (B) Sulfur- and phosphorus-containing xenobiotics.

Sulindac is a sulfoxide that exists in 2 stereochemical forms (as do most sulfoxides), and a racemic mixture of *R*- and *S*-sulindac is used therapeutically as a NSAID. As shown in Fig. 6-15, the sulfoxide group in sulindac is reduced to the corresponding sulfide (which is achiral), which is then oxidized back to sulindac by

retro-reduction (futile cycling). In human liver, the sulfoxidation of sulindac sulfide is catalyzed by FMO3 with little or no contribution from CYP. At low substrate concentrations (30 μM), FMO3 converts sulindac sulfide to *R*- and *S*-sulindac in an 87:13 ratio (Hamman *et al.*, 2000). Consequently, although sulindac is administered as

Figure 6-39. Catalytic cycle of flavin monooxygenase (FMO). X and XO are the xenobiotic substrate and oxygenated product, respectively. The C(4a)-hydroperoxyflavin and C(4a)-hydroxyflavin of FAD are depicted as FADHOH and FADHOOH, respectively.

a racemic mixture (ie, a 1:1 mixture of *R*- and *S*-enantiomers), the reduction of this drug to the corresponding sulfide and its preferential sulfoxidation by FMO3 to *R*-sulindac results in stereoselective enrichment of *R*-sulindac in plasma and urine.

This retro-reduction of sulfide *S*-oxides or amine *N*-oxides formed by FMO (or CYP) back to the parent may occur more often than is currently recognized, but it can be observed in vitro when the levels of an *N*- or *S*-oxide metabolite increase rapidly at first but then quickly reach a plateau as a balance between oxidation and reduction is reached (Cashman, 2008). There are at least 7 systems that can catalyze the retro-reduction of FMO metabolites: (1) AO, (2) quinone reductase, (3) hemoglobin itself or other heme-containing proteins such as CYP (which may or may not be enzymatically catalyzed), (4) XOR, (5) NADPH-cytochrome P450 reductase, (6) the mARC with NADH-cytochrome *b*₅/cytochrome *b*₅, and (7) gut microflora (Cashman, 2008; Testa and Krämer, 2008, 2010). For instance, amitriptyline *N*-oxide, imipramine *N*-oxide, cyclobenzaprine *N*-oxide, and brucine *N*-oxide are reduced back to the parent tertiary amine by quinone reductase, heme, and/or gut microflora (Cashman, 2008; Testa and Krämer, 2008, 2010). Nicotine *N*-oxide is retro-reduced to nicotine by AO (Cashman, 2008). Recombinant human CYP1A1, 2A6, 2D6, and 3A4 can also retro-reduce tamoxifen *N*-oxide to the tertiary amine (Cashman, 2008). The retro-reduction of TMA *N*-oxide to TMA by gut microflora is discussed later in this section (Cashman, 2008; Testa and Krämer, 2008, 2010).

In the case of sulindac sulfide, stereoselective sulfoxidation occurs not only with human FMO3 (the major drug-metabolizing FMO in human liver) but also with porcine FMO1 (the major form expressed in pig liver) and rabbit FMO2 (the major form expressed in rabbit lung) (Hamman *et al.*, 2000). However, this conformity is the exception, rather than the rule. For example, in contrast to the stereoselective oxygenation of (*S*)-nicotine and cimetidine by human FMO3 (see above), FMO1 (which is the major FMO expressed in pig, rat, and rabbit liver) converts (*S*)-nicotine to a 1:1 mixture of *cis*- and *trans*-(*S*)-nicotine *N*-1'-oxide, and similarly converts cimetidine to a 1:1 mixture of (+) and (–) cimetidine *S*-oxide, respectively. Therefore, statements concerning the role of FMO in

the disposition of xenobiotics in humans may not apply to other species, or vice versa.

Several sulfur-containing xenobiotics are oxygenated by FMO to electrophilic reactive intermediates. Such xenobiotics include various thiols, thioamides, 2-mercaptoimidazoles, thiocarbamates, and thiocarbamides. The electrophilic metabolites of these xenobiotics do not inactivate FMO, but they can covalently modify and inactivate neighboring proteins, including CYP. Some of these same xenobiotics are substrates for CYP, and their oxygenation to electrophilic metabolites leads to inactivation of CYP, a process known variously as MDI, mechanism-based inhibition, and suicide inactivation. 2-Mercaptoimidazoles undergo sequential *S*-oxygenation reactions by FMO, first to sulfenic acids and then to sulfinic acids ($R-SH \rightarrow R-SOH \rightarrow R-SO_2H$). These electrophilic metabolites, such as the sulfenic acid metabolite produced from spironolactone thiol (see above), bind to critical nucleophiles (such as proteins) or interact with GSH to form disulfides. The thiocarbamate functionality present in numerous agricultural chemicals is converted by FMO to *S*-oxides (sulfoxides), which can be further oxygenated to sulfones. These reactions involve *S*-oxygenation adjacent to a ketone, which produces strong electrophilic acylating agents, which may be responsible for the toxicity of many thiocarbamate herbicides and fungicides. The hepatotoxicity of thiobenzamide is dependent on *S*-oxidation by FMO and/or CYP. As shown in Fig. 6-38B, the *S*-oxidation of thiobenzamide produces an *S*-oxide, which can rearrange to an oxathiirane (a 3-membered ring of carbon, sulfur, and oxygen) on photolysis or thermolysis. However, such oxathiiranes are readily reduced back to the *S*-oxide. In vivo, the *S,S*-dioxide is more likely to form, which readily tautomerizes to iminosulfinic acid, binds covalently to protein (which leads to hepatocellular necrosis), or rearranges to benzamide, a reaction known as *oxidative group transfer*. In general, thiols with a negative charge on the *S*-atom (eg, dithioacids) tend to be good substrates of FMOs, whereas less nucleophilic *S*-atoms tend to be oxidized by CYP (Testa and Krämer, 2008, 2010).

Endogenous FMO substrates include cysteamine, which is oxidized to the disulfide, cystamine, and TMA, which is converted to TMA *N*-oxide (Fig. 6-38). By converting cysteamine to cystamine, FMO may serve to produce a low-molecular weight disulfide exchange agent, which may participate in the formation of disulfide bridges during peptide synthesis or the renaturation of proteins. By converting TMA to TMA *N*-oxide, FMO3 (but neither FMO1 nor 5) converts a malodorous and volatile dietary product derived from the reduction of dietary TMA *N*-oxide by gut bacteria (eg, from choline, lecithin, carnitine, and especially fish, which contain large amounts of TMA *N*-oxide) to an inoffensive metabolite. TMA smells of rotting fish (because bacteria in dead fish rapidly convert the high levels of TMA *N*-oxide to TMA), and people who are genetically deficient in FMO3 suffer from trimethylaminuria or *fish odor syndrome*, which is caused by the excretion of TMA in urine, sweat, and breath (Ayesh and Smith, 1992; Phillips and Shephard, 2008). Although the lack of functional FMO3 (and hence trimethylaminuria) occurs only rarely (eg, ~1% of British Caucasians), it is now known to be caused by one of at least 30 mutations that decrease or abolish FMO3 activity (Cashman *et al.*, 2000; Cashman and Zhang, 2006; Phillips and Shephard, 2008). As might be expected, trimethylaminuria is associated with an impairment of nicotine *N*-oxidation and other pathways of drug biotransformation that are primarily catalyzed by FMO3 (Rettie and Fisher, 1999). For instance, benzydamine *N*-oxygenation and oxidation of sulindac sulfide has been correlated with FMO3 genotype in trimethylaminurics (Cashman and Zhang, 2006; Testa and Krämer, 2008, 2010; Francois *et al.*,

Table 6-9

Putative Tissue Levels of Flavin Monooxygenase (FMO) Enzymes Present in Animals and Humans

Data from Cashman and Zhang (2006) and Zhang and Cashman (2006).

*Human tissue levels are based on FMO mRNA levels.

[‡]FMO2 mRNA levels in human lung are high, but this mRNA is not translated into functional enzyme due to the presence of a truncation mutation in Caucasians and Asians. Approximately 33% of sub-Saharan Africans, 26% of African Americans, 7% of Puerto Ricans, and 2% of Mexicans have 1 normal allele and express a functional protein (Veeramah *et al.*, 2008).

2009). Some polymorphisms decrease while others increase the activity of FMO3 toward certain substrates, while others affect the promoter region and alter the amount of enzyme expressed (Phillips and Shephard, 2008).

Humans and other mammals express 5 different flavin monooxygenases (FMO1, FMO2, FMO3, FMO4, and FMO5) in a species- and tissue-specific manner, as shown in Table 6-9, based on mRNA levels, which may not reflect protein levels (adapted from Cashman, 1995; Cashman and Zhang, 2006; Zhang and Cashman, 2006). The major hepatic FMOs expressed in humans are FMO3 and FMO5, whereas FMO1 is the major FMO expressed in rat, rabbit, and pig liver. In humans FMO1 is expressed in fetal liver and is very rapidly downregulated after birth (although not in kidney) while hepatic FMO3 is gradually upregulated over months to years, in contrast to other mammals (Shephard *et al.*, 2007; Phillips and Shephard, 2008; Testa and Krämer, 2008, 2010). This delay between the hepatic silencing of FMO1 and expression of FMO3 means that most infants probably have very little drug-metabolizing FMO present in the liver for several months (Shimizu *et al.*, 2011). In addition, given the fact that apparently only FMO3 catalyzes the *N*-oxidation of TMA produced from gut bacteria, this begs the question of why all infants do *not* have *fish odor syndrome*. In a cohort of 6 patients with genetically confirmed trimethylaminuria, the average age of presentation was 6 (± 3.6) years (Chalmers *et al.*, 2006). As a genetic deficiency of FMO3, trimethylaminuria is obviously present from birth. However, the phenotype only becomes apparent when an affected child is weaned, and foods with high amounts of choline (eg, eggs, liver, etc) or TMA *N*-oxide (eg, seafood) are introduced (Chalmers *et al.*, 2006). Diagnostic delay also presumably leads to the higher than expected average age of presentation. Transient trimethylaminuria can however occur in neonates and infants

if their diet sporadically contains higher than usual levels of choline, etc (Testa and Krämer, 2008, 2010).

Previously, FMO3 has been considered to be the dominant FMO in human liver, and although FMO5 expression is higher, it has activity toward fewer xenobiotic substrates, and likely plays only a minor role in xenobiotic metabolism, with the exception of E7016, the poly(ADP-ribose) polymerase inhibitor noted above (Cashman and Zhang, 2006; Lai *et al.*, 2011). FMO5 is also the most highly expressed FMO in the small intestine, in terms of mRNA. In humans, high levels of FMO1 are expressed in the kidney, and low levels of FMO2 are expressed in the lungs of Caucasians and Asians.

Lung microsomes from most mammals, particularly rabbit, mouse, monkey, and other nonhuman primates, contain high levels of functional FMO2, and of the FMO transcripts detected in human lung, the FMO2 transcript is found at the highest levels by far (Zhang and Cashman, 2006). The uncharacteristically low level of active FMO2 in human lung is caused by a mutation (a C \rightarrow T transition at codon 472 in exon 9) in the major human FMO2*2A allele found in essentially all Caucasian and Asian populations, which results in a premature stop codon and the synthesis of a nonfunctional, truncated protein (one lacking the last 64 amino acid residues from the C-terminus) (Dolphin *et al.*, 1998; Veeramah *et al.*, 2008; Francois *et al.*, 2009). In contrast, 26% of African Americans, 7% of Puerto Ricans, and 2% of Mexicans have one normal allele and express a functional protein (Cashman and Zhang, 2006). In sub-Saharan Africa, approximately 33% of individuals possess at least one functional FMO2*1 allele, and in some subpopulations the incidence approaches 50% (Veeramah *et al.*, 2008). In pulmonary microsomes from individuals who express one or more functional FMO2 alleles, the protein level is equal to or greater than that of CYP enzymes. Functional FMO2 has

high activity toward thioureas and thioamides, which implies that individuals who express a functional FMO2 may be more susceptible to the toxic effects of sulfenic or sulfinic acids formed from *S*-oxygenation of phenylthiourea, α -naphthylthiourea, and ethyl-enthiourea, whereas Caucasians and Asians may be more susceptible to thioether-containing organophosphate pesticides such as phorate and disulfoton, for which the parent compounds are more toxic than products of the FMO2-catalyzed reaction (Cashman and Zhang, 2006; Veeramah *et al.*, 2008). FMO2 has also been shown to catalyze *S*-oxygenation of the second-line antitubercular drugs ethionamide and thiacetazone, leading to the formation of reactive metabolites such as the sulfenic and sulfinic acids, carbodiimide derivatives, and *S*-oxides (Francois *et al.*, 2009). Because these second-line antitubercular agents are prodrugs that must be converted by the mycobacteria in FMO-like reactions to the reactive products, it is possible that administration to individuals with at least one FMO2*1 allele could decrease their efficacy and increase pulmonary toxicity.

FMO4 is expressed at low levels in the brain of several mammalian species, where it might terminate the action of several centrally active drugs and other xenobiotics. It is unstable, however, which makes its characterization somewhat difficult (Cashman and Zhang, 2006).

The various forms of FMO are distinct gene products with different physical properties and substrate specificities. For example, FMO2 *N*-oxygenates *n*-octylamine, whereas such long aliphatic primary amines are not substrates for FMO1, although they stimulate its activity toward other substrates (in some cases causing a change in stereospecificity). Conversely, short-chain tertiary amines, such as chlorpromazine, orphenadrine, and imipramine, are substrates for FMO1 but not FMO2. FMO2 exhibits no activity toward phenothiazine derivatives with only a 3-carbon side chain or 1,3-diphenylthiourea (Krueger *et al.*, 2006). FMO3 is highly selective in the *N*-oxygenation of TMA, whereas FMO5 is selective for the *N*-oxygenation of short-chain aliphatic primary amines such as *N*-octylamine, but has little activity toward other typical FMO substrates, with the exception of E7016, the poly(ADP-ribose) polymerase inhibitor noted previously (Krueger *et al.*, 2006; Lai *et al.*, 2011). The substrate specificity of FMO4 also is somewhat restricted. Certain substrates are oxygenated stereospecifically by one FMO enzyme but not another. For example, FMO2 and FMO3 convert (*S*)-nicotine exclusively to *trans*-(*S*)-nicotine *N*-1'-oxide, whereas the *N*-oxides of (*S*)-nicotine produced by FMO1 are a 1:1 mixture of *cis* and *trans* isomers. FMO2 is heat stable under conditions that completely inactivate FMO1, and FMO2 is resistant to anionic detergents that inactivate FMO1. Low concentrations of bile acids, such as cholate, stimulate FMO activity in rat and mouse liver microsomes but inhibit FMO activity in rabbit and pig liver.

The FMO enzymes expressed in liver microsomes are not under the same regulatory control as CYP enzymes. In rats, the expression of FMO1 is suppressed rather than induced by treatment with phenobarbital or 3-methylcholanthrene (although some studies point to a modest [~3-fold] induction of rat FMO1 by 3-methylcholanthrene). Indole-3-carbinol, which induces the same CYP enzymes as 3-methylcholanthrene, causes a marked decrease in FMO activity in rat liver and intestine. A similar decrease in FMO3 activity occurs in human volunteers following the consumption of large amounts of Brussels sprouts, which contain high levels of indole-3-carbinol and related indoles. The decrease in FMO3 activity may result from direct inhibition of FMO3 by indole-3-carbinol and its derivatives rather than from an actual decrease in enzyme levels (Cashman, 1999). Increased levels of nitric oxide (NO), as occurs during acute inflammation (eg, sepsis or endotoxemia),

which activates nitric oxide synthase-2 (NOS-2), can inhibit FMO (as well as CYP) (Mitchell, 2008). However, the AhR agonist, TCDD, was found to induce FMO2 and FMO3 mRNA levels in mice by 30- and 80-fold, respectively (Tijet *et al.*, 2006).

The levels of FMO3 and, to a lesser extent, the levels of FMO1 in mouse liver microsomes are sexually differentiated (female > male) due to suppression of expression by testosterone. The opposite is true of FMO1 levels in rat liver microsomes, the expression of which is positively regulated by testosterone and negatively regulated by estradiol. In pregnant rabbits, lung FMO2 is positively regulated by progesterone and/or corticosteroids.

Species differences in the relative expression of FMO and CYP appear to determine differences in the toxicity of the pyrrolizidine alkaloids, senecionine, retrorsine, and monocrotaline. These compounds are detoxified by FMO, which catalyzes the formation of tertiary amine *N*-oxides, but are activated by CYP, which oxidizes these alkaloids to pyrroles that generate toxic electrophiles through the loss of substituents on the pyrrolizidine nucleus (details of which appear in the section "Cytochrome P450"). Rats have a high pyrrole-forming CYP activity and a low *N*-oxide-forming FMO activity, whereas the opposite is true of guinea pigs. This likely explains why pyrrolizidine alkaloids are highly toxic to rats but not to guinea pigs. Many of the reactions catalyzed by FMO are also catalyzed by CYP, but differences in the oxidation of pyrrolizidine alkaloids by FMO and CYP illustrate that this is not always the case. Species differences in the levels of FMO can also complicate the findings of preclinical toxicology and metabolism studies because most toxicologically useful small animal species express FMO1 as the dominant hepatic FMO in contrast to human, in which FMO3 is the dominant form (Cashman, 2008). However, one animal model that may be more similar to the human hepatic expression of FMO is the female mouse, which has relatively high levels of FMO3 and 5 (Cashman, 2008).

Cytochrome P450 Of all the xenobiotic-biotransforming enzymes, the CYP enzyme system ranks first in terms of catalytic versatility and the sheer number of xenobiotics it detoxifies or activates to reactive intermediates. The highest levels of CYP enzymes involved in xenobiotic biotransformation are found in liver endoplasmic reticulum (microsomes), but CYP enzymes are present in virtually all tissues. Some of the so-called microsomal CYP enzymes are also located on the inner membrane of mitochondria, the importance of which is discussed in the section "CYP2E1." CYP enzymes play a very important role in determining the intensity and duration of action of drugs, and they also play a key role in the detoxication of xenobiotics. CYP enzymes in liver and extrahepatic tissues play important roles in the activation of xenobiotics to toxic and/or tumorigenic metabolites. The catalytic versatility of CYP enzymes is apparent from Table 6-2, which shows some of the many chemical groups that can be metabolized by CYP.

Microsomal and mitochondrial CYP enzymes play key roles in the biosynthesis or catabolism of steroid hormones, bile acids, fat-soluble vitamins such as vitamins A and D, fatty acids, and eicosanoids such as prostaglandins, thromboxane, prostacyclin, and leukotrienes, which underscores the catalytic versatility of CYP.

The human CYP superfamily contains 55 functional genes and 60 pseudogenes (Zhou *et al.*, 2009a; Guengerich *et al.*, 2010; <http://drnelson.uthsc.edu/CytochromeP450.html>). Many sources place the number of functional genes at 57; however, the 2 additional genes, namely, CYP2A7 (originally named IIA4) and CYP4B1, encode enzymes incapable of incorporating heme, rendering them catalytically inactive (note, however, that functional CYP4B1 is expressed in other mammalian species) (Yamano *et al.*, 1990; Ding *et al.*,

Table 6-10

Classification of the 55 Functional Human CYP Enzymes

1995; Baer and Rettie, 2006). As shown in Table 6-10, the 55 human CYP enzymes can be broadly categorized on the basis of their role in (1) xenobiotic biotransformation, (2) fatty acid/eicosanoid hydroxylation/epoxidation, (3) steroidogenesis, (4) bile acid synthesis, vitamin D activation/inactivation, (5) retinoic acid metabolism, and (6) unknown function (a diminishing group of so-called orphan enzymes). In several cases, there is no clear functional distinction in terms of endobiotic and xenobiotic metabolism because, as noted in Table 6-10, there are many examples of CYP enzymes playing an important role in the metabolism of both an endobiotic and a drug or other xenobiotic. CYP2J2 and, in animals, CYP4B1 are examples of enzymes that ride the xenobiotic–endobiotic fence. In terms of endobiotic metabolism, CYP enzymes play a role in both catabolism and anabolism (several different CYP enzymes play a role in steroid hormone and bile acid synthesis). For example, CYP enzymes both activate vitamin D₃ to 1 α ,25-dihydroxyvitamin D₃ (1,25-(OH)₂-D₃) (CYP2R1, CYP2J2, CYP3A4, CYP27A1, and CYP27B1) and inactivate the active metabolite (CYP24A1 and CYP3A4). Arachidonic acid is epoxidated by CYP2C8, CYP2C9, and especially CYP2J2 to vasodilatory epoxyeicosatrienoic acids (EETs) but is converted by ω -hydroxylation to the vasoconstrictor 20-hydroxyeicosatetraenoic acid (20-HETE) by various CYP4A and CYP4F enzymes. The major xenobiotic-biotransforming CYP enzymes in human liver microsomes belong to families 1, 2, and 3, which are shown in Table 6-11 along with their homologs in the nonclinical species widely used in drug safety testing.

All CYP enzymes are heme-containing proteins. In some cases, such as many members of the CYP4 family, the heme moiety is covalently attached to the protein but in most other cases it

is attached noncovalently (Ortiz de Montellano, 2008). The heme iron in CYP is usually in the ferric (Fe^{III}) state. When reduced to the ferrous (Fe^{II}) state, CYP can bind ligands such as O₂ and carbon monoxide (CO). The complex between ferrous CYP and CO absorbs light maximally at 450 nm, from which CYP derives its name (*Pigment 450*). The absorbance maximum of the CO complex differs slightly among different CYP enzymes and ranges from 447 to 452 nm. All other hemoproteins that bind CO absorb light maximally at ~420 nm. The unusual absorbance maximum of CYP is due to an unusual fifth ligand to the heme (a cysteine thiolate). The amino acid sequence around the cysteine residue that forms the thiolate bond with the heme moiety is highly conserved in all CYP enzymes. When this thiolate bond is disrupted, CYP is converted to a catalytically inactive form called cytochrome P420. By competing with oxygen, CO inhibits CYP. The inhibitory effect of CO can be reversed by irradiation with light at 450 nm, which photodissociates the CYP–CO complex. These properties of CYP are of historical importance (Omura, 2011). The observation that treatment of rats with certain chemicals, such as 3-methylcholanthrene, causes a shift in the peak absorbance of CYP (from 450 to 448 nm) provided some of the earliest evidence for the existence of multiple forms of CYP in liver microsomes. The conversion of CYP to cytochrome P420 by detergents and phospholipases helped to establish the hemoprotein nature of CYP. The inhibition of CYP by CO and the reversal of this inhibition by photodissociation of the CYP–CO complex established CYP as the microsomal and mitochondrial enzyme involved in drug biotransformation and steroid biosynthesis (Omura, 2011).

The basic reaction catalyzed by CYP enzymes is monooxygenation in which one atom of oxygen is incorporated into a substrate,

Note: CYP1A1 and CYP1B1 are extrahepatic enzymes, although CYP1A1 is an AhR-inducible hepatic enzyme. Data from Baillie and Rettie (2011) and Nelson (2009).

designated RH, and the other is reduced to water with reducing equivalents derived from NADPH, as follows:

Although CYP functions as a monooxygenase, the products are not limited to alcohols and phenols due to rearrangement reactions (Guengerich, 1991, 2001b, 2007; Isin and Guengerich, 2007). During catalysis, CYP binds directly to the substrate and molecular oxygen, but it does not interact directly with NADPH or NADH. The mechanism by which CYP receives electrons from NAD(P)H depends on the subcellular localization of CYP. In the endoplasmic reticulum, which is where most of the CYP enzymes involved in xenobiotic biotransformation are localized, electrons are relayed from NADPH to CYP via a flavoprotein called NADPH-cytochrome P450 reductase (also known as an oxidoreductase; gene symbol POR). Within this flavoprotein, electrons are transferred from NADPH to CYP via FMN and FAD. In mitochondria, which house many of the CYP enzymes involved in steroid hormone biosynthesis and vitamin D metabolism, electrons are transferred from NAD(P)H to CYP via 2 proteins: an iron-sulfur protein called ferredoxin (gene symbol FDX1) and an FMN-containing flavoprotein called ferredoxin reductase (gene symbol FDXR). These proteins are also known as adrenodoxin and adrenodoxin reductase. In bacteria such as *Pseudomonas putida*, which express P450cam (CYP101A1), electron flow is similar to that in mitochondria (NADH → flavoprotein → putidaredoxin → P450).

There are some notable exceptions to the general rule that CYP requires a second enzyme (ie, a flavoprotein) for catalytic activity. One exception applies to 2 CYP enzymes involved in the conversion of arachidonic acid to eicosanoids, namely, thromboxane A synthase (CYP5A1, gene symbol TBXAS1) and prostaglandin I₂ synthase, which is also known as prostacyclin synthase (CYP8A1, gene symbol PTGIS). These 2 CYP enzymes convert the endoperoxide,

PGH₂, to thromboxane (TXA₂) and prostacyclin (PGI₂) in platelets and the endothelial lining of blood vessels, respectively. In both cases, CYP functions as an isomerase and catalyzes a rearrangement of the oxygen atoms introduced into arachidonic acid by cyclooxygenase (see Fig. 6-33). The plant CYP, allene oxide synthase (CYP74A1), and certain invertebrate CYP enzymes also catalyze the rearrangement of oxidized chemicals (Guengerich, 2001b).

The second exception is represented by CYP102 (P450BM3) from the bacterium *Bacillus megaterium*, which produces a CYP enzyme linked directly to a flavoprotein to form a single, self-sufficient fusion protein. Some bacterial CYP enzymes are thermophilic (such as CYP119, CYP174A1, and CYP231A2), which has attracted attention for their potential industrial applications (Nishida and Ortiz de Montellano, 2005). The thermophilic P450 enzyme from *Sulfolobus acidocaldarius*, namely, CYP119, was used to confirm (and settle a long-standing debate) that the final step in the catalytic cycle of CYP is formation of compound I (por⁺Fe^{IV}=O), as in the case of peroxidases, which is discussed later in this section (Rittle and Green, 2010). Most mammalian CYP enzymes are not synthesized as a single enzyme containing both the hemoprotein and flavoprotein moieties, but this arrangement is found in the nitric oxide (NO) synthases. In addition to its atypical structure, the P450 enzyme expressed in *B. megaterium*, CYP102, is unusual for another reason: it is inducible by phenobarbital, which provided insight into the mechanism of CYP induction.

Phospholipids and cytochrome b₅ also play an important role in CYP reactions (McLaughlin *et al.*, 2010). CYP and NADPH-cytochrome P450 reductase are embedded in the phospholipid bilayer of the endoplasmic reticulum, which facilitates their interaction. With the notable exception of CYP2W1 (discussed later in this section), CYP and NADPH-cytochrome P450 reductase face the cytoplasmic side of the endoplasmic reticulum. When the C-terminal region that anchors NADPH-cytochrome P450 reductase in the membrane is cleaved with trypsin, the truncated flavoprotein can no longer support CYP reactions, although it is

still capable of reducing cytochrome *c* and other soluble electron acceptors. The ability of phospholipids to facilitate the interaction between NADPH-cytochrome P450 reductase and CYP does not appear to depend on the nature of the polar head group (serine, choline, inositol, ethanolamine), although certain CYP enzymes (those in the CYP3A subfamily) have a requirement for phospholipids containing unsaturated fatty acids. In vitro experiments established that cytochrome b_5 can stimulate various CYP reactions by either increasing V_{\max} or decreasing K_m , which was initially interpreted as evidence that cytochrome b_5 can donate the second of 2 electrons required by CYP. However, the same stimulation occurs with heme-depleted cytochrome b_5 (Yamazaki *et al.*, 1996, 2001). The stimulatory effect of cytochrome b_5 is now attributed to its effect on CYP conformation and/or its ability to facilitate the interaction between CYP and NADPH-cytochrome P450 reductase. Experiments in conditional knockout mice establish that cytochrome b_5 has an important stimulatory effect on CYP in vivo (McLaughlin *et al.*, 2010). Liver microsomes contain numerous forms of CYP but contain a single form of NADPH-cytochrome P450 reductase (POR) and cytochrome b_5 (CYB5A).

For each molecule of NADPH-cytochrome P450 reductase in rat liver microsomes, there are 5 to 10 molecules of cytochrome b_5 and 10 to 20 molecules of CYP. In human liver microsomes the ratio of CYP to NADPH-cytochrome P450 reductase is slightly lower (closer to 5:1). NADPH-cytochrome P450 reductase will reduce electron acceptors other than CYP, which enables this enzyme to be measured based on its ability to reduce cytochrome *c* (which is why NADPH-cytochrome P450 reductase is often called NADPH-cytochrome *c* reductase). NADPH-cytochrome P450 reductase can transfer electrons much faster than CYP can use them, which more than likely accounts for the low ratio of NADPH-cytochrome P450 reductase to CYP in liver microsomes. Low levels of NADPH-cytochrome P450 reductase may also be a safeguard to protect cells from the often deleterious one-electron reduction reactions catalyzed by this flavoprotein (see Fig. 6-16). NADPH-cytochrome P450 reductase also supports heme oxygenase, a Nrf2-inducible enzyme, the significance of which is discussed in the section “CYP2E1.”

Whereas microsomal cytochrome b_5 is encoded by CYB5A, CYB5B encodes the cytochrome b_5 found in the outer mitochondrial membrane where it supports the molybdoenzyme mARC in the dehydroxylation of certain amidoximes and related compounds (see the section “Dehydroxylation—mARC, Cytochrome b_5 , b_5 Reductase, and Aldehyde Oxidase” and Fig. 6-22).

The catalytic cycle of CYP involves 8 steps (A → H), as shown in Fig. 6-40 for the oxidation of a substrate (RH) to its hydroxylated metabolite (ROH) (Dawson, 1988; Guengerich, 2007; Rittle and Green, 2010; Johnston *et al.*, 2011; Hrycay and Bandiera, 2012). In this scheme, iron is shown bound to its fifth ligand, a heme thiolate provided by a highly conserved cysteine (Cys) residue. The first steps of the cycle (A → G) involve the activation of oxygen to compound I, and the final steps involve substrate oxidation by compound I (G → H) followed by release of the metabolite (ROH) to restore the enzyme to its resting (ferric) state (H → A). Following the binding of substrate (RH) to CYP (A → B), the heme iron is reduced from the ferric (Fe^{III}) to the ferrous (Fe^{II}) state by the introduction of a single electron from NADPH-cytochrome P450 reductase (B → C). In many cases the reduction of CYP is facilitated by substrate binding because binding of the substrate in the vicinity of the heme moiety converts the heme ferric iron from a low-spin to a high-spin state, although some enzymes, such as CYP1A2 and CYP2E1, are naturally in the high-spin state and can be reduced in the absence of substrate. It is at stage C, when the iron is in

the ferrous state, that CYP can bind oxygen and CO. It is at this stage of the cycle that, under reduced oxygen tension, CYP can reduce certain substrates (see “Other Reactions” at the bottom of the catalytic cycle shown in Fig. 6-40). In the third step (C → D) oxygen binds to the ferrous iron, which transfers an electron to oxygen to form ferrisuperoxo anion (ie, ferric-bound superoxide anion), designated $\text{Cys-Fe}^{\text{III}}\text{O}_2^-$. At this stage the cycle can be interrupted (uncoupled) to release superoxide anion and restore the enzyme to its resting (ferric) state (see “Other Reactions” in Fig. 6-40). In the fourth step (D → E), a second electron is introduced from NADPH-cytochrome P450 reductase, which is delocalized over the thiolate bond, to form the supernucleophilic ferriperoxo intermediate $^-\text{Cys-Fe}^{\text{III}}\text{O}_2^-$. Uncoupling of the cycle at this stage releases hydrogen peroxide and restores the enzyme to its resting (ferric) state (see “Other Reactions” in Fig. 6-40). In the fifth step (E → F), addition of a proton (H^+) converts the supernucleophilic ferriperoxo intermediate to its corresponding hydroperoxide, the ferrihydroperoxy intermediate $^-\text{Cys-Fe}^{\text{III}}\text{OOH}$. In the sixth step (F → G), addition of a second proton and release of water converts the ferrihydroperoxy intermediate to compound I, an iron^{IV}-oxo porphyrin radical cation species (an oxidizing species previously described in the section “Peroxidase-Dependent Cooxidation”). The formation of compound I ($\text{por}^+\text{Fe}^{\text{IV}}=\text{O}$) by protonation of the ferrihydroperoxy intermediate involves the heterolytic cleavage of oxygen with the 2-electron oxygen atom going to water, a reaction facilitated by the strong electron-donating effects of the heme thiolate anion. Heterolytic (2-electron) cleavage of oxygen to produce compound I places the iron in the perferryl (Fe^{V}) oxidation state, which is a considerably stronger oxidant than that formed by homolytic cleavage of oxygen, which produces the less reactive $\text{Por Fe}^{\text{IV}}-\text{OH}$ with iron in oxidation state IV. (Note: It is somewhat confusing that compound I is written as $\text{por}^+\text{Fe}^{\text{IV}}=\text{O}$ because, without taking the porphyrin ring into account, the formula gives the erroneous impression that the iron is in the Fe^{IV} [ferryl] state, whereas it is actually in the Fe^{V} [perferryl] state.) In the seventh step (G → H), the highly electrophilic oxygen from compound I is transferred to the substrate (RH) to produce metabolite (ROH). In the final step (H → A), the metabolite is released, which restores the enzyme to its initial resting (ferric) state.

Compound I is the electrophilic oxo species responsible for the vast majority of CYP-catalyzed reactions (Hrycay and Bandiera, 2012). It can be formed as described above with NADPH and oxygen, or it can be formed by oxygen transfer from various organic hydroperoxides and peracids (X-OOH , such as cumene hydroperoxide, *tert*-butylhydroperoxide, and *meta*-chloroperbenzoic acid) in a one-step reaction called the “peroxide shunt,” as shown in “Other Reactions” in Fig. 6-40. Formation of CYP compound I from peroxy compounds ($\text{P450} + \text{X-OOH} \rightarrow \text{P450 compound I} + \text{X-OH}$) is identical to the formation of compound I in peroxidases (see the section “Peroxidase-Dependent Cooxidation”). However, by virtue of its unusual fifth ligand (the heme thiolate from cysteine) and, perhaps more importantly, its active site topology, CYP can catalyze a far greater array of oxidative reactions (or catalyze them much faster) than those typically seen with peroxidases (even chloroperoxidase, which is unusual among peroxidases for containing a Cys thiolate as the fifth ligand to the heme like that in CYP). CYP reactions supported by organic peroxides and peracids are not affected by CO, an inhibitor of reactions supported by NADPH/O_2 .

Although P450 compound I generated by the peroxide shunt is as catalytically versatile as that generated by NADPH/O_2 , differences in the ratio of metabolites formed from a single substrate, differences in the relative rates of oxidation of 2 or more substrates, and differences in kinetic isotope effects (the influence of deuterium

Other reactions

One-electron reduction	C (Cys—Fe ^{II} RH)	→	A (Cys—Fe ^{III} + RH [•])
Superoxide anion production	D (Cys—Fe ^{III} O ₂ ⁻ RH)	→	B (Cys—Fe ^{III} RH) + O ₂ ⁻
Hydrogen peroxide production	E (-Cys—Fe ^{III} O ₂ ⁻ RH) + 2H ⁺	→	B (Cys—Fe ^{III} RH) + H ₂ O ₂
Hydrogen peroxide shunt	B (Cys—Fe ^{III} RH) + H ₂ O ₂	→	F (-Cys—Fe ^{III} OOH RH) + H ⁺

Figure 6-40. Catalytic cycle of cytochrome P450. Cytochrome P450 is represented as Cys-Fe^{III}, where Cys represents the fifth ligand (a cysteine thiolate) to the ferric heme iron. RH and ROH represent the substrate and product (hydroxylated metabolite), respectively. The intermediates in the catalytic cycle are as follows: A, ferric resting state; B, substrate bound; C, ferrous intermediate; D, ferrisuperoxo anion intermediate; E, ferriperoxo intermediate with an electron delocalized over the Cys thiolate bond; F, ferrihydroperoxy intermediate (with a negative charge on the Cys thiolate bond); G, compound I, an iron^V-oxo porphyrin cation, which is responsible for most substrate oxidation reactions; H, enzyme in its resting state prior to the release of a product formed by hydrogen abstraction followed by oxygen rebound (see text for details). Fe^{II}, Fe^{III}, Fe^{IV}, and Fe^V refer to iron in the ferrous, ferric, ferryl, and perferryl state, respectively. It should be noted that although it is written as por⁺Fe^{IV}=O, compound I is in the highly oxidized perferryl (Fe^V) state when the oxidation state of the porphyrin ring is also taken into account.

substitution at the site of oxidation) have led to the “multiple oxidants” hypothesis. The concept is supported by the finding that site-directed mutagenesis of a highly conserved threonine residue in bacterial and mammalian CYP enzymes can differentially affect reaction rates. For example, site-directed mutagenesis (Thr268Ala) of the bacterial enzyme CYP102A1 (P450BM3) increases the rate of sulfoxidation relative to *N*-demethylation of a single substrate, namely, dimethyl-(4-methylsulfanylphenyl)amine, whereas another mutation (Phe87Ala) has the opposite effect. Although the concept that CYP forms 2 or more oxidizing species is well accepted, the basis for the multiplicity is a source of considerable debate (Chandrasena *et al.*, 2004; Jin *et al.*, 2004; Newcomb and Chandrasena, 2005; Sheng *et al.*, 2009; Hrycay and Bandiera, 2012). The 2 major competing theories are the 2-state and the 2-oxidant hypotheses, both of which have supporting evidence. The 2-state

hypothesis posits that compound I is the only oxidizing species but it exists in 2 states, a low-spin state (that favors *N*-demethylation) and a high-spin state (that favors sulfoxidation) (Newcomb and Chandrasena, 2005; Hrycay and Bandiera, 2012). The 2-oxidant hypothesis posits that compound I is the major electrophilic oxidizing species but that its precursor, the ferrihydroperoxy intermediate (-Cys-Fe^{III}OOH), can function as a relatively strong nucleophilic but weak electrophilic oxidizing species (Chandrasena *et al.*, 2004; Jin *et al.*, 2004; Sheng *et al.*, 2009). This is supported by the observation that hydrogen peroxide (which does not form compound I but instead forms the preceding ferrihydroperoxy intermediate or its equivalent, namely, ferric iron-bound hydrogen peroxide) can support certain reactions that are not supported by organic hydroperoxides and peracids. The 2 mechanisms of generating multiple oxidizing species are not mutually exclusive and both may be

needed to explain all the catalytic properties of CYP. There are also competing theories concerning the mechanism of substrate oxidation by P450 compound I (Hrycay and Bandiera, 2012). Hereafter, the mechanism of carbon hydroxylation is discussed in terms of just one possibility, namely, hydrogen atom transfer (HAT) from the site of substrate hydroxylation by compound I to form a carbon radical followed by oxygen rebound in a nonconcerted, stepwise manner even though experiments with so-called ultrarapid radical clocks support a nonradical mechanism (Newcomb and Chandrasena, 2005; Hrycay and Bandiera, 2012). In reactions involving heteroatoms (N and S) the initial step involves (among other possibilities) single electron transfer (SET) leading to *S*- and *N*-oxygenation or HAT leading to *S*- and *N*-dealkylation, as discussed later in this section (Li *et al.*, 2009a; Roberts and Jones, 2010).

CYP catalyzes several types of oxidation reactions, including:

1. Hydroxylation of an aliphatic or aromatic carbon
2. Epoxidation of a double bond
3. Heteroatom (*S*-, *N*-, and *I*-) oxygenation and *N*-hydroxylation
4. Heteroatom (*O*-, *S*-, and *N*-) dealkylation
5. Oxidative group transfer
6. Cleavage of esters and carbamates
7. Dehydrogenation

In the first 3 cases, oxygen from P450 compound I is incorporated into the substrate, which otherwise remains intact. In the fourth case, oxygenation of the substrate is followed by a rearrangement reaction leading to cleavage of an amine (*N*-dealkylation) or an ether (*O*- and *S*-dealkylation). Oxygen from P450 compound I is incorporated into the alkyl-leaving group, producing an aldehyde or ketone. In the fifth case, oxygenation of the substrate is followed by a rearrangement reaction leading to loss of a heteroatom (oxidative group transfer). The sixth case, the cleavage of esters and carbamates, resembles heteroatom dealkylation in that the functional group is cleaved with incorporation of oxygen from P450 compound I into the leaving group, producing an aldehyde. In the seventh case, 2 hydrogens are abstracted from the substrate with the formation of a double bond (C=C, C=O, or C=N), with the reduction of oxygen from P450 compound I to water. It should be noted that this long list of reactions does not encompass all the reactions catalyzed by CYP (Guengerich, 2001b, 2007). CYP can catalyze reductive reactions (such as azo-reduction, nitro-reduction, *N*-oxide reduction, sulfoxide reduction, and reductive dehalogenation), ring expansion or ring formation, dearylation, dearomatization, isomerization (such as the conversion of PGH₂ to thromboxane and prostacyclin), and oxidative dehalogenation (as described previously for FMO; see Fig. 6-38). During the synthesis of steroid hormones, CYP catalyzes the cleavage of carbon-carbon bonds, which occurs during the conversion of cholesterol to pregnenolone by cholesterol side-chain cleavage enzyme (CYP11A1, which is also known as P450_{sc}) and the aromatization of a substituted cyclohexane, which occurs during the conversion of androgens to estrogens by aromatase (CYP19A1, also known as CYP19 and P450_{arom}).

Examples of aliphatic and aromatic hydroxylation reactions catalyzed by CYP are shown in Figs. 6-41 and 6-42, respectively. The hydroxylation of aromatic hydrocarbons may proceed via an oxirane intermediate (ie, an arene oxide) that isomerizes to the corresponding phenol. Alternatively, aromatic hydroxylation can proceed by a mechanism known as direct insertion. The *ortho*- and *para*-hydroxylation of chlorobenzene proceed via 2,3- and 3,4-epoxidation, whereas *meta*-hydroxylation proceeds by direct insertion, as shown in Fig. 6-43. When aromatic hydroxylation involves direct insertion, hydrogen abstraction (ie, cleavage of the

C-H bond) is the rate-limiting step, so that substitution of hydrogen with deuterium or tritium considerably slows the hydroxylation reaction. This *isotope effect* is less marked when aromatic hydroxylation proceeds via an arene oxide intermediate. Arene oxides are electrophilic and, therefore, potentially toxic metabolites that are detoxified by such enzymes as epoxide hydrolase (see Figs. 6-8 to 6-10) and GST (see the section “Glutathione Conjugation”). Depending on the ring substituents, the rearrangement of arene oxides to the corresponding phenol can lead to an intramolecular migration of a substituent (such as hydrogen or a halogen) from one carbon to the next. This intramolecular migration occurs at the site of oxidation and is known as the NIH shift, so named for its discovery at the National Institutes of Health.

Aliphatic hydroxylation involves insertion of oxygen into a C-H bond. The initial step involves HAT to form a carbon radical followed by oxygen rebound, shown as follows:

In the case of simple, straight-chain hydrocarbons, such as *n*-hexane, aliphatic hydroxylation occurs at both the terminal methyl groups and the internal methylene groups. In the case of fatty acids (both saturated and unsaturated) and their derivatives (ie, retinoic acid and eicosanoids such as prostaglandins and leukotrienes), aliphatic hydroxylation occurs at the ω -carbon (terminal methyl group) and the ω -1 carbon (penultimate carbon), as shown for lauric acid in Fig. 6-41. For thermodynamic reasons, most CYP enzymes preferentially catalyze the ω -1 hydroxylation of fatty acids and their derivatives, but one group of CYP enzymes (those encoded by the CYP4 gene family) preferentially catalyzes the less energetically favorable ω -hydroxylation of fatty acids, which can be further oxidized to dicarboxylic acids and undergo chain shortening by β -oxidation (Baer and Rettie, 2006; Johnston *et al.*, 2011).

Like CYP, the molybdoenzymes AO and XO can also catalyze the carbon oxidation of xenobiotics as outlined in the section “Molybdenum Hydroxylases (Molybdoenzymes).” As an electrophilic oxidizing enzyme, CYP generally prefers to catalyze the oxidation of carbon atoms with a high electron density, whereas the nucleophilic oxidizing enzymes AO and XO preferentially catalyze the oxidation of carbon atoms with a low electron density (such as the sp² carbon atom double bonded to a nitrogen atom in various nitrogen heterocycles). For this reason, xenobiotics that are good substrates for CYP enzymes tend to be poor substrates for AO, and vice versa (Pryde *et al.*, 2010).

Xenobiotics containing a carbon-carbon double bond (ie, alkenes) can be epoxidated (ie, converted to an oxirane) in an analogous manner to the oxidation of aromatic compounds to arene oxides. Just as arene oxides can isomerize to phenols, so aliphatic epoxides can isomerize to the corresponding ene-ol, the formation of which may involve an intramolecular migration (NIH shift) of a substituent at the site of oxidation (examples of intramolecular shifts accompanying epoxidation are given in the section “Activation of Xenobiotics by Cytochrome P450”). Like arene oxides, aliphatic epoxides are also potentially toxic metabolites that are inactivated

Figure 6-41. Examples of reactions catalyzed by cytochrome P450: hydroxylation of aliphatic carbon.

by other xenobiotic-metabolizing enzymes such as epoxide hydrolase and GST. Alkynes can be epoxidated by CYP to ketocarbenes (which can be further oxidized to carboxylic acids). The conversion of an alkyne to a ketocarbene via epoxidation or other possible oxidation intermediates is shown in the following scheme:

Oxidation of some aliphatic alkenes and alkynes produces metabolites that are sufficiently reactive to bind covalently to the heme moiety of CYP, a process known as suicide inactivation or MDI (discussed later in the section “Inhibition of Cytochrome P450”). As previously discussed in the section “Epoxide Hydrolases,” not all epoxides are highly reactive electrophiles. Although the 3,4-epoxidation of coumarin produces a hepatotoxic metabolite, the 10,11-epoxidation of carbamazepine produces a stable, relatively nontoxic metabolite (Fig. 6-43). EETs are endogenous epoxides with vasodilatory, anti-inflammatory, and angiogenic properties (Imig and Hammock, 2009; Wang *et al.*, 2010c). They are formed

by CYP2C8, CYP2C9, and CYP2J2 (discussed later in this section) and inactivated by sEH (see the section “Epoxide Hydrolases”).

In the presence of NADPH and O_2 , liver microsomes catalyze the oxygenation of several sulfur-containing xenobiotics, including chlorpromazine, cimetidine, lansoprazole, pantoprazole, and omeprazole. Sulfur-containing xenobiotics can potentially undergo 2 consecutive sulfoxidation reactions: one that converts the sulfide (S) to the sulfoxide (SO), which occurs during the sulfoxidation of chlorpromazine and cimetidine, and one that converts the sulfoxide (SO) to the sulfone (SO_2), which occurs during the sulfoxidation of omeprazole and lansoprazole, as shown in Fig. 6-44. Albendazole is converted first to a sulfoxide and then to a sulfone. Both CYP and FMO can sulfoxidate sulfides to sulfoxides ($S \rightarrow SO$) but only CYP can convert sulfoxides to sulfones ($SO \rightarrow SO_2$) (see the section “Flavin Monooxygenases”) (Testa and Krämer, 2008, 2010). Accordingly, the sulfoxidation of the proton pump inhibitors omeprazole, lansoprazole, and pantoprazole to sulfones is catalyzed by CYP (CYP3A4) and not by FMO. Examples of sulfoxidation reactions catalyzed by FMO and/or CYP are shown in Figs. 6-38B and 6-44. In the presence of NADPH and O_2 , liver microsomes catalyze the oxygenation of several nitrogen-containing xenobiotics, including chlorpromazine, doxylamine, ofloxacin, morphine, nicotine, MPTP, methapyrilene, methaqualone, metronidazole, pargyline, pyridine, senecionine, strychnine, TMA, trimipramine, and verapamil, all of which are converted to stable *N*-oxides. Whereas *S*-oxygenation might be catalyzed by both CYP and FMO, *N*-oxygenation is more likely to be catalyzed by just one of these enzymes. FMO

Figure 6-42. Examples of reactions catalyzed by cytochrome P450: hydroxylation of aromatic carbon.

prefers to *N*-oxygenate aliphatic amines (particularly tertiary and cyclic amines) with a highly nucleophilic/basic nitrogen atom (pK_a 5–10) but, in contrast to CYP, FMO cannot *N*-oxygenate aromatic amines, for which reason the *N*-oxygenation of pyridines and (iso)quinolones is usually catalyzed only by CYP, as is the case for pyridine-containing xenobiotics such as the tobacco-specific nitrosamine NNK and the antihistamine temelastine, and the isoquinoline-containing muscle relaxant 6,7-dimethoxy-4-(4'-chlorobenzyl)isoquinoline. Methods to distinguish the role of CYP versus FMO in microsomal *N*- and *S*-oxygenation reactions are described in the section “Flavin Monooxygenases.”

Although direct oxygen transfer is possible (Li *et al.*, 2009a), the initial step in heteroatom oxygenation by CYP could involve SET from the heteroatom (*N*, *S*, or *I*) to P450 compound I, shown as follows for sulfoxidation:

SET from *N*, *O*, or *S* to P450 compound I may also be the initial step in heteroatom dealkylation, but in this case abstraction of the electron from the heteroatom is quickly followed by abstraction of a proton (H^+) from the α -carbon atom (the carbon atom attached to the heteroatom) to form a carbon radical. Oxygen rebound leads

to hydroxylation of the α -carbon, which then rearranges to form the corresponding aldehyde or ketone with cleavage of the α -carbon from the heteroatom, as shown in the following scheme for the *N*-dealkylation of an *N*-alkylamine:

Figure 6-43. Examples of reactions catalyzed by cytochrome P450: epoxidation.

Alternatively, it seems more likely that the initial step in heteroatom dealkylation may be HAT from the α -carbon atom to compound I to produce a carbon radical that undergoes oxygen rebound and rearrangement as shown in the following scheme (Li *et al.*, 2009a; Roberts and Jones, 2010):

In general, CYP catalyzes the *N*-dealkylation, not the *N*-oxygenation, of amines. *N*-Oxygenation by CYP can occur if the nitrogen is next to an electron-donating group (making the nitrogen electron rich) or if α -protons are either absent (eg, aromatic amines) or inaccessible (eg, quinidine). In the case of aromatic amines (anilines; *aryl*-NH₂), *N*-oxidation by CYP usually results in the formation of hydroxylamines (*aryl*-NHOH). Some hydroxylamines are further oxidized to the corresponding nitroso metabolite, as observed with sulfamethoxazole (*aryl*-NH₂ → *aryl*-NOH → *aryl*-NO). Primary aromatic amides (*aryl*-CONH₂) are not substrates for *N*-oxidation, but secondary aromatic amides (*aryl*-NHCOR) are often *N*-hydroxylated by CYP (often by CYP1A2) to produce *N*-hydroxyamines (also known as hydroxamic acids). *N*-Hydroxylamines and hydroxyamides are of toxicological interest because under acidic conditions they can dissociate to form reactive nitrenium ions. Phenacetin, an aromatic amide (*aryl*-NH-CO-CH₃), causes kidney toxicity because it is converted by *N*-hydroxylation to a hydroxamic acid (*aryl*-NOH-CO-CH₃) that in the low pH of urine undergoes acid-catalyzed conversion to a reactive nitrenium ion (*aryl*-NOH-CO-CH₃ + H⁺ → *aryl*-N⁺-CO-CH₃ + H₂O) (Testa and Krämer, 2008, 2010). *N*-Hydroxylation of aromatic amines with subsequent *O*-acetylation or *O*-sulfonation is 1 mechanism by which tumorigenic aromatic amines, such as 2-AAF and 4-aminobiphenyl, are converted to electrophilic reactive intermediates that bind covalently to DNA (discussed later in the sections “Glucuronidation and Formation of Acyl-CoA Thioesters” and “Acetylation”).

Numerous xenobiotics are *N*-, *O*-, or *S*-dealkylated by CYP (but not by FMO), and some examples of these heteroatom dealkylation reactions are shown in Fig. 6-45. The dealkylation of xenobiotics containing an *N*-, *O*-, or *S*-methyl group results in the formation of formaldehyde, which can easily be measured by a simple colorimetric assay to monitor the demethylation of substrates *in vitro*. The expiration of ¹³C- or ¹⁴C-labeled carbon dioxide following the demethylation of drugs containing a ¹³C- or ¹⁴C-labeled methyl group has been used to probe CYP activity *in vivo* (Watkins, 1994). The activity of the human CYP enzymes involved in the *N*-demethylation of aminopyrine, erythromycin, and caffeine can be assessed by this technique. Although caffeine has 3 *N*-methyl

groups, all of which can be removed by CYP, the major pathway in humans involves *N*₃-demethylation of caffeine to paraxanthine (see Fig. 6-45). Fig. 6-45 also presents an example of a xenobiotic (octamethylcyclotetrasiloxane, a component of cosmetics and deodorants) that undergoes silicone demethylation by CYP (Varaparth *et al.*, 1999).

Whereas the metabolism of *N*-methyl amines by CYP generally results in *N*-demethylation, with the hydroxylation of the methyl group leading to the release of formaldehyde, the metabolism of *N*-methyl amides and carbamates by CYP can result in the formation of a stable methyl-hydroxylated metabolite, one that does not release formaldehyde (which would otherwise complete an *N*-demethylation reaction) possibly because of the hydroxymethyl metabolite formation of a 6-membered configuration that is stabilized by hydrogen bonding, illustrated as follows:

Zolpidem and camazepam are amide- and carbamate-containing drugs, respectively, that undergo such *N*-methyl-hydroxylation reactions.

Seto and Guengerich have shown that the *N*-demethylation and *N*-deethylation of *N*-ethyl-*N*-methylaniline not only proceed at different rates (with *N*-demethylation proceeding up to 20 times faster than *N*-deethylation) but also proceed by different mechanisms (Seto and Guengerich, 1993; Guengerich, 2001a). The initial step in the *N*-deethylation reaction involves HAT from the α -carbon atom (ie, the carbon atom attached to the nitrogen), whereas the initial step in the *N*-demethylation reaction involves a much faster reaction, namely, a SET from the nitrogen atom, which is transferred to P450 compound I. Although the *N*-demethylation of *N,N*-substituted amines proceeds by the relatively rapid process of SET, the *N*-demethylation of *N,N*-substituted amides, where the adjacent carbonyl causes electrons to be withdrawn from the nitrogen atom, proceeds by the relatively slow process of HAT, for which reason the latter reactions, in contrast to the former, show a large intrinsic isotope effect when the hydrogen atoms are replaced with deuterium (because it requires more energy to break a C-D bond than a C-H bond).

In addition to *N*-dealkylation, some primary amines can also undergo oxidative deamination by CYP, which is an example of oxidative group transfer. The mechanism of oxidative deamination is similar to that of *N*-dealkylation: the α -carbon adjacent to the primary amine is hydroxylated, which produces an unstable intermediate that rearranges to eliminate ammonia with the formation of an aldehyde or ketone. The conversion of amphetamine to phenylacetone is an example of CYP-catalyzed oxidative deamination, as shown in Fig. 6-46. However, primary aliphatic amines tend to be poor substrates for CYP; in fact, primary alkylamines, such as the *N*-demethylated metabolite of fluoxetine, are metabolically stable and potent inhibitors of CYP inhibitors (discussed later in the section “Inhibition of Cytochrome P450”). Oxidative deamination is also catalyzed by MAO and FMO (Testa and Krämer, 2008, 2010).

Figure 6-44. Examples of reactions catalyzed by cytochrome P450: heteroatom oxygenation.

In the example given above, however, the substrate, amphetamine, contains an α -methyl group that renders it a poor substrate for MAO (as described in the section “Amine Oxidases”).

In addition to oxidative deamination, CYP catalyzes 2 other types of oxidative group transfer, namely, oxidative desulfuration and oxidative dehalogenation. In all cases the heteroatom (N, S, or halogen) is replaced with oxygen. As shown in Fig. 6-47, oxidative desulfuration converts parathion, which has little insecticidal activity, to paraoxon, which is a potent insecticide. The same reaction converts thiopental to pentobarbital. Diethyldithiocarbamate methyl ester, a metabolite of disulfiram, also undergoes oxidative desulfuration. The initial reaction involves S-oxidation by CYP or FMO to a sulfine ($R_1R_2C=S \rightarrow R_1R_2C=S^+-O^-$). In the presence of GSH and GST, this sulfine either is converted back to the parent compound ($R_1R_2C=S^+-O^- + 2GSH \rightarrow R_1R_2C=S + H_2O$) or undergoes desulfuration ($R_1R_2C=S + 2GSH \rightarrow R_1R_2C=O + GSSG + H_2S$) (Madan *et al.*, 1994). CYP catalyzes both reductive and oxidative dehalogenation reactions (Guengerich, 1991). During oxidative dehalogenation,

a halogen and hydrogen from the same carbon atom are replaced with oxygen ($R_1R_2CHX \rightarrow R_1R_2CO$) to produce an aldehyde or acylhalide, as shown in Fig. 6-19 for the conversion of halothane ($CF_3CHClBr$) to trifluoroacetylchloride (CF_3COCl). Oxidative dehalogenation does not involve a direct attack on the carbon-halogen bond, but it involves the formation of an unstable halohydrin by oxidation of the carbon atom bearing the halogen substituent. The carbon-halogen bond is broken during the rearrangement of the unstable halohydrin. When the carbon atom contains a single halogen, the resulting product is an aldehyde, which can be further oxidized to a carboxylic acid or reduced to a primary alcohol. When the carbon atom contains 2 halogens, the dihalohydrin intermediate rearranges to an acylhalide, which can be converted to the corresponding carboxylic acid (see Fig. 6-19). Aldehydes and, in particular, acylhalides are reactive compounds that can bind covalently to protein and other critical cellular molecules. The immune hepatitis caused by repeated exposure of humans to halothane and related volatile anesthetics is dependent on oxidative dehalogenation by

Figure 6-45. Examples of reactions catalyzed by cytochrome P450: heteroatom dealkylation.

Figure 6-46. Examples of reactions catalyzed by cytochrome P450: oxidative group transfer.

Figure 6-47. Examples of reactions catalyzed by cytochrome P450 that resemble hydrolytic reactions: cleavage of a thiophosphate (parathion), a carboxylic acid ester (2,6-dimethyl-4-phenyl-3,5-pyridinecarboxylic acid diethyl ester), and a carbamate (loratadine).

CYP, with neoantigens produced by the trifluoroacetylation of proteins, as shown in Fig. 6-19. Another example of oxidative dehalogenation by CYP is provided by studies of dasatinib metabolism by Li *et al.* (2009b), who, in order to prevent the formation of a reactive quinoneimine metabolite that bound to GSH, used fluoro and chloro substitution in an attempt to block *para*-hydroxylation of the substituted aniline in dasatinib, which is a metabolism-dependent inhibitor of CYP3A4. The halogen substitutions did not block the formation of GSH adducts of the *para*-hydroxylated metabolite. The mechanism of oxidative dehalogenation of the substituted aniline in dasatinib (followed by glutathionylation) was presumed to arise from an epoxide intermediate that underwent dehalogenation during its conjugation with GSH. Another example of oxidative defluorination is shown in Fig. 6-38 for the oxidative defluorination of 4-fluoro-*N*-methylaniline by FMO (Driscoll *et al.*, 2010).

CYP can catalyze the reductive dehalogenation of halogenated alkanes (see Figs. 6-18 and 6-19) and the reduction of certain azo- and nitro-containing xenobiotics, although these latter reactions are largely catalyzed by gut microflora (see Figs. 6-11 and 6-12). The ability of CYP to reduce xenobiotics can be understood from the catalytic cycle shown in Fig. 6-40. Binding of a substrate to CYP is followed by a one-electron reduction by NADPH-cytochrome P450 reductase. Under aerobic conditions, reduction of the heme iron to the ferrous state permits binding of oxygen. Anaerobic conditions, in contrast, interrupt the cycle at this point, which allows CYP to reduce those substrates capable of accepting an electron. Therefore, CYP can catalyze reduction reactions, such as azo-reduction, nitro-reduction, *N*-oxide reduction, sulfoxide reduction, and reductive dehalogenation, particularly under conditions of low oxygen tension. In effect, the substrate rather than molecular oxygen accepts electrons and is reduced. In fact, oxygen acts as an inhibitor of these reactions because it competes with the substrate for the reducing equivalents. The toxicity of many halogenated alkanes is dependent on their biotransformation by reductive dehalogenation. The first step in reductive dehalogenation is a one-electron reduction catalyzed by CYP, which produces a potentially toxic, carbon-centered radical and inorganic halide. The conversion of CCl₄ to a trichloromethyl radical and other toxic metabolites is shown in Fig. 6-18. The activation of the prodrug AQ4N (ie, 1,4-bis{[2-(dimethylamino-*N*-oxide)ethyl]amino}-5,8-dihydroxyanthracene-9,10-dione) by *N*-oxide reduction to form 4QA (ie, 1,4-bis{[2-(dimethylamino)ethyl]amino}-5,8-dihydroxyanthracene-9,10-dione), a potent topoisomerase II inhibitor, by the hypoxia-inducible enzymes CYP2S1 and CYP2W1 represents a potentially new cancer chemotherapy, as discussed later in this section.

The oxidative desulfuration of parathion (see Fig. 6-46) involves the production of an intermediate that rearranges to paraoxon (as shown in Fig. 6-47). This same intermediate can decompose to 4-nitrophenol and diethylphosphorothioic acid, which are the same products formed by the hydrolysis of parathion (Fig. 6-47). In addition to facilitating the hydrolysis of phosphoric acid esters, CYP also catalyzes the cleavage of certain carboxylic acid esters and carbamates, as shown in Fig. 6-47. Carboxylic acid esters typically are cleaved by carboxylesterases and cholinesterases (see the section "Hydrolysis"), which results in the formation of an acid and an alcohol ($R_1COOCH_2R_2 + H_2O \rightarrow R_1COOH + R_2CH_2OH$). In contrast, CYP converts carboxylic acid esters to an acid plus aldehyde ($R_1COOCH_2R_2 + [O] \rightarrow R_1COOH + R_2CHO$), as shown in Fig. 6-47. The deacylation of loratadine, a carbamate, is the major route of biotransformation of this non-sedating antihistamine. The reaction is catalyzed predominantly by CYP (namely, CYP3A4 with a minor contribution from CYP2D6), with little contribution from carboxylesterases (Yumibe *et al.*, 1996).

CYP can also catalyze the dehydrogenation of a number of compounds, including acetaminophen, nifedipine, and related dihydropyridine calcium channel blockers, sparteine, nicotine, and testosterone, as shown in Fig. 6-48. Dehydrogenation by CYP converts acetaminophen to its hepatotoxic metabolite, *N*-acetylbenzo-*p*-quinoneimine (NAPQI), as shown in Fig. 6-35. The formation of a double bond during the conversion of digitoxin (dt₃) to 15'-dehydro-dt₃ leads to cleavage of the terminal sugar residue to produce digitoxigenin bisdigitoxoside (dt₂) (Fig. 6-48), which can similarly be converted to 9'-dehydro-dt₂, which undergoes digitoxosyl cleavage to digitoxigenin monodigitoxoside (dt₁). In contrast to digitoxin, the latter metabolite is an excellent substrate for glucuronidation. In rats, the CYP enzymes responsible for converting digitoxin to dt₁ (namely, the CYP3A enzymes) and the UGT responsible for glucuronidating dt₁ are inducible by dexamethasone, PCN, and spironolactone, all of which protect rats from the toxic effects of digitoxin. The dehydrogenation of nicotine produces nicotine Δ^{1'}5'-iminium ion, which is oxidized by cytosolic AO to cotinine, a major metabolite of nicotine excreted in the urine of cigarette smokers (see Fig. 6-48). Although nicotine can be *N*-oxygenated by FMO, dehydrogenation by CYP2A6 is responsible for 80% of the clearance of nicotine from cigarette smoking (Hukkanen *et al.*, 2005).

Testosterone is dehydrogenated by CYP to 2 metabolites: 6-dehydrotestosterone, which involves formation of a carbon-carbon double bond, and androstenedione, which involves formation of a carbon-oxygen double bond, as shown in Fig. 6-48. The conversion of testosterone to androstenedione is one of several cases where CYP converts a primary or secondary alcohol to an aldehyde or ketone, respectively. The reaction can proceed by formation of a *gem*-diol (2 hydroxyl groups on the same carbon atom), with subsequent dehydration to a keto group, as shown in Fig. 6-25 for the conversion of ethanol to acetaldehyde. However, *gem*-diols are not obligatory intermediates in the oxidation of alcohols by CYP, and in fact the conversion of testosterone to androstenedione by CYP2B1 (the major phenobarbital-inducible CYP enzyme in rats) does not involve the intermediacy of a *gem*-diol but proceeds by direct dehydrogenation (Fig. 6-48). In contrast, a *gem*-diol is involved in the formation of androstenedione from *epi*-testosterone (which is identical to testosterone except the hydroxyl group at C₁₇ is in the α-configuration, not the β-configuration) (Wood *et al.*, 1988). The fact that formation of androstenedione from *epi*-testosterone involves formation of a *gem*-diol, whereas its formation from testosterone does not, makes it difficult to generalize the mechanism by which CYP converts alcohols to aldehydes and ketones.

Liver microsomes from all mammalian species contain numerous CYP enzymes (Table 6-11), each with the potential to catalyze the various types of reactions shown in Figs. 6-41 to 6-48. In other words, all of the CYP enzymes expressed in liver microsomes have the potential to catalyze xenobiotic hydroxylation, epoxidation, dealkylation, oxygenation, dehydrogenation, and so forth. The broad and often overlapping substrate specificity of liver microsomal CYP enzymes precludes the possibility of naming these enzymes for the reactions they catalyze, which are now categorized into families and subfamilies and named individually on the basis of their amino acid sequence. As shown in Tables 6-10 and 6-11, the CYP enzymes involved in xenobiotic biotransformation belong mainly to the CYP1, 2, and 3 gene families, although on a case-by-case basis CYP enzymes in other gene families play a key role in xenobiotic biotransformation. The CYP enzymes involved in endobiotic metabolism generally have the same name in all mammalian species. Some of the xenobiotic-biotransforming CYP enzymes have the same name in all mammalian species, whereas others are named in a species-specific manner. For example, all mammalian

Figure 6-48. Examples of reactions catalyzed by cytochrome P450: dehydrogenation.

species contain 2 CYP enzymes belonging to the CYP1A subfamily, and in all cases these are known as CYP1A1 and CYP1A2 because the function and regulation of these enzymes are highly conserved among mammalian species. The same is true of CYP1B1, 2E1, 2R1, 2S1, 2U1, and 2W1, all of which are highly conserved homologs that can be given the same name across mammalian species. In most other cases, functional or evolutionary relationships are not immediately apparent; hence, the CYP enzymes are named in a species-specific manner, and the names are assigned in chronological order regardless of the species of origin. For example, human liver microsomes express CYP2D6, but this is the only functional member of the CYP2D subfamily found in human liver. CYP2D7 and 2D8 are human pseudogenes. The other members of this subfamily (ie, CYP2D1-CYP2D5 and CYP2D9 onward) are the names given to CYP2D enzymes in other species.

Without exception, the levels and activity of each CYP enzyme have been shown to vary from one individual to the next, due to environmental and/or genetic factors. Decreased CYP enzymatic activity can result from (1) a genetic mutation that either blocks the synthesis of a CYP enzyme or leads to the synthesis of a catalytically compromised, inactive, or unstable enzyme, which gives rise to the PM and IM genotypes; (2) exposure to an environmental factor (such as an infectious disease or an inflammatory process) that suppresses CYP enzyme expression, or (3) exposure to a xenobiotic that inhibits or inactivates a preexisting CYP enzyme. By inhibiting

CYP, one drug can impair the biotransformation of another, which may lead to an exaggerated pharmacological or toxicological response to the second drug. In this regard, inhibition of CYP by a drug (and suppression of CYP by infection, vaccination, or inflammation) essentially mimics the effects of a genetic deficiency in CYP enzyme expression (ie, these environmental factors mimic the IM or PM genotype depending on the degree to which they decrease CYP activity). Genetic deficiencies in CYP expression, CYP inhibition, and, to a lesser extent, CYP suppression all contribute significantly to interindividual variability in drug metabolism and toxicity, and inhibition of CYP activity is a major cause of drug–drug interactions. Examples of the impact of these genetic and environmental factors on drug metabolism and toxicity are given later in this section in the overviews of individual CYP enzymes and in the section “Inhibition of Cytochrome P450.”

Increased CYP enzymatic activity can result from (1) gene duplication leading to overexpression of a CYP enzyme, which gives rise to the UM genotype; (2) gene mutations in the coding or promoter region that increase expression, activity, or stability of CYP; (3) exposure to drugs and other xenobiotics that induce the synthesis or retard the degradation of CYP; or (4) exposure to drugs and other xenobiotics that stimulate the activity of a preexisting enzyme (a process known as homotropic or heterotropic activation depending on whether the drug stimulates its own metabolism or the metabolism of other drugs, respectively). Activation of CYP has been

documented in vitro and in some in situ situations, such as the pronounced (up to 25-fold) activation of *R*-warfarin 10-hydroxylation by quinidine in rabbit liver microsomes and perfused rabbit liver (Chen *et al.*, 2004a). However, in general, activation does not appear to be a major cause of drug–drug interactions. Although duplication of functional CYP2D6 genes has been documented (and shown to be relevant to drug metabolism and safety [see the section “CYP2D6”]), induction of CYP by xenobiotics is the most common mechanism by which CYP enzyme activity is increased to a pharmacologically relevant extent. By inducing CYP, one drug can stimulate the metabolism of a second drug and thereby decrease or ameliorate its therapeutic effect. Enzyme induction is a particular concern when it compromises the therapeutic effectiveness of drugs that have a narrow therapeutic index and are being used to treat a life-threatening illness, such as anti-HIV drugs, antirejection drugs (such as cyclosporine and tacrolimus), and oral anticoagulants (such as warfarin), or when it is used with drugs that exhibit a quantal (all-or-nothing) dose–response relationship, such as oral contraceptive steroids (which either block or do not block ovulation and thereby provide or do not provide protection against pregnancy).

The environmental factors known to affect P450 levels include medications (eg, prescription drugs as well as herbal remedies), foods (eg, cruciferous vegetables, charcoal-broiled beef), social habits (eg, alcohol consumption, cigarette smoking), and disease status (diabetes, infection, inflammation, vaccination, liver and kidney disease, and both hyperthyroidism and hypothyroidism). When environmental factors influence CYP enzyme levels, considerable variation may be observed during repeated measures of xenobiotic biotransformation (eg, drug metabolism) in the same individual. Such variation is not observed when alterations in CYP activity are determined genetically.

Due to their broad substrate specificity, it is possible that 2 or more CYP enzymes can contribute to the metabolism of a single compound. Three human CYP enzymes, CYP1A2, CYP2E1, and CYP3A4, can convert the commonly used analgesic, acetaminophen, to its hepatotoxic metabolite, NAPQI (Figs. 6-34 and 6-48). It is also possible for a single CYP enzyme to catalyze 2 or more metabolic pathways for the same drug. For example, CYP2D6 catalyzes both the *O*-demethylation and 5-hydroxylation (aromatic ring hydroxylation) of methoxyphenamine, and CYP3A4 catalyzes the 3-hydroxylation and *N*-oxygenation of quinidine, the 1'- and 4-hydroxylation of midazolam, the *tert*-butyl-hydroxylation and *N*-dealkylation of terfenadine, and several pathways of testosterone oxidation, including 1 β -, 2 β -, 6 β -, and 15 β -hydroxylation and dehydrogenation to 6-dehydrotestosterone (Figs. 6-41 and 6-48).

The pharmacological or toxic effects of certain drugs are exaggerated in a significant percentage of the population due to a heritable deficiency in a CYP enzyme (Meyer, 1994; Tucker, 1994; Zhou *et al.*, 2009b). The observation that individuals who are genetically deficient in a particular CYP enzyme are PMs of one or more drugs illustrates a very important principle, namely, that the rate of elimination of drugs can be largely determined by a single CYP enzyme. This observation seems to contradict the fact that CYP enzymes have broad and overlapping substrate specificities. The resolution to this apparent paradox lies in the fact that although more than one human CYP enzyme can catalyze the biotransformation of a xenobiotic, they may do so with markedly different affinities. Consequently, xenobiotic biotransformation in vivo, where only low substrate concentrations are usually achieved, is often determined by the CYP enzyme with the highest affinity (lowest apparent K_m) for the xenobiotic. For example, the 5-hydroxylation of lansoprazole, which represents the key route of elimination of this proton pump inhibitor, is catalyzed by both

CYP2C19 and CYP3A4. However, these reactions are catalyzed by CYP3A4 with such low affinity that the 5-hydroxylation (and hence the clearance) of lansoprazole in vivo is largely determined by CYP2C19 (Pearce *et al.*, 1996b). When several CYP enzymes catalyze the same reaction, their relative contribution to xenobiotic biotransformation is determined by the kinetic parameter, V_{max}/K_m , which is a measure of in vitro intrinsic clearance at low substrate concentrations (<10% of K_m).

A drug whose clearance is largely determined by a single CYP enzyme (or any single route of elimination) is said to have high *victim* or *object* potential, meaning its rate of clearance will be decreased by genetic polymorphisms and inhibitory drugs that result in a loss of that particular CYP activity and increased by drugs and other xenobiotics that induce that particular CYP enzyme. For example, a drug that is largely cleared by CYP2D6 will be slowly metabolized in CYP2D6 PMs and rapidly metabolized in CYP2D6 UMs, whereas a drug whose clearance is largely determined by CYP3A4 will be slowly metabolized in the presence of ketoconazole (and other CYP3A4 inhibitors) and rapidly metabolized in the presence of rifampin or St. John's wort (and other CYP3A4 inducers). The extent to which genetic polymorphisms and CYP inhibitors/inducers impact the disposition of a drug (or any other xenobiotic) is determined by f_m , the fraction of clearance attributable to the affected enzyme. This principle applies to all xenobiotic-biotransforming enzymes and is explained in detail in Point 24 in the section “Introduction.” Point 24 also covers the principle of drug–drug interactions in terms of perpetrator–victim interactions (in which the disposition of one drug, the victim, is impacted by a single perpetrator such as an inhibitory drug or a genetic polymorphism) and perpetrator–perpetrator–victim interactions, otherwise known as “maximum exposure,” which involves the dramatic (synergistic) impact of 2 perpetrators blocking 2 parallel pathways of clearance of the victim drug (Collins *et al.*, 2006; Ogilvie and Parkinson, in press).

Accordingly, for drugs under development, considerable attention is paid to identifying which CYP enzyme or enzymes are involved in eliminating the drug, a process known as *reaction phenotyping* or *enzyme mapping*. Four in vitro approaches have been developed for reaction phenotyping (Ogilvie *et al.*, 2008). Each has its advantages and disadvantages, and a combination of approaches is usually required to identify which human CYP enzyme is responsible for metabolizing a xenobiotic. The 4 approaches to reaction phenotyping are as follows:

1. Correlation analysis, which involves measuring the rate of xenobiotic metabolism by several samples of human liver microsomes and correlating reaction rates with the variation in the level or activity of the individual CYP enzymes in the same microsomal samples. This approach is successful because the levels of the CYP enzymes in human liver microsomes vary enormously from sample to sample as shown in Table 6-12.
2. Chemical inhibition, which involves an evaluation of the effects of known CYP enzyme inhibitors on the metabolism of a xenobiotic by human liver microsomes. Chemical inhibitors of CYP, which are discussed later, must be used cautiously because most of them can inhibit more than one CYP enzyme. Some chemical inhibitors are metabolism-dependent inhibitors that require biotransformation to a metabolite that inactivates or noncompetitively inhibits CYP.
3. Antibody inhibition, which involves an evaluation of the effects of inhibitory antibodies against selected CYP enzymes on the biotransformation of a xenobiotic by human liver microsomes. Due to the ability of antibodies to inhibit selectively

Table 6-12

Specific Content of Individual Cytochrome P450 (CYP) Enzymes in Human Liver Microsomes (HLM)

		MEAN	RANGE (MINIMUM–MAXIMUM)	FOLD VARIATION (MAXIMUM/MINIMUM)
CYP1A2	17.7	25.1	3.26–65.5	20.1
CYP2A6	49.2	56.2	5.45–168	30.8
CYP2B6	6.86	6.72	4.05–14.9	3.7
CYP2C8	29.3	30.0	5.66–83.5	14.8
CYP2C9	80.2	76.3	40.2–115	2.9
CYP2C19	3.64	5.31	2.08–22.2	10.7
CYP2D6	11.5	17.2	6.16–36.4	5.9
CYP2E1	51.3	66.1	36.3–147	4.0
CYP3A4	64.0	60.4	6.22–270	43.4
CYP3A5	3.54	3.86	2.48–17.1	6.9
CYP3A7	ND	2.40	BLQ–9.39	NA
CYP3A43	1.30	4.10	BLQ–6.42	NA
CYP4A11	ND	21.8	9.29–46.5	5.0
P450 OR	ND	71.6	41.7–99.0	2.4

ND, not determined; BLQ, below limit of quantitation; NA, not applicable; P450 OR, NADPH-cytochrome P450 reductase.

*Data from Kawakami *et al.* (2011).

[†]Data from Ohtsuki *et al.* (2012).

and noncompetitively, this method alone can potentially establish which human CYP enzyme is responsible for biotransforming a xenobiotic. Unfortunately, the utility of this method is limited by the availability of specific inhibitory antibodies.

4. Biotransformation by purified or recombinant (cDNA-expressed) human CYP enzymes, which can establish whether a particular CYP enzyme can or cannot biotransform a xenobiotic, but it does not address whether that CYP enzyme contributes substantially to reactions catalyzed by human liver microsomes. The information obtained with purified or recombinant human CYP enzymes can be improved by taking into account large differences in the extent to which the individual CYP enzymes are expressed in human liver microsomes. The specific content of the major xenobiotic-biotransforming enzymes in human liver microsomes has been determined by mass spectrometry and the values are summarized in Table 6-12. The extrapolation of metabolic rates obtained with recombinant enzymes to those expected to occur in liver microsomes can be based on specific content, relative activity factors (RAF), or a combination of both called intersystem extrapolation factor (ISEF) (Proctor *et al.*, 2004; Ogilvie *et al.*, 2008).

Some CYP enzymes, such as CYP1A1 and CYP1B1, are expressed at such low levels in human liver microsomes that they do not contribute significantly to the hepatic biotransformation of xenobiotics that are excellent substrates for these enzymes. Other CYP enzymes are expressed in some but not all livers, as discussed later under each individual enzyme subheading. It should be

emphasized that reaction phenotyping *in vitro* is not always carried out with pharmacologically or toxicologically relevant substrate concentrations. As a result, the CYP enzyme that appears responsible for biotransforming the drug *in vitro* may not be the CYP enzyme responsible for biotransforming the drug *in vivo* (Ogilvie *et al.*, 2008). This may be particularly true of CYP3A4, which metabolizes several drugs with high capacity but low affinity.

Reaction phenotyping (often in conjunction with clinical observation) has been used to characterize the substrate specificity of many of the CYP enzymes expressed in human liver microsomes, as discussed later under each individual enzyme subheading.

Examples of reactions catalyzed by individual human CYP enzymes are shown in Figs. 6-41 to 6-48, and lists of substrates, inhibitors, and inducers for each CYP enzyme are given in Table 6-13. The examples listed in Table 6-13 are largely based on examples cited by the US FDA (<http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/DrugInteractionsLabeling/ucm080499.htm>), which has provided, where possible, the following lists to guide the conduct of *in vitro* and *in vivo* pharmacokinetic drug–drug interaction studies: (1) preferred and acceptable CYP substrates and chemical inhibitors for reaction phenotyping *in vitro*; (2) sensitive probe substrates to monitor CYP activity *in vivo* (a sensitive substrate is one whose clearance is largely [$>80\%$] determined by a single CYP enzyme such that loss of that CYP enzyme causes a 5-fold or higher increase in exposure); (3) drugs that are strong or weak inhibitors of CYP enzymes *in vivo*; (4) preferred and acceptable inhibitors and inducers for use as positive controls for CYP inhibition and induction studies *in vitro*; and (5) drugs that are effective

Note: All FDA classifications are based on information available as of February 21, 2012 at the following URL: <http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/DrugInteractionsLabeling/ucm093664.htm>.

^{*}Classified by the FDA as a "sensitive substrate" (ie, drugs whose plasma AUC values have been shown to increase by ≥ 5 -fold when coadministered with a known CYP inhibitor).

[†]FDA-preferred in vitro substrate, inhibitor, or inducer.

[‡]FDA-acceptable in vitro substrate, inhibitor, or inducer.

[§]FDA-provided examples of in vivo substrates, inhibitors, or inducers for oral administration. Substrates in this category have plasma AUCs that are increased by at least 2-fold (5-fold for CYP3A4 substrates) when coadministered with inhibitors of the enzyme. Inhibitors in this category increase the AUC of substrates for that enzyme by at least 2-fold (5-fold for CYP3A4). Inducers in this category decrease the plasma AUC of substrates for that enzyme by at least 30%.

^{**}Classified by the FDA as a "substrate with narrow therapeutic range" (ie, drugs whose exposure-response indicates that increases in their exposure levels by concomitant use of CYP inhibitors may lead to serious safety concerns such as torsades de pointes).

^{††}Classified by the FDA as a "weak inhibitor" (ie, caused a ≥ 1.25 -fold but < 2 -fold increase in plasma AUC or 20%–50% decrease in the clearance of sensitive CYP substrates when the inhibitor was given at the highest approved dose and the shortest dosing interval in clinical evaluations).

^{‡‡}Classified by the FDA as a "moderate inhibitor" (ie, caused a ≥ 2 -fold but < 5 -fold increase in plasma AUC or 50%–80% decrease in the clearance of sensitive CYP substrates when the inhibitor was given at the highest approved dose and the shortest dosing interval in clinical evaluations).

^{§§}Classified by the FDA as a "strong inhibitor" (ie, caused a ≥ 5 -fold increase in plasma AUC or ≥ 80 % decrease in the clearance of CYP substrates in clinical evaluations).

^{***}Classified by the FDA as a "moderate inducer" (ie, caused a ≥ 50 %–80% decrease in AUC of CYP substrates in clinical evaluations).

^{†††}Classified by the FDA as a "weak inducer" (ie, caused a ≥ 20 %–50% decrease in AUC of CYP substrates in clinical evaluations).

^{‡‡‡}Classified by the FDA as a "strong inducer" (ie, caused a ≥ 80 % decrease in AUC of CYP substrates in clinical evaluations).

The global features of the major xenobiotic-biotransforming human CYP enzymes are as follows:

1. Two CYP enzymes, namely, CYP2D6 and CYP3A4, metabolize the majority of orally effective drugs, but they often metabolize different drugs and they do not metabolize all drugs; consequently, there are many drugs whose clearance is largely determined by CYP enzymes other than CYP2D6 or CYP3A4. Interindividual variation in CYP2D6, which is largely confined to the liver, is largely determined by genetic factors, whereas interindividual variation in CYP3A4, which is expressed in liver and small intestine, is largely determined by environmental factors (such as inhibitory and inducing drugs).
2. The induction of CYP3A4 is often associated with induction of CYP2A6, 2B6, 2C8, 2C9, and 2C19. CYP1A2 and CYP2E1 are also inducible enzymes, but they are induced by different mechanisms and xenobiotics. Consequently, CYP1A2, 2E1, and 3A4 represent 3 distinct classes of inducible human CYP enzymes. CYP induction is invariably associated with the upregulation of other xenobiotic-biotransforming enzymes, as discussed later in the section “Induction of Cytochrome P450—Xenosensors.” CYP2D6 is considered a noninducible enzyme, although its levels increase during pregnancy and decrease following renal impairment (Rostami-Hodjegan *et al.*, 1999; Sit *et al.*, 2010).
3. Genetic polymorphisms have been identified for all of the human CYP enzymes involved in drug metabolism. Zhou *et al.* (2009a) estimated that each human CYP gene contains an average of ~15 nonsynonymous SNPs, many of which are associated with altered drug metabolism or susceptibility to disease (a selection of which will be discussed later under each individual enzyme subheading). The incidence of CYP polymorphisms varies greatly among different ethnic groups. In the case of CYP2D6, genetic polymorphisms are common among Caucasian and impact the metabolism, safety, and efficacy of many drugs, as summarized in Point 23 in the section “Introduction.” Based on CYP2D6 genotype, individuals can be categorized as PMs, IMs, EMs, and UMs (and the EMs can be subdivided into low, medium, and high EMs), as shown in Table 6-4. There is a vast literature describing SNPs and other genetic polymorphisms affecting the human CYP enzymes involved in xenobiotic biotransformation, too large—and often too confusing—to be summarized here (reviewed in Zhou *et al.*, 2009a). (Information on CYP genetic polymorphisms can be found at <http://www.cypalleles.ki.se>.) Genetic polymorphisms in the coding region can increase or decrease CYP activity, sometimes in a substrate-dependent manner, making generalizations difficult. They can also alter the stability of CYP enzymes without altering their enzymatic activity. Genetic polymorphisms in the promoter region can impair transcription (and thereby decrease CYP levels) or increase CYP levels by increasing its constitutive expression or inducibility by activated xenosensors. In many cases neither the impact of a particular SNP is known nor is it known in many cases whether the SNP is in linkage disequilibrium with another genetic polymorphism. Studies on a genetic polymorphism in CYP2C8—the *3 allele—illustrate the complexity of this field of research. The *3 allele of CYP2C8 is in partial linkage disequilibrium with the *2 allele of CYP2C9 (ie,

individuals with one allelic variant will likely have the second too). Furthermore, based on in vitro studies CYP2C*3 was considered a *loss-of-function* allele, but in vivo studies with 3 different CYP2C8 substrates established that the CYP2C8*3 allele is a *gain-of-function* allele. These findings sound a word of caution about interpreting the impact of genetic polymorphisms on drug disposition, adverse effects, efficacy, and disease processes. That said, there are many cases of CYP genetic polymorphisms having a reproducible, clinically relevant impact on drug disposition, examples of which are given below under each individual enzyme subheading.

There are also many reports of CYP polymorphisms predisposing individuals to diseases or conferring protection against them. This literature is often confusing. For example, in the case of CYP2J2 (which converts arachidonic acid to EETs that are thought to be cardioprotective), a genetic polymorphism in the promoter region that causes a decrease in CYP2J2 expression was examined in 4 separate studies for its effects on coronary artery disease (CAD) (reviewed in Zordoky and El-Kadi, 2010). The CYP2J2 polymorphism was associated with an increased risk of CAD in one study (in Germans) and a decreased risk in another study (in African Americans) and had no discernible effect in 2 other studies (in Swedes and a Caucasian population). Four other studies on the impact of the same genetic polymorphism of CYP2J2 (ie, lower expression) on hypertension gave similar results: 1 showed increased risk (in Russians), one showed decreased risk (in Caucasians [but only in males]), and 2 showed no association. Given the incongruity of these studies, the impact of genetic polymorphisms on disease will not be discussed below with the notable exception of the impact of CYP1A and CYP2A6 polymorphisms on cigarette-smoking-induced cancer of the lung and upper aerodigestive tract (UADT).

The salient features of each of the major xenobiotic-biotransforming CYP enzymes, with emphasis on the CYP enzymes in human liver microsomes, are summarized in the following subsections.

CYP1A1, 1A2, and 1B1 All mammalian species examined possess 3 members of the CYP1 family, namely, CYP1A1, CYP1A2, and CYP1B1. They have attracted considerable attention because they are highly inducible by AhR agonists such as TCDD and PAHs and because they play a major role in the activation/detoxication of carcinogenic/mutagenic compounds such as PAHs, aflatoxin B₁, various aromatic amines/amides, and PhIP and 2-amino-3-methylimidazo[4,5-f]quinoline (IQ), 2 representatives of the many heterocyclic amines (products of amino acid pyrolysis) known as cooked food mutagens. A possible d’Artagnan to these 3 musketeers is CYP2S1, which resembles CYP1A1 and CYP1B1 in being an AhR-inducible, extrahepatic enzyme capable of metabolizing PAHs, but it will be discussed later in the section “CYP2R1, 2S1, 2U1, and 2W1.” High levels of CYP1A2 are expressed in liver (see Table 6-12) but not in extrahepatic tissues. In contrast, liver contains low or undetectable levels of CYP1A1 and CYP1B1 but these enzymes are expressed in a great number of extrahepatic tissues (Shimada, 2006). Only CYP1A2 contributes significantly to the in vivo clearance of drugs (extensively reviewed by Zhou *et al.*, 2010b).

The ability of CYP1 enzymes to activate a wide variety of compounds to mutagenic metabolites underscores the widespread practice of using liver microsomes from Aroclor 1254–induced rats in the Ames bacterial mutagenicity assay (because these microsomes have high levels of CYP1A1 and CYP1A2, among many other induced CYP enzymes). This and many other in vitro studies, including heterologous expression of CYP1 enzymes in mammalian

cells, have established that CYP1A1 and CYP1B1 are adept at oxidizing PAHs such as B[a]P and DMBA to DNA-reactive diol epoxides, as illustrated in Fig. 6-10. (A second pathway of DMBA activation is shown later in the section “Sulfonation.”) Similar *in vitro* studies have clearly established that CYP1A2 is highly effective in catalyzing the initial step (*N*-hydroxylation) in the activation of numerous carcinogenic aromatic amines (4-aminobiphenyl, 2-aminonaphthalene, 2-AF), aromatic amides (2-acetylaminofluorene), and heterocyclic amines (PhIP, IQ, etc) to mutagenic metabolites (these activation pathways will be discussed in the sections “Glucuronidation and Formation of Acyl-CoA Thioesters” for 2-aminonaphthalene, “Sulfonation” for 2-AAF, and “Acetylation” for 2-aminofluorene and 2-AAF). In the case of PAHs, it was noted that these carcinogens are also AhR agonists; hence, it was long assumed that PAHs can induce CYP1 enzymes and thereby induce their own activation to carcinogenic metabolites. Consequently, it came as a huge surprise when experiments with knockout mice indicated that these *in vitro* findings did not translate in a predictable manner to the *in vivo* situation (reviewed in Nebert and Dalton, 2006; Shimada, 2006; Ma and Lu, 2007).

Compared with their wild-type littermates, CYP1A1, CYP1A2, and CYP1B1 knockout mice would be expected to be less susceptible and possibly resistant to the tumorigenic effects of PAHs such as B[a]P and DMBA, and to aromatic amines such as 4-aminobiphenyl and cooked food mutagens. However, contrary to expectation, deletion of CYP1A1 *potentiated* the toxicity of oral B[a]P, which caused increased spleen and thymus weight, leukocytopenia, and extreme hypercellularity in the bone marrow (and death within 30 days) in CYP1A1 knockout mice but not in wild-type mice. CYP1A1 knockout mice also had *higher* levels of B[a]P–DNA adducts in extrahepatic tissues. However, both wild-type mice and CYP1A1 knockout mice were susceptible to B[a]P toxicity when the PAH was administered by intraperitoneal injection instead of the oral route of administration. These findings strongly suggest that induction of CYP1A1 in the intestine and liver and metabolism of PAHs in these presystemic organs provide protection against orally administered PAHs (Nebert and Dalton, 2006; Shimada, 2006; Ma and Lu, 2007).

Contrary to expectation, deletion of CYP1A2 similarly potentiates the toxicity and liver tumorigenicity of aromatic/heterocyclic amines. Deletion of CYP1A2 (CYP1A2 null mice) increased the toxicity of 4-aminobiphenyl (methemoglobinemia), adduct formation in liver and bladder (2 targets of arylamine carcinogenicity in rodents), and the incidence of hepatocellular tumors and preneoplastic foci. Deletion of CYP1A2 likewise increased adduct and tumor formation by the cooked food mutagens (heterocyclic amines) known as PhIP and IQ. These results strongly suggest that the role of CYP1A2 in aromatic/heterocyclic amine/amide metabolism is protective, and that enzymes other than CYP1A2 (such as peroxidases, extrahepatic CYP enzymes, and/or UGTs) play an important role in their activation (or, alternatively, it is the parent compound that causes tumor formation) (Nebert and Dalton, 2006; Shimada, 2006; Ma and Lu, 2007).

In contrast to the unexpected results observed with CYP1A1 and CYP1A2 knockout mice, gene deletion of CYP1B1 does in fact have the anticipated protective effect against PAH tumorigenicity. CYP1B1 mice are completely protected against DMBA tumor formation (Nebert and Dalton, 2006; Shimada, 2006; Ma and Lu, 2007). Similar protection against DMBA and/or B[a]P has been achieved with CYP1B1 inhibitors such as 1-ethinylpyrene (an irreversible inhibitor of both CYP1B1 and CYP1A1) and the specific (or more selective) CYP1B1 inhibitor 1,4-phenylenebis(methylene)-selonocyanate (*p*-XSC). These results suggest CYP1B1 plays a

key role in activating PAHs to diol epoxides that cause skin and mammary tumors in experimental animals. Of particular interest is the finding that, although both CYP1A1 and CYP1B1 convert PAHs to DNA-reactive diol epoxides, the latter enzyme does so with higher affinity (Nebert and Dalton, 2006; Shimada, 2006; Ma and Lu, 2007).

The studies in knockout mice establish that induction of CYP1A1 protects against *oral* PAH toxicity (through first-pass [presystemic] elimination) but does not protect against parenterally administered PAH toxicity. In humans, the most prevalent exposure to parenterally administered PAHs is through cigarette smoking. Not surprisingly, therefore, a large number of studies have examined the impact of genetic polymorphisms in CYP1A1 and, to a lesser extent, in CYP1B1 on the incidence of lung and UADT cancers in cigarette smokers and, in some cases, nonsmokers (Chen *et al.*, 2010, 2011b; Zhan *et al.*, 2011). Allelic variants that increase CYP1A1 and CYP1B1 have been investigated for their potential to predispose to environmental tobacco smoke (ETS)–induced lung, UADT, and other cancers. In the case of CYP1A1, the focus has been on 2 mutually linked polymorphisms, namely, *2A and *2B; the former is point mutation in the 3′-flanking region and is commonly called the *MspI* polymorphism. By itself *MspI* has no effect on CYP1A1 activity or expression. However, *MspI* (*2A) is linked to *2B, a point mutation in exon 7 that leads to an Ile₄₆₂Val substitution, which is near the heme-binding site. The latter polymorphism is associated with increased activity or inducibility of CYP1A1 (Crofts *et al.*, 1994). In the case of CYP1B1, the focus of attention has been on the *3 allele caused by a Leu₄₃₂Val substitution that increases CYP1B1 activity (Li *et al.*, 2000). Studies of the impact of these gain-of-function polymorphisms of CYP1A1 and CYP1B1 on the incidence of lung and other cancers are numerous and the outcomes varied. Within a study, an association between gain-of-function alleles and cancer incidence is often found in a subgroup based on ethnicity or gender, and in some studies the association (increased risk) is observed in both smokers and nonsmokers. In the case of CYP1A1, 2 meta-analysis studies, one based on 18,397 subjects (Zhan *et al.*, 2011) and the other based on 30,368 subjects (Chen *et al.*, 2011b), concluded that the overall risk of cigarette smoking lung cancer posed by the gain-of-function polymorphism in CYP1A1 was low (odds ratio ~1.2) but that slightly higher risks could be discerned in subgroups based on ethnicity. In the case of CYP1B1, a meta-analysis based on 6501 subjects similarly concluded that the overall risk of cigarette smoking lung cancer posed by the gain-of-function polymorphism in CYP1B1 was low (odds ratio 1.46) but variable among different ethnic groups (Chen *et al.*, 2010). The authors concluded that the gain-of-function polymorphism in CYP1B1, which had a larger odds ratio than that of CYP1A1, was a low-penetrant risk for developing lung cancer.

The early studies of CYP1A1 induction were based on measurement of aryl hydrocarbon hydroxylase (AHH) activity, which took advantage of the conversion of B[a]P to the fluorescent metabolite 3-hydroxy-B[a]P (Conney, 1982). This assay was supplanted when it was discovered that CYP1A1 and CYP1A2 catalyze 7-ethoxyresorufin *O*-dealkylation (EROD) to form the highly fluorescent metabolite resorufin, which is one of the reactions shown in Fig. 6-45 (Burke and Mayer, 1974). These studies are of historical interest because they provided some of the earliest evidence for the existence of multiple forms of CYP, one of which (namely, CYP1A1) was highly inducible by 3-methylcholanthrene. Why was 3-methylcholanthrene studied for its effects on AHH activity? It was studied because of the observation reported in 1952 that treating rats with a low dose of one carcinogen, namely, 3-methylcholanthrene, could delay or entirely prevent liver tumor formation by a

second carcinogen, namely, 3'-methyl-4-dimethylaminoazobenzene (reviewed by Ma and Lu, 2007). Therefore, the more recent studies in knockout mice reinforced (arguably rediscovered) the protective effect of CYP1 induction. The possibility that CYP1A induction is associated with adverse effects stemmed in part from the discovery that TCDD (or dioxin), an industrial and environmental chemical that is highly toxic to certain species, is an extraordinarily potent inducer of CYP1A enzymes in rodents, and that strain differences in TCDD toxicity in mice correlate with CYP inducibility (Poland and Glover, 1974). As outlined in the section "Induction of Cytochrome P450—Xenosensors," TCDD is the most potent AhR agonist known, and it is this xenosensor, not the induction of CYP1A enzymes per se, that mediates the toxicity of TCDD, which is abrogated in AhR knockout mice. However, the impact of CYP1 gene deletion on the teratogenic effects of TCDD is interesting. Gene deletion of CYP1A1 or CYP1B1 has no effect on TCDD teratogenicity. However, gene deletion of CYP1A2 in dams predisposes to TCDD teratogenicity by exposing the embryos to higher levels of TCDD. The loss of CYP1A2 does result in decreased metabolism of TCDD, which is essentially metabolically stable, but is likely due to loss of hepatic binding of TCDD to CYP1A2 (Dragin *et al.*, 2006).

CYP1B1 is expressed in the eye, and genetic polymorphisms that decrease CYP1B1 function are associated with primary congenital glaucoma. CYP1B1 knockout mice also have structural eye defects, which suggest that CYP1B1 has an important physiological role in eye development. In addition to metabolizing PAHs, CYP1B1 also catalyzes the 4-hydroxylation of 17 β -estradiol, which produces a catechol that can potentially oxidize to a toxic *ortho*-quinone. Methylation of 4-hydroxyestradiol acts as a detoxication pathway in some tissues, as discussed in the section "Methylation." In addition to being under the transcriptional control of AhR, the expression of human CYP1B1 is controlled posttranscriptionally by the microRNA known as miR-27b, a small noncoding RNA that blocks the synthesis of CYP1B1 by binding to near-perfect matching sequences in the 3' untranslated region of CYP1B1. The level of miR-27b is decreased and the level of CYP1B1 is correspondingly increased (overexpressed) in breast cancerous cells (and other cancerous tissues) (Tsuchiya *et al.*, 2006). The overexpression of CYP1B1 in malignant cells (coupled with its ability to activate xenobiotics to reactive metabolites) is being exploited to activate a prodrug to a cytotoxic metabolite as a possible cancer treatment. A related approach is the development of CYP1B1 DNA vaccine, which has been shown in clinical trials to kill CYP1B1-expressing cancer cells (Maecker *et al.*, 2003).

Of the 3 CYP1 enzymes, only CYP1A2 contributes significantly to the *in vivo* clearance of drugs (extensively reviewed by Gunes and Dahl, 2008; Zhou *et al.*, 2010b). Drugs and other xenobiotics that are substrates, inhibitors, or inducers of human CYP1A2 are shown in Table 6-13. CYP1A2 catalyzes the *O*-dealkylation of phenacetin and the 4-hydroxylation of acetanilide, both of which produce acetaminophen, which can be converted by CYP1A2 and other CYP enzymes to a toxic NAPQI (Fig. 6-35). As shown in Fig. 6-45, CYP1A2 catalyzes the N_3 -demethylation of caffeine to paraxanthine. By measuring rates of formation of paraxanthine in blood, urine, or saliva or by measuring the exhalation of isotopically labeled CO₂ from ¹³C- or ¹⁴C-labeled caffeine, the N_3 -demethylation of caffeine can be used as an *in vivo* probe of CYP1A2 activity, which varies enormously from 1 individual to the next.

As in the case of CYP1A1 and CYP1B1, the function and regulation of CYP1A2 is reasonably conserved across mammalian species, but there are some notable differences. For example, furafylline is a metabolism-dependent inhibitor of human but not rodent CYP1A2 (Racha *et al.*, 1998) and omeprazole and other

proton pump inhibitors are inducers of human but not rodent CYP1A2 (Diaz *et al.*, 1990).

Although the levels of CYP1A2 vary enormously from 1 individual to the next, genetic defects in CYP1A2 (ie, CYP1A2 PMs) are extremely rare. Several clinical studies have reported gender differences in CYP1A2, with most—but not all—studies reporting slightly higher CYP1A2 in males compared with females (with wide variation in both genders). Rasmussen *et al.* (2002) reported that, based on a clinical study of caffeine metabolism in 378 individuals, males have higher CYP1A2 activity than females. Although oral contraceptive treatment reduces CYP1A2 activity, the gender difference reported by Rasmussen *et al.* was significant even when women on oral contraceptive steroids were excluded from the analysis. Rasmussen *et al.* (2002) also demonstrated a strong correlation in CYP1A2 activity between identical (monozygous) twins and concluded that, despite the large number of environmental factors that can potentially influence CYP1A2 expression (such as cigarette smoking and treatment with proton pump inhibitors, which induce CYP1A2, and oral contraceptive therapy, which suppresses CYP1A2), genetic factors account for 70% to 75% of the observed variation in CYP1A2 activity. Some but not all studies suggest an association between genetic polymorphisms that impair CYP1A2 function and elevated levels of clozapine. Decreased levels of clozapine are observed in cigarette smokers (Gunes and Dahl, 2008). In conjunction with caffeine consumption, a genetic polymorphism that decreases CYP1A2 expression and impairs caffeine metabolism is associated with a small increase in the risk of hypertension and nonfatal myocardial infarction (Zordoky and El-Kadi, 2010).

CYP2A6, CYP2A7, and 2A13 Enzymes belonging to the CYP2A gene family show marked species differences in catalytic function. For example, 2 of the 3 CYP2A enzymes expressed in rat liver, namely, CYP2A1 and CYP2A2, primarily catalyze the 7 α - and 15 α -hydroxylation of testosterone, respectively. In contrast, the CYP2A enzyme expressed in human liver, namely, CYP2A6, catalyzes the 7-hydroxylation of coumarin, as shown in Fig. 6-42. Just as rat CYP2A1 and CYP2A2 have little or no capacity to 7-hydroxylate coumarin, human CYP2A6 has little or no capacity to hydroxylate testosterone. Mouse liver microsomes contain 4 CYP2A enzymes, one of which catalyzes the 7 α -hydroxylation of testosterone (CYP2A12), one of which catalyzes the 15 α -hydroxylation of testosterone (CYP2A4), and one of which catalyzes the 7-hydroxylation of coumarin (CYP2A5). Functionally, CYP2A5 can be converted to CYP2A4 by a single amino acid substitution (Phe₂₀₆Leu). In other words, this single amino substitution converts CYP2A5 from a coumarin 7-hydroxylating enzyme to a testosterone 15 α -hydroxylating enzyme (Lindberg and Negishi, 1989). Differences in CYP2A function have important implications for the adverse effects of coumarin, which is hepatotoxic to rats but not humans. Whereas coumarin is detoxified in humans by conversion to 7-hydroxycoumarin, which is subsequently conjugated with glucuronic acid and excreted, a major pathway of coumarin biotransformation in rats involves formation of the hepatotoxic metabolite, coumarin 3,4-epoxide, as shown in Fig. 6-43. In addition to catalyzing the 7-hydroxylation of coumarin, CYP2A6 converts 1,3-butadiene to butadiene monoxide and nicotine to nicotine $\Delta^{1'S}$ -iminium ion, which is further oxidized by AO to cotinine, as shown in Fig. 6-48.

Humans possess 2 functional CYP2A genes, namely, CYP2A6 and 2A13, and one nonfunctional CYP2A gene, namely, CYP2A7. CYP2A7 (originally named IIA4) is a full-length gene that encodes an enzyme incapable of incorporating heme, rendering it catalytically inactive (Yamano *et al.*, 1990; Ding *et al.*, 1995). CYP2A6 is expressed in the liver but few extrahepatic tissues (with the notable

exception of mammary gland), whereas CYP2A13 is expressed mainly in the lung (bronchus and trachea) and bladder, with lower levels in reproductive organs such as testis, ovary, uterus, and mammary gland. Hepatic CYP2A6 plays a major role in the metabolism of coumarin and nicotine, and plays a role in the metabolism of tegafur, fadrozole, methoxyflurane, and valproic acid. 8-Methoxypsoralen, a structural analog of coumarin, is a potent, metabolism-dependent inhibitor of CYP2A6 (and CYP2A13), whereas the aromatase inhibitor letrozole is a potent competitive inhibitor (Jeong *et al.*, 2009). Other inhibitors of CYP2A6 are listed in Table 6-13. CYP2A13 does not appear to contribute to drug clearance, but it may play an important role in the activation of xenobiotics to toxic and carcinogenic metabolites in lung and bladder. Both CYP2A6 and CYP2A13 activate nitrosamines to DNA-reactive (mutagenic) metabolites, especially those nitrosamines with bulky alkyl substituents such as NNK, *N*'-nitrosonorcotinine, and related nitrosamines found in tobacco smoke. (CYP2E1 also activates nitrosamines, but it preferentially activates nitrosamines with small alkyl substituents such as *N*-nitrosodimethylamine.)

The identification of 3 Japanese individuals who were PMs of SM-12502, an antiplatelet drug whose clearance is largely determined by CYP2A6, led to the identification of a genetic polymorphism that, in homozygous individuals, leads to the complete loss of CYP2A6 (CYP2A6*4/*4). The incidence of the CYP2A6 PM genotype is high in Asians (up to 15%) and relatively low in Caucasians (0%–4.2%) and black Africans and African Americans (0.9%–1.9%) (Liu *et al.*, 2011). Individuals who are genetically deficient in CYP2A6 have a considerably lower risk of cigarette-smoking-induced lung cancer presumably because these individuals have a reduced capacity for activating tobacco-smoke nitrosamines to carcinogenic metabolites (Kamatani *et al.*, 2005). In support of this interpretation, the CYP2A inhibitor 8-methoxypsoralen protects mice from NNK-induced lung adenomas. CYP2A6 PMs are not only PMs of nitrosamines but also PMs of nicotine. Therefore, decreased cigarette consumption may also contribute to the lowered risk of lung cancer in CYP2A6 PMs. CYP2A6 is detectable in human lung, but the levels are considerably less than those of CYP2A13, which can activate the same carcinogens as CYP2A6. Therefore, it is not immediately obvious why a genetic deficiency in CYP2A6 protects against lung cancer. A similar situation occurs with CYP2D6 inasmuch as individuals lacking this hepatic enzyme (ie, CYP2D6 PMs) also have a slightly decreased risk of cigarette-smoking-induced lung cancer (Rostami-Hodjegan *et al.*, 1998).

It seems somewhat paradoxical but just as CYP2A6 PMs have a decreased risk of lung cancer, so they have an increased risk of nasopharyngeal cancer, which is rare in Caucasians (Western countries) but endemic in Southern China and Southeast Asia. It has been postulated that, in the absence of CYP2A6, higher levels of nitrosamines and other carcinogens reach the nasal epithelium where they can be activated to carcinogenic metabolites by CYP2E1 and CYP2A13, both of which are expressed in nasal epithelium (Tiwawech *et al.*, 2006).

Like CYP2A6, CYP2A13 can activate several carcinogens including many of the nitrosamines (eg, NNK) and aromatic amines (eg, 4-aminobiphenyl) that are present in cigarette smoke, and the mycotoxin aflatoxin B₁. CYP2A13 is suspected of playing a role in the activation of carcinogens in tobacco smoke because it is localized in the 2 sites where cigarette smoking causes cancer, namely, the lung bronchus and bladder (Nakajima *et al.*, 2006).

In view of high prevalence of the CYP2A6 PM genotype in Chinese populations, it is noteworthy that the estimated 300 million cigarette smokers in China consume approximately one third of the world's cigarettes. Although CYP2A6 PMs smoke fewer

cigarettes than CYP2A6 EMs, the protective effect of this loss-of-function polymorphism does not prevent an estimated 1 million smokers dying annually from tobacco-related diseases each year in China, a number that is predicted to rise to 2.2 million by 2020 (Liu *et al.*, 2011).

CYP2B6 CYP2B6 is expressed in human liver and, to a lesser extent, in kidney, intestine, and lung. It plays a significant role in the metabolism of the antidepressant bupropion, the antiretrovirals efavirenz and nevirapine, the anesthetics propofol and ketamine, the antineoplastics cyclophosphamide, ifosfamide, and tamoxifen, the antimalarial artemisinin, the synthetic opioids methadone and pethidine (Demerol), the anti-Parkinsonian selegiline, and the endocrine disrupter methoxychlor (Wang and Tompkins, 2008). The activation of cyclophosphamide by CYP2B6 (and CYP3A4) is shown in Fig. 6-50. CYP2B6 also catalyzes the *N*-demethylation of *S*-mephenytoin but not the 4'-hydroxylation, which is catalyzed by CYP2C19. Some but not all of these substrates can be used in vitro or in vivo to assess CYP2B6 activity, as shown in Table 6-13. Several drugs have been shown to inhibit CYP2B6 (Table 6-13), and many of them do so in a metabolism-dependent manner, such as clopidogrel, ticlopidine, and thio-TEPA, all of which inactivate other CYP enzymes. 2-Phenyl-2-(1-piperidinyl) propane (PPP) is a potentially selective inactivator of CYP2B6 for in vitro studies (Walsky *et al.*, 2006; Walsky and Obach, 2007). CYP2B6 is an inducible enzyme; it is generally coinduced with CYP3A4 and several CYP2C enzymes by xenobiotics that activate CAR and/or PXR, such as rifampin, the EIAEDs such as phenobarbital, phenytoin, carbamazepine, clotrimazole, and felbamate, and the herbal preparation of St. John's wort, which is the topic of a subsequent section (see the section "Induction of Cytochrome P450—Xenosensors").

There is considerable interindividual variation in CYP2B6 activity, partly due to environmental factors (such as treatment with enzyme inducers) and partly due to genetic factors. Several SNPs that, to varying degrees, impair CYP2B6 expression and/or activity have been identified. The CYP2B6*6 allele (Gln₁₇₂His, Lys₂₆₂Arg) is common in Asians (15%–40%), Caucasians (20%–30%), and African Americans (over 50%), which is associated with a marked decrease in CYP2B6 activity. One functional consequence of the CYP2B6*6 polymorphism is impaired clearance of efavirenz, leading to increased plasma levels and adverse effects (Wang and Tompkins, 2008). CYP2B6*6 is also associated with impaired cyclophosphamide metabolism and *S*-mephenytoin *N*-demethylation. Another loss-of-function allele, namely, CYP2B6*5 (Arg₄₈₇Cys), is common in Caucasians (14%–25%) and curiously results in a decrease in CYP2B6 expression and activity but only in females (Wang and Tompkins, 2008).

CYP2C Enzymes Humans express 4 CYP2C enzymes, namely, CYP2C8, CYP2C9, 2C18, and 2C19. With the exception of CYP2C18, these CYP2C enzymes play a significant role in drug metabolism, and their inhibition or induction is the basis of a number of clinically important drug interactions. In the case of CYP2C9 and 2C19, genetic polymorphisms give rise to a relatively common IM or even PM phenotype, which also impacts the metabolism and safety or efficacy of certain drugs. As a general rule, CYP2C8 metabolizes large, acidic drugs, including several glucuronide conjugates, whereas CYP2C9 metabolizes (or is inhibited by) smaller acid- or sulfonamide-containing drugs, and CYP2C19 metabolizes neutral or weakly basic drugs often with a high degree of stereoselectivity (ie, it preferentially metabolizes one enantiomer over the other). All 4 enzymes appear to be inducible by CAR/PXR agonists such as phenobarbital, rifampin, and St. John's wort (hyperforin); hence, they tend to be coinduced together with CYP2B6 and

CYP3A4. Substrates, inhibitors, and inducers of CYP2C8, 2C9, and 2C19 are listed in Table 6-13.

CYP2C8, CYP2C9, and CYP2C19 are abundant enzymes in human liver (see Table 6-12) but low levels of CYP2C8 and 2C9 are also expressed in a wide range of tissue and in vascular endothelium where, together with CYP2J2, they epoxidate arachidonic acid to vasoactive EETs (see the sections “CYP2J2” and “Epoxide Hydrolases”) (Chen and Goldstein, 2009; Zordoky and El-Kadi, 2010). CYP2C8 and CYP2C9 can also hydroxylate *all-trans*-retinoic acid and 9-*cis*- and 13-*cis*-retinoic acid (Marill *et al.*, 2000, 2002).

CYP2C8 and CYP2C9 show a marked preference for metabolizing large and small acidic drugs, respectively, and these substrates are ionized (negatively charged) at physiological pH and highly bound to albumin in plasma. In many cases substrates for CYP2C8, which metabolizes large acidic drugs, are also substrates for one or more of the organic anion polypeptide transporters (OATPs) in the intestine and liver. Accordingly, drug interactions with CYP2C8 may also involve drug interactions at the level of OATP especially if transporter-mediated uptake into liver becomes a rate-limiting step in clearance.

As shown in Table 6-11, rats and mice express a large number of CYP2C enzymes (13 and 15, respectively). The expression of CYP2C11 in adult male but not adult female rats (together with male-predominant expression of CYP3A2, which also has a broad substrate specificity) is a key factor underlying many gender differences in xenobiotic and steroid metabolism in mature rats (Waxman and Holloway, 2009).

CYP2C8 CYP2C8 has been implicated in the metabolism of over 60 drugs including the thiazolidinediones rosiglitazone, pioglitazone, and troglitazone (withdrawn), amiodarone, amodiaquine, carbamazepine, cerivastatin (withdrawn), chloroquine, cilostazol, *R*-ibuprofen, lovastatin, morphine, paclitaxel (Taxol®), repaglinide, rosuvastatin, simvastatin, tazarotene (a retinoid derivative), torsemide, verapamil, and zopiclone (Lai *et al.*, 2009). However, with the exception of the antidiabetic drug, repaglinide, all of the above drugs are metabolized to a significant extent by enzymes other than CYP2C8, and in the case of repaglinide its disposition is influenced by the transporter OATP1B1 (SLCO1B1). Repaglinide is classified by the FDA as a sensitive CYP2C8 substrate with the qualification that it is only suitable as an *in vivo* probe for drug–drug interaction studies if the investigational drug being evaluated as a CYP2C8 inhibitor does not inhibit OATP1B1. In the presence of the CYP2C8/OATP1B1 inhibitor gemfibrozil, exposure to repaglinide (based on plasma AUC) increases about 8-fold (from 5.5- to 15-fold) but gemfibrozil causes only a ~2.3-fold increase in the plasma AUC of rosiglitazone, another potential *in vivo* probe of CYP2C8.

Substrates for CYP2C8 tend to be large and acidic as evidenced by the observation that CYP2C8 metabolizes several glucuronides (Nishihara *et al.*, 2012, and references therein). For example, whereas 17 β -estradiol and diclofenac are metabolized by CYP2C9, the glucuronide metabolites of these compounds (namely, estradiol-17 β -glucuronide and diclofenac acyl glucuronide) are metabolized by CYP2C8 (at the same site as that metabolized by CYP2C9, which is distal to the glucuronide moiety). The importance of CYP2C8-dependent metabolism of glucuronides is discussed in the section “Glucuronidation and Formation of Acyl-CoA Thioesters.” The ability of CYP2C8 to metabolize glucuronide conjugates plays an important role in the mechanism by which the hypolipidemic drug gemfibrozil inhibits the metabolism, and thereby increases the toxicity (a sometimes fatal muscle disorder known as rhabdomyolysis) of cerivastatin (Baycol), a member of

the statin class of cholesterol synthesis inhibitors that was withdrawn from the market (Ogilvie *et al.*, 2006; Baer *et al.*, 2009). Gemfibrozil glucuronide, but not gemfibrozil itself, is an irreversible metabolism-dependent inhibitor of CYP2C8 (Ogilvie *et al.*, 2006). During the benzylic hydroxylation of gemfibrozil, CYP2C8 forms a benzylic radical (as shown previously in the scheme for the mechanism of carbon hydroxylation [this section]) that evades oxygen rebound and alkylates the heme moiety (at the α -meso position), which inactivates the enzyme (Baer *et al.*, 2009). The sometimes fatal interaction between gemfibrozil (the perpetrator drug) and cerivastatin (the victim drug) was a significant factor in the decision to withdraw cerivastatin from the US, European, and Japanese markets.

A large number of genetic polymorphisms have been identified in the CYP2C8 gene, one of which is particularly noteworthy, namely, the *3 allele, which is common in Caucasians (~12%) but rare in Asians, black Africans, and African Americans (Daily and Aquilante, 2009). CYP2C8*3 is a double mutation (Arg₁₃₉Lys and Lys₃₉₀Arg). It is of particular interest for 2 reasons. First, the *3 allele of CYP2C8 is in partial linkage disequilibrium with the *2 allele of CYP2C9, meaning individuals often carry both allelic variants, which complicates the clinical assessment of either one of these genetic polymorphisms on drug metabolism or diseases processes. Second, CYP2C8*3 is of particular interest because of the disconnect between *in vitro* and *in vivo* findings. *In vitro* studies identified the CYP2C8*3 as a *loss-of-function* allelic variant. However, clinical studies established that *3 is a *gain-of-function* allelozyme that is associated with increased clearance of repaglinide, rosiglitazone, and pioglitazone, but not paclitaxel (Daily and Aquilante, 2009). Both the linkage between the *3 allele for CYP2C8 and the *2 allele for CYP2C9 and the discrepancy between *in vitro* and *in vivo* findings on CYP2C8*3 sound a word of caution about interpreting the impact of genetic polymorphisms on drug disposition, adverse effects, efficacy, and disease processes.

CYP2C9 CYP2C9 plays a role in the metabolism of over 100 drugs including NSAIDs (eg, diclofenac, celecoxib, ibuprofen, flurbiprofen, naproxen, piroxicam, mefenamic acid, and suprofen), oral hypoglycemics (eg, glyburide, glipizide, glimepiride, tolbutamide), oral anticoagulants (eg, *S*-warfarin, *S*-acenocoumarol, and phenprocoumon), diuretics and uricosurics (eg, sulfapyrazone sulfide, torsemide, tienilic acid [ticrynafen]), angiotensin II blockers (eg, candesartan, irbesartan, losartan), anticonvulsants (eg, phenytoin), and many others (Zhou *et al.*, 2009b). It also metabolizes Δ^9 -tetrahydrocannabinol. Substrates and inhibitors of CYP2C9 tend to be carboxylic acid-, tetrazole-, or sulfonamide-containing compounds, but there are exceptions to this general rule. In fact, the most potent CYP2C9 inhibitors known, namely, benzbromarone and 2-methyl-3-(3',5'-diiodo-4'-hydroxybenzoyl)benzofuran, are neither acid- nor sulfonamide-containing compounds but they resemble these agents in that they are phenolic anions (negatively charged) at physiological pH (Rettie and Jones, 2005).

CYP2C9 is a polymorphically expressed enzyme. Of the more than 30 variants identified, 2 particular loss-of-function alleles, the *2 and *3 variants, are recognized for their clinically significant impact on drug disposition and safety (Zhou *et al.*, 2009b; Van Booven *et al.*, 2010). CYP2C9*2 (Arg₁₄₄Cys) is prevalent in Caucasians (10%–15%) but not in Asians or African Americans, as is the case with the *3 allele of CYP2C8. These 2 alleles (on different enzymes) are in partial linkage disequilibrium as noted above in the preceding section. CYP2C9*3 (Ile₃₅₉Leu) is widespread across all ethnic groups, being highest in Caucasians (5%–16%) followed by African Americans (~10%) and Asians (1%–5%)

(Van Booven *et al.*, 2010). CYP2C9*2 and *3 have moderately and markedly decreased catalytic activity, respectively. Individuals who are homozygous for the *3 allele are considered CYP2C9 PMs. They are PMs of *S*-warfarin, tolbutamide, and phenytoin. These 3 drugs have a low therapeutic index, and their dose must be reduced in CYP2C9 PMs to prevent adverse drug events. Dose adjustment is also required when these drugs are combined with a CYP2C9 inhibitor or inducer, examples of which are given in Table 6-13. In the case of the anticoagulant warfarin, CYP2C9 genotype is 1 of 3 important genetic factors that affect dosing requirements, the second being the therapeutic target of warfarin vitamin K epoxide reductase complex 1 (VKORC1) (McDonald *et al.*, 2009; Lurie *et al.*, 2010). A third genetic factor is a genetic polymorphism in CYP4F2 (Val₄₃₃Met) that impairs the metabolism of vitamin K₁. Individuals with this CYP4F2 polymorphism require a higher warfarin dose to compete with the increased levels of the vitamin K₁ in the liver (McDonald *et al.*, 2009; Lurie *et al.*, 2010).

Tienilic acid, suprofen, and silybin are all metabolism-dependent inhibitors of CYP2C9. Tienilic acid is of interest because it was withdrawn from the market due to its hepatotoxicity (see Table 6-3). CYP2C9 converts tienilic acid to an electrophilic thiophene sulfoxide that can react either with water to give 5-hydroxytienilic acid or with a nucleophilic amino acid in CYP2C9 to form a covalent adduct, which inactivates the enzyme (Lecoeur *et al.*, 1994). Antibodies directed against the adduct between CYP2C9 and tienilic acid are thought to be responsible for the immunoallergic hepatitis that develops in about 1 out of every 10,000 patients treated with this uricosuric diuretic drug. As shown in Table 6-3, these autoantibodies against CYP2C9 are known as anti-LKM₂ because they are directed against liver and kidney microsomes. The subscript number 2 distinguishes these antibodies against CYP2C9 from those against CYP2D6, which are known as anti-LKM₁. It should be noted that tienilic acid can also be activated to a reactive acyl glucuronide, as outlined in the section "Glucuronidation and Formation of Acyl-CoA Thioesters."

CYP2C18 In contrast to the other 3 CYP2C enzymes expressed in human liver, CYP2C18 plays little or no role in drug metabolism. CYP2C18 is the most abundant CYP2C enzyme in skin and lung, and it is also expressed in brain, uterus, mammary gland, kidney, and duodenum. CYP2C18 is more than an order of magnitude more active than either CYP2C9 or CYP2C19 at catalyzing the *para*-hydroxylation of phenytoin to HPPH, and CYP2C18 can further hydroxylate HPPH to a catechol (Kinobe *et al.*, 2005). Autoxidation of this catechol to an *ortho*-quinone is thought to be responsible, at least in part, for rare incidences of hypersensitivity reactions to phenytoin. Therefore, although hepatic CYP2C9 and CYP2C19 are largely responsible for determining the systemic clearance of phenytoin, it is possible that CYP2C18 is responsible for activating phenytoin by the catechol/quinone pathway in the skin, the tissue where the first signs of hypersensitivity to phenytoin are observed.

CYP2C19 CYP2C19 is a polymorphically expressed enzyme that metabolizes several drugs with a high degree of stereospecificity such that, in the case of drugs administered as a racemic mixture, it metabolizes one enantiomer faster than the other, as in the case of mephenytoin (Mesantoin®), which is of historical interest with respect to CYP2C19. A genetic polymorphism for the metabolism of *S*-mephenytoin was first described in 1984 (reviewed in Wilkinson *et al.*, 1989). The deficiency affects the 4'-hydroxylation (aromatic ring hydroxylation) of this anticonvulsant drug (see Fig. 6-42). The other major pathway of *S*-mephenytoin metabolism, namely, *N*-demethylation to *S*-nirvanol, is not affected. (This pathway was subsequently shown to be catalyzed by CYP2B6.) Consequently,

PMs excrete little or no 4'-hydroxymephenytoin in their urine, but they do excrete increased amounts of the *N*-demethylated metabolite, *S*-nirvanol (*S*-phenylethylhydantoin). The enzyme responsible for this genetic polymorphism is CYP2C19, and it is highly stereoselective for the *S*-enantiomer of mephenytoin (de Morais *et al.*, 1994). In contrast to the *S*-enantiomer, the *R*-enantiomer is not converted to 4'-hydroxymephenytoin, but it is *N*-demethylated to *R*-nirvanol (*R*-phenylethylhydantoin). Individuals who are genetically deficient in CYP2C19 are at increased risk of adverse events from Mesantoin® (a racemic mixture of the *S*- and *R*-enantiomers of mephenytoin). An exaggerated central response has been observed in CYP2C19 PMs administered Mesantoin® at doses that were without effect in CYP2C19 EMs.

CYP2C19 plays an important role in the metabolism of the proton pump inhibitors omeprazole, lansoprazole, pantoprazole, and rabeprazole, representative structures of which are shown in Fig. 6-44. The sulfoxide group in proton pump inhibitors is a chiral center, and CYP2C19 preferentially metabolizes one enantiomer over the other: it preferentially hydroxylates the *R*-enantiomer in the case of omeprazole, and it preferentially hydroxylates the *S*-enantiomer in the case of lansoprazole. These reactions are equivalent inasmuch as these 2 proton pump inhibitors are hydroxylated on opposite ends of the molecule (on the pyridine ring in the case of omeprazole and on the benzimidazole ring in the case of lansoprazole), meaning the sulfoxide in each case binds to the active site of CYP2C19 in the same orientation (Kim *et al.*, 2003). CYP2C19 PMs are poor metabolizers of omeprazole and lansoprazole. However, CYP2C19 PMs are not at increased risk for ADEs but actually derive greater therapeutic benefit (better control of GERD) from standard doses of proton pump inhibitors (Furuta *et al.*, 2005). Esomeprazole, the *S*-enantiomer of omeprazole, was approved for the treatment of GERD and related gastric acid disorders. Compared with the *R*-enantiomer, esomeprazole is not rapidly metabolized by CYP2C19, and its improved pharmacokinetic behavior provides CYP2C19 EMs with the same therapeutic benefit as CYP2C19 PMs administered omeprazole. This is due in part to the ability of esomeprazole to function as a metabolism-dependent inhibitor of CYP2C19 and inhibit its own metabolism in CYP2C19 EMs (Ogilvie *et al.*, 2011). Other substrates, inhibitors, and inducers of CYP2C19 are listed in Table 6-13.

Two genetic polymorphisms, the *2 and *3 alleles (and their variants *2A, *2B, and *2C, and *3A and *3B), are responsible for the majority of CYP2C9 PMs (Zhou *et al.*, 2009a). Both the *2 and *3 are null alleles; hence, individuals homozygous for either allele (*2/*2 and *3/*3) and heterozygotes (*2/*3) are devoid of functional CYP2C9. The incidence of the CYP2C9 PM genotype varies considerably from one ethnic group to the next: it ranges from 13% to 23% in Japanese, Chinese, Korean, Vietnamese, and Indian populations, but the incidence is considerably lower in black African and African Americans (3%–5%), and in Caucasians (1%–7% depending on geographical location) (Zhou *et al.*, 2009a). A high incidence of CYP2C9 PMs is found in Australian aboriginals (~26%) and in South Pacific Polynesian populations (~14%). In the Polynesian island of Vanuatu, 79% of the population has been identified as CYP2C9 PMs. When administered standard drug doses, CYP2C9 PMs have elevated plasma levels of proton pump inhibitors (omeprazole, lansoprazole, pantoprazole, and, to a lesser extent, rabeprazole), diazepam, escitalopram, sertraline, and voriconazole, not to mention the *S*-enantiomer of mephenytoin in individuals administered Mesantoin, which was the original observation that led to the discovery of the CYP2C9 PM genotype. No CYP2C9 UMs individuals with functional CYP2C9 gene duplications have been identified; however, CYP2C9*17 (Ile₃₃₁Val) has

Figure 6-49. Biotransformation of clopidogrel to inactive metabolites by carboxylesterase (CES1) and paraoxonase (PON1) and its active, antiplatelet metabolite by cytochrome P450 (especially CYP2C19).

been identified as a gain-of-function allele with allele frequencies of about 20% in Caucasians and black Africans but only ~2% in Asian populations (Li-Wan-Po *et al.*, 2010). Based on the magnitude of the increase in clearance of drugs such as escitalopram, CYP2C19 activity in individuals who are homozygous for this gain-of-function allele (*17/*17) can be considered high-activity EMs rather than UMs (Li-Wan-Po *et al.*, 2010). CYP2C19 is regulated by CAR/PXR; hence, its activity in IMs and EMs can be increased by enzyme-inducing drugs (see Table 6-13).

CYP2C19 has attracted considerable attention for its role in converting the antiplatelet drug clopidogrel to its pharmacologically active metabolite. This activation process is shown in Fig. 6-49. It is unusual for several reasons. First, the therapeutically active component is a reactive metabolite that binds covalently to the ADP-binding

receptor (P2Y₁₂) on platelets. Second, the oxidative pathway leading to formation of this active metabolite is in competition with 2 hydrolytic pathways, one that hydrolyzes clopidogrel, which is catalyzed by CES1 (a carboxylesterase), and another that hydrolyzes the first oxidative metabolite (a thiolactone), which is catalyzed by PON1 (a paraoxonase). Third, the active metabolite formed by CYP and the inactive metabolite formed from the intermediary thiolactone by PON1 are isomers, as shown in Fig. 6-49 (based on studies by Dansette *et al.*, 2011). Fourth, clopidogrel provides an example of Type F toxicity whereby PMs (individuals who fail to produce the active metabolite) derive diminished therapeutic benefit and, in the case of clopidogrel, are at increased risk of thrombosis and CAD, whereas high-activity EMs who produce too much of the active metabolite (and hence too much platelet inhibition) are at increased

risk from bleeding and hemorrhage. Much of the pharmacogenomic data strongly implicate CYP2C19 as the most important enzyme for clopidogrel activation, based on poor response to clopidogrel in carriers of the loss-of-function CYP2C19 alleles (ie, the *2 and *3 alleles), and also increased bleeding in carriers of the gain-of-function CYP2C19*17 allele (Sibbing *et al.*, 2010; Scott *et al.*, 2011). A dominant role for PON1 in clopidogrel activation has been proposed (Bouman *et al.*, 2011). This rather compelling (but controversial) proposal was explained by Dansette *et al.* (2011) by showing that the ring-opened thiol produced by PON1 (with the double bond in the α/β position relative to the thiol) is an inactive isomer of the true active metabolite produced by CYP2C19 (with the double bond in the β/γ position relative to the thiol), as shown in Fig. 6-49.

Because of its tendency to cause gastric bleeding as an adverse event, clopidogrel was often prescribed together with a proton pump inhibitor (to raise gastric pH and lessen the severity of gastric bleeding). It was established that omeprazole and its *S*-enantiomer esomeprazole, but not pantoprazole or lansoprazole, compromise the antiplatelet effect of clopidogrel. It was subsequently established that omeprazole (and its *S*-enantiomer esomeprazole), but not pantoprazole or lansoprazole, is a metabolism-dependent inhibitor of CYP2C19 (Ogilvie *et al.*, 2011). This drug–drug interaction and the pharmacogenomic data strongly implicate CYP2C19 as the major enzyme responsible for converting clopidogrel to its pharmacologically active metabolite.

CYP2D6 In the late 1950s, clinical trials in the United States established that sparteine was as potent as oxytocin for inducing labor at term. However, the duration and intensity of action of sparteine was dramatically increased in ~7% of all patients tested. The exaggerated response to sparteine included prolonged (tetanic) uterine contraction and abnormally rapid labor. In some cases, sparteine caused the death of the fetus. The drug was not recommended for clinical use because these adverse effects were unpredictable and occurred at doses that were well tolerated by other patients. The antihypertensive drug, debrisoquine, was subsequently found to cause a marked and prolonged hypotension in 5% to 10% of patients, and a genetic polymorphism for the metabolism of debrisoquine and sparteine was discovered in 1977–1979. PMs lack CYP2D6, which catalyzes the 4-hydroxylation of debrisoquine and the dehydrogenation (Δ^2 - and Δ^3 -oxidation) of sparteine (see Fig. 6-48).

Genetic polymorphisms of CYP2D6 have been so extensively studied that it is possible not only to categorize individuals into 4 phenotypes, namely, PMs, IMs, EMs, and UMs but also to subdivide the EMs into 3 categories, namely, High-Activity EM, medium-activity EM, and Low-Activity EM, as summarized in Table 6-4. More than 100 allelic variants of CYP2D6 have been identified (Zhou *et al.*, 2009a; <http://www.cypalleles.ki.se/cyp2d6.htm>). Many of the allelic variants that result in a partial or complete loss of CYP2D6 activity are listed in the legend to Table 6-4. The incidence of the CYP2D6 PM genotype varies considerably from one ethnic group to the next: it is 5% to 7% in Caucasians, 2% to 4% in black Africans and African Americans, and 1% to 2% in Asian (Thai, Chinese, and Japanese) populations. Similarly, the incidence of the CYP2D6 gene duplication, which gives rise to the CYP2D6 UM genotype, varies among ethnic groups: it is up to 29% in Ethiopians, 20% in Saudi Arabians, 5% to 10% in Southern European Caucasians, but only 1% to 2% of Northern European Caucasians, 5% to 10% of Turkish subjects, and 2% or less in black African, African-American, and Asian subjects.

CYP2D6 plays a major role in drug metabolism, second only to CYP3A4 in terms of the sheer number of drugs it metabolizes (Zhou, 2009a,b; Zhou *et al.*, 2009a). CYP2D6 prefers to

metabolize lipophilic amines, which is the fundamental structure of most cardiovascular and CNS drugs. Accordingly, CYP2D6 metabolizes various tricyclic antidepressants, nontricyclic antidepressants, SSRIs, neuroleptics, β -blockers, antiarrhythmics, antiemetics, opioids, and antihistamines, examples of which are given in Table 6-13. CYP2D6 plays an important role in tamoxifen metabolism (discussed later in this section). CYP2D6 also metabolizes several drugs of abuse including methamphetamine (“meth” or “ice”), methylenedioxymethamphetamine (NMDA or “ecstasy”), *N*-ethyl-3,4-methylenedioxyamphetamine (MDE or “eve”), and 3,4-methylenedioxyamphetamine (MDA or “the love drug”). Those drugs of abuse containing a methylenedioxy (benzodioxole) moiety are also metabolism-dependent inhibitors of CYP2D6 (Van *et al.*, 2006). CYP2D6 also metabolizes the neurotoxin MPTP (see Fig. 6-29 and the section “Amine Oxidases”). Individuals lacking CYP2D6 have an exaggerated response to some but not all the drugs mentioned above or shown in Table 6-13. Large increases (>5-fold) in systemic exposure are observed in CYP2D6 PMs with atomoxetine, desipramine, dextromethorphan, metoprolol, perphenazine, and reserpine, some of which are useful in vivo probes of CYP2D6 activity. Drugs whose clearance is impaired in CYP2D6 PMs are cleared faster in UMs.

Whether the impact of CYP2D6 polymorphisms on the pharmacokinetics of a drug translate into changes in pharmacodynamic response depends on the nature of the polymorphism (ranging from PM to UMs), the magnitude of the PK response (which is determined by $f_{m_{CYP2D6}}$, the fractional contribution of CYP2D6 to drug clearance [see Point 24 in the section “Introduction”]), and the pharmacological and toxicological properties of the metabolites. For example, the metabolites produced by CYP2D6 from the antiarrhythmic drug encainide are more potent than those of the parent drug; hence, QT prolongation is more apparent in CYP2D6 EMs than PMs. On the hand, propafenone is a more potent β -blocker than its metabolites; hence, PMs experience prolonged hypotension from a standard dose of propafenone. CYP2D6 status affects the pharmacokinetics of most β -blockers but many of them have active metabolites such that changes in pharmacokinetics have little or no effect on their overall pharmacological activity (Tucker, 1994; Turner *et al.*, 2001; Ingelman-Sundberg, 2005; Zhou, 2009a). CYP2D6 PMs are at increased risk from the hepatotoxic and other adverse effects (sedation, extrapyramidal, and psychomotor symptoms) of perhexiline, for which reason perhexiline joined sparteine and debrisoquine in being denied regulatory approval by the US FDA.

The analgesic codeine (which is *O*-demethylated to morphine) and the anticancer drug tamoxifen (which is hydroxylated and *N*-demethylated to endoxifen) are converted to pharmacologically active metabolites by CYP2D6. Consequently, CYP2D6 PMs derive less therapeutic benefit than CYP2D6 EMs. In contrast, in the case of codeine, CYP2D6 UMs are at increased risk from morphine toxicity. The death of an elderly man administered a recommended dose of codeine and the death of a baby who was breastfed by a woman on codeine have been attributed to the CYP2D6 UM genotype that causes rapid conversion of codeine to morphine (which causes respiratory suppression) (Gasche *et al.*, 2004; Koren *et al.*, 2006). CYP2D6 converts the breast cancer drug tamoxifen to endoxifen (which is 30- to 100-fold more potent than tamoxifen in suppressing estrogen-dependent cell proliferation); hence, CYP2D6 PMs are at increased risk for breast cancer recurrence following tamoxifen adjuvant therapy (Goetz *et al.*, 2005; Schroth *et al.*, 2009). The effects of codeine in CYP2D6 UMs (who form too much active metabolite) and tamoxifen in PMs (who form too little active metabolite) represent examples of Type A and Type F toxicity, respectively.

The propensity for CYP2D6 to metabolize so many cardiovascular and CNS drugs (and other lipophilic amines) can be attributed in large part to the binding of the amine function to anionic residues (Glu216 and Asp301) in the substrate-binding site. Substrate oxidation usually occurs 5 to 7.5 Å from the basic nitrogen atom. Other substrate binding orientations are possible, which is why CYP2D6 can *N*-dealkylate drugs, even drugs that contain a single amine function (ie, drugs that appear to bind upside down in the active site) (Bonn *et al.*, 2008; Unwalla *et al.*, 2010).

Quinidine is a potent inhibitor of CYP2D6 because it interacts favorably with the anionic sites on CYP2D6 but it cannot be oxidized at a site 5 to 7.5 Å from its basic nitrogen atoms. Quinidine, paroxetine, and fluoxetine (and especially norfluoxetine, its *N*-demethylated metabolite) are strong CYP2D6 inhibitors in vivo, and a PM phenotype can be induced pharmacologically with these particular inhibitors. Quinine, the levorotatory diastereomer of quinidine, is not a potent inhibitor of CYP2D6, and neither drug is a potent inhibitor of the CYP2D enzymes expressed in rats. Compared with other SSRIs, fluoxetine causes surprisingly prolonged inhibition of CYP2D6; this is attributable in part to the long half-life of norfluoxetine (a primary amine), which also inhibits CYP2D6 (Liston *et al.*, 2002). Paroxetine has a relatively short plasma half-life (16–24 hours) but causes prolonged inhibition of CYP2D6 because it contains a methylenedioxy (benzodioxole) moiety that causes MDI of CYP2D6 (Venkatakrishnan and Obach, 2005). Because of the low dose of paroxetine (20 mg), maximum inactivation of CYP2D6 activity is not achieved without 7 to 10 days of paroxetine treatment. Bupropion, a commonly used in vitro probe of CYP2D6 activity, causes clinically relevant inhibition of CYP2D6 even though it is a relatively weak inhibitor of the enzyme in vitro (in human liver microsomes) (Reese *et al.*, 2008). Bupropion represents one of a handful of examples of system-dependent inhibition (Parkinson *et al.*, 2010) (see the section “Inhibition of Cytochrome P450”). The ability of bupropion to inhibit CYP2D6 in vivo is attributable in large part to its reduction to inhibitory metabolites (erythrohydrobupropion and threohydrobupropion). Accordingly, the in vivo inhibition of CYP2D6 by bupropion is better predicted in human hepatocytes than in human liver microsomes (Parkinson *et al.*, 2010).

The prominent determinants of CYP2D6 activity in vivo are genetic polymorphisms and treatment with inhibitory drugs. CYP2D6 is considered a noninducible enzyme, although its levels increase during pregnancy and decrease following renal impairment (Rostami-Hodjegan *et al.*, 1999; Sit *et al.*, 2010).

Compared with hepatic levels, low levels of CYP2D6 are present in several tissues including brain, kidney, lung, intestine, breast, and placenta (Zhou, 2009a,b). The metabolism of CNS drugs by CYP2D6 in the brain has attracted considerable interest, as has its ability to convert *m*- and *p*-tyramine to dopamine and to catalyze the 21-hydroxylation of certain steroid hormones such as progesterone.

Individuals lacking CYP2D6 have an unusually low incidence of some chemically induced neoplastic diseases (Idle, 1991). For example, CYP2D6 PMs appear to be relatively resistant to lung cancer, whereas CYP2D6 UMs appear to be at increased risk, although the effects are modest (Rostami-Hodjegan *et al.*, 1998; Agundez *et al.*, 2001). It has been hypothesized that CYP2D6 may play a role in the metabolic activation of chemical carcinogens, such as those present in the environment, in the diet, and/or in cigarette smoke. According to this hypothesis, CYP2D6 PMs have a low incidence of cancer because they fail to activate chemical carcinogens, whereas CYP2D6 UMs have an increased risk because they rapidly and/or extensively activate procarcinogens. However, CYP2D6 plays little or no role in the activation of known chemical

carcinogens to DNA-reactive or mutagenic metabolites, with the notable exception of the tobacco-smoke-specific nitrosamine, NNK, which is also activated by numerous other CYP enzymes (see the section “CYP2A6, CYP2A7, and 2A13”).

CYP2E1 As shown in Fig. 6-25, CYP2E1 was first identified as the microsomal ethanol oxidizing system (MEOS) (Lieber, 1999). It is now recognized as a key enzyme involved in the activation of acetaminophen (Tylenol) to its reactive metabolite NAPQI (see Fig. 6-35), a leading cause of DILI (Kaplowitz, 2005). CYP2E1 also biotransforms a large number of volatile halogenated alkanes (chloroform, carbon tetrachloride, vinyl chloride, and many more), halogenated anesthetics (halothane, enflurane, and others), small aromatic and nitrogen aromatic compounds (benzene, styrene, toluene, pyridine, pyrazole, and others), alkanes (ethane–hexane), alcohols (ethanol–pentanol), the colon carcinogen azoxymethane, and numerous mutagenic/carcinogenic nitrosamines (reviewed in Pohl and Scinicariello, 2011). In many cases CYP2E1 converts the aforementioned xenobiotics to reactive (toxic/mutagenic/carcinogenic) metabolites, as shown in Table 6-14 and as illustrated for carbon tetrachloride in Fig. 6-18, halothane in Fig. 6-19, benzene in Fig. 6-32, and *N*-nitrosamine, urethane (ethyl carbamate), trichloroethylene, and tetrachloroethylene in Fig. 6-50 (Guengerich, 1991). CYP2E1 activates acetylhydrazine, a metabolite formed following the *N*-acetylation of isoniazid, to a hepatotoxic metabolite. The severity of isoniazid hepatotoxicity is influenced by genetic polymorphisms that decrease *N*-acetyltransferases (NAT) and increase CYP2E1 activity, as discussed in the section “Acetylation.”

Studies in CYP2E1 knockout mice have established an important role for CYP2E1 in the in vivo activation of some of the aforementioned xenobiotics. Compared with wild-type mice, CYP2E1 knockout mice are protected (partially or completely) from the hepatotumorigenic effects of urethane (ethyl carbamate), the preneoplastic changes induced in the colon by azoxymethane, the myelotoxicity of benzene, and the hepatotoxicity of acetaminophen (Gonzalez, 2003, 2007; Ghanayem, 2006). CYP2E1 is 1 of 3 enzymes that catalyze the conversion of acetaminophen to NAPQI, the others being CYP1A2 and CYP3A4. Double knockout mice, in which both CYP2E1 and CYP1A2 are deleted, are even more resistant to acetaminophen hepatotoxicity than CYP2E1 knockout mice (Gonzalez, 2007). These findings in mice are thought to translate to the situation in humans. It is interesting to note, however, that human CYP2E1 knockin mice (transgenic mice harboring human CYP2E1 in place of the mouse enzyme, also known as CYP2E1-humanized mice) are more resistant to acetaminophen hepatotoxicity than wild-type mice, suggesting mouse CYP2E1 may be more active than human CYP2E1 in converting acetaminophen to NAPQI (Cheung and Gonzalez, 2008). The role of CYP2E1 in acetaminophen hepatotoxicity is discussed later in this section.

The only orally administered drug (as opposed to volatile anesthetics) that is primarily metabolized by CYP2E1 is chlorzoxazone, an FDA-approved muscle relaxant (Paraflex®). The urinary excretion of 6-hydroxychlorzoxazone and the plasma ratio of 6-hydroxychlorzoxazone to chlorzoxazone have been used as in vivo probes of CYP2E1. In human liver microsomes, CYP2E1 activity can be conveniently measured by the 6-hydroxylation of chlorzoxazone and the hydroxylation of 4-nitrophenol (Table 6-13). The 6-hydroxylation of chlorzoxazone can also be catalyzed by CYP1A1, but this enzyme is rarely expressed in human liver and only low levels are present in extrahepatic tissues. CYP2E1 is one of the CYP enzymes that require cytochrome *b₅*, which lowers the K_m for certain substrates (Levin *et al.*, 1986).

Table 6-14

Examples of Xenobiotics Activated by Human P450

CYP1A2	CYP2E1
Acetaminophen	Acetaminophen
2-Acetylaminofluorene	Acrylonitrile
4-Aminobiphenyl	Benzene
2-Aminofluorene	Carbon tetrachloride
2-Naphthylamine	Chloroform
NNK	Dichloromethane
Amino acid pyrolysis products	1,2-Dichloropropane
(DiMeQx, MeIQ, MeIQx, Glu P-2, IQ, PhIP, Trp P-1, Trp P-2)	Ethylene dibromide
Tacrine	Ethylene dichloride
CYP2A6 and 2A13	Ethyl carbamate
NNK and bulky nitrosamines	Halothane
<i>N</i> -Nitrosodiethylamine	<i>N</i> -Nitrosodimethylamine
Aflatoxin B ₁	Styrene
CYP2B6	Trichloroethylene
6-Aminochrysene	Vinyl chloride
Cyclophosphamide	CYP3A4
Ifosfamide	Acetaminophen
CYP2C8, 9, 18, 19	Aflatoxin B ₁ and G ₁
Tienilic acid	6-Aminochrysene
Phenytoin	Benzo[<i>a</i>]pyrene 7,8-dihydrodiol
Valproic acid	Cyclophosphamide
CYP2D6	Ifosfamide
NNK	1-Nitropyrene
CYP2F1	Sterigmatocystin
3-Methylindole	Senecionine
Acetaminophen	<i>Tris</i> (2,3-dibromopropyl)phosphate
Valproic acid	CYP4B1 (in animals but not humans)*
CYP1A1 and 1B1	Ipomeanol
Benzo[<i>a</i>]pyrene and other polycyclic aromatic hydrocarbons	3-Methylindole
	2-Aminofluorene

NNK, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, a tobacco-specific nitrosamine. Data from Guengerich and Shimada (1991).

*Due to lack of heme incorporation human CYP4B1 is probably inactive.

The function and regulation of CYP2E1 are relatively well conserved across mammalian species. CYP2E1 is expressed constitutively in liver and several extrahepatic tissues, such as the kidney, pancreas, brain, lung, intestine, nasal epithelium, bone marrow, and lymphocytes. The levels of CYP2E1 in human liver microsomes do not show the high degree of interindividual variation characteristic of other enzymes, as shown in Table 6-12. Numerous genetic polymorphisms in the CYP2E1 gene have been identified but none impact function and/or expression in a manner that gives rise to a PM or UM phenotype (reviewed in Pohl and Scinicariello, 2011). In humans and most other mammalian species, CYP2E1 is moderately inducible (<5-fold) by ethanol, isoniazid, pyrazole, acetone, and other ketone bodies (which form during uncontrolled diabetes). In contrast to the induction of most other CYP enzymes, the induction of CYP2E1 often involves increased translation of preexisting mRNA and/or protein stabilization rather than transcriptional activation of the CYP2E1 gene; hence, induction of CYP2E1 often occurs in the absence of an increase in mRNA levels (Gonzalez, 2007). An exception to this general rule is the induction of CYP2E1 by diabetes, which involves transcriptional activation and a marked increase in CYP2E1 mRNA. CYP2E1 can be inhibited by 4-methylpyrazole (fomepizole), which also inhibits ADH (class I ADH), and by disulfiram (Antabuse), which also inhibits ALDH (ADH2).

Disulfiram is one of many sulfur-containing agents that competitively or irreversibly inhibit CYP2E1, such as chlormethiazole, diallylsulfide, diethyldithiocarbamate, and phenylethylisothiocyanate (Pohl and Scinicariello, 2011).

Alcohol can potentiate the hepatotoxicity of acetaminophen. Several mechanisms have been proposed, including increased activation of acetaminophen due to the induction of CYP2E1, increased oxidative stress (ROS production), and decreased inactivation of NAPQI and ROS due to a lowering of GSH levels. Likewise fasting potentiates acetaminophen hepatotoxicity, presumably by inducing CYP2E1 (which is inducible by ketone bodies) and lowering UDPGA levels, which impairs the direct conjugation of acetaminophen and directs more drug toward the formation of NAPQI (Whitcomb and Block, 1994).

CYP2E1 is receiving considerable attention for several reasons that impact our understanding of its role in acetaminophen and alcohol toxicity. First, during its catalytic cycle CYP2E1 is prone to uncoupling (see Fig. 6-40), such that, during the metabolism of ethanol (alcohol) and acetaminophen, roughly 50% of its catalytic cycles result in the production of superoxide anion and related ROS instead of metabolite formation (Gonzalez, 2005; Lu and Cederbaum, 2008). Second, in rat liver, approximately 40% of CYP2E1 is phosphorylated and localized to the inner membrane

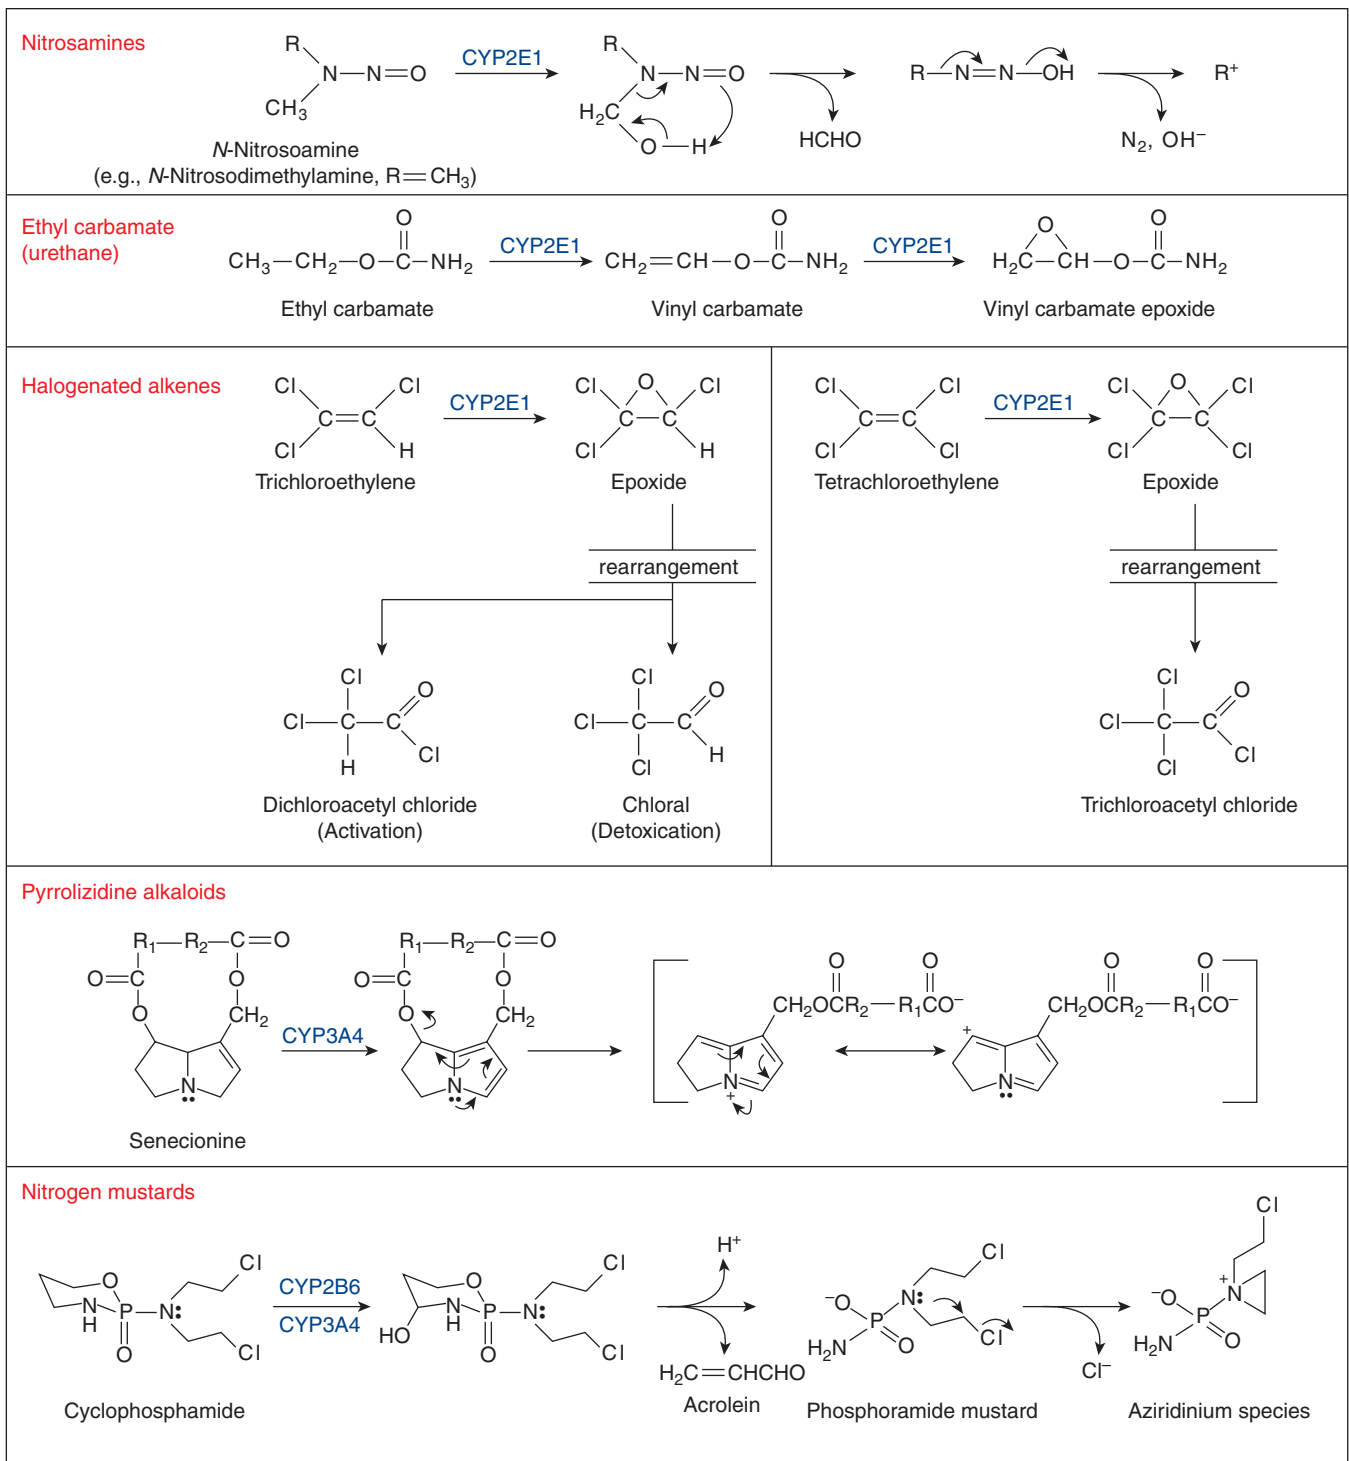

Figure 6-50. Additional mechanisms of cytochrome P450–dependent activation of xenobiotics to reactive (electrophilic) metabolites.

of mitochondria (Knockaert *et al.*, 2011a,b). Like all microsomal enzymes, CYP2E1 has a canonical N-terminal signal recognition peptide (SRP) that targets its translation to the rough endoplasmic reticulum (in ribosomes bound to the endoplasmic reticulum) but the process is relatively inefficient such that about half of CYP2E1 is transcribed by membrane-free ribosomes. CYP2E1 contains a mitochondrial targeting signal (2 positively charged amino acids, Lys₂₄ and Lys₂₅) and a serine residue (Ser₁₂₉) that, when phosphorylated by cAMP-dependent protein kinase A (PKA), complexes with heat-shock proteins (Hsp70 and Hsp90) and is translocated to the inner membrane of mitochondria (Knockaert *et al.*, 2011b). Cell culture

experiments in which CYP2E1 is expressed only in mitochondria or in both mitochondria and microsomes established that mitochondrial CYP2E1 is catalytically active (it is presumably supported by ferredoxin/ferredoxin reductase, the electron transporters that support endobiotic biotransformation by mitochondrial CYP enzymes) and is sufficient to cause oxidative stress, GSH depletion, and cell toxicity in response to acetaminophen or alcohol (Knockaert *et al.*, 2011a). A variety of evidence points to mitochondrial toxicity by NAPQI and ROS as the key event in acetaminophen hepatotoxicity (Jaeschke *et al.*, 2012). For example, studies with radioactive acetaminophen (4'-hydroxyacetanilide) and its nonhepatotoxic *meta*

isomer 3'-hydroxyacetanilide show comparable levels of overall covalent binding to mouse liver proteins but covalent binding of acetaminophen is predominantly in mitochondria, whereas binding of the nonhepatotoxic regioisomer is in the cytoplasm (reviewed in Jaeschke *et al.*, 2012). The mitochondrial localization of CYP2E1 and its ability to form NAPQI and ROS in the mitochondrion appear to be important determinants of acetaminophen hepatotoxicity. It is of interest that several CYP enzymes in addition to CYP2E1 have been located inside mitochondria (Knockaert *et al.*, 2011a,b).

There is growing evidence that the potentially deleterious ROS produced by microsomal CYP2E1 and other CYP enzymes (notably CYP1A2; the other high-spin enzyme that, like CYP2E1, can produce ROS even in the absence of substrate) is actively inhibited during the process known as ER stress, which is triggered by the accumulation of unfolded proteins (the ER plays a key role in protein folding and posttranslational modification of proteins prior to their exit to the Golgi and other destinations), which occurs in response to ischemia/reperfusion injury and exposure to certain xenobiotics such as tunicamycin (an *N*-glycosylation inhibitor) and thapsigargin (an ER calcium ATPase inhibitor) (Rasheva and Domingos, 2009; Tabas and Ron, 2011). Extensive ER stress (ie, a prolonged unfolded protein response [UPR], which is mediated by PERK, ATF6, and IRE1) results in the activation of caspases and Bcl-2, which leads to apoptotic cell death. However, mild ER stress activates Nrf2 and the antiapoptotic factor BI-1. Both activation of Nrf2 (through its phosphorylation by PERK, one of the 3 main ER stress responders) and BI-1 protect the endoplasmic reticulum from further damage by inhibiting the production of ROS by CYP2E1 (and presumably other CYP enzymes such as CYP1A2) by 2 distinct mechanisms (Lee *et al.*, 2007; Kim *et al.*, 2009). In the case of Nrf2, this transcription factor causes a marked (~10-fold) induction of heme oxygenase (among other antioxidant defense enzymes), which inhibits CYP activity by competing for electrons from NADPH-cytochrome P450 reductase (which serves both enzymes) (Reed *et al.*, 2011). Heme oxygenase can also inactivate certain CYP enzymes by converting their heme moiety to biliverdin (Kutty *et al.*, 1988). BI-1 also inhibits CYP but does so by complexing with NADPH-cytochrome P450 reductase (the 2 proteins coimmunoprecipitate), which inhibits ROS production by CYP2E1 (Kim *et al.*, 2009). From these studies it is emerging that CYP2E1 and possibly CYP1A2, the 2 high-spin CYP enzymes, produce ROS and contribute to oxidative stress, processes that are augmented by xenobiotics such as acetaminophen and alcohol and processes that are particularly damaging during ER stress.

CYP2F1 CYP2F1 is a human enzyme; its homologs in mouse and rat are CYP2F2 and CYP2F4, respectively. These enzymes are expressed in the respiratory tract (lung and nasal mucosa), although CYP2F1 is expressed in human lung at much lower levels than CYP2F2 is expressed in mice. In mice CYP2F2 plays an important role in activating various pulmonary/nasal toxicants including 3-methylindole, naphthalene, 1-nitronaphthalene, styrene, benzene, B[a]P, dichloroethylene, and trichloroethylene. For example, CYP2F2 knockout mice are resistant to the toxic effects of naphthalene on the lung and nasal olfactory mucosa (Li *et al.*, 2011a) and they are similarly resistant to the toxic effects of styrene on lung Clara cells and terminal bronchial cells (Cruzan *et al.*, 2012). Studies on the metabolic activation of 3-methylindole (a constituent in tobacco smoke) are interesting for illustrating how 2 respiratory enzymes, CYP2F2 and CYP2A5 (the homologs of human CYP2F1 and CYP2A13), can make the same initial reactive metabolites with different subsequent fates (Zhou *et al.*, 2012). Both CYP2F2 and CYP2A convert 3-methylindole to a carbon radical and epoxide, but these are further converted by CYP2A5

to stable metabolites: the carbon radical is converted to indole-3-carbinol by oxygen rebound and the epoxide is converted to an amide (3-methyloxindole) by rearrangement. In contrast, CYP2F2 converts these intermediates to reactive metabolites: the carbon radical is converted by dehydrogenation to a Michael acceptor, 3-methyleneindolenine, whereas the epoxide is either released or converted to iminium ions, all of which react with GSH. In animals, the activation of 3-methylindole can also be activated by another pulmonary enzyme, namely, CYP4B1, an enzyme that is thought to be functionally inactive in humans due to lack of heme incorporation (see the section "CYP4 Enzymes").

CYP2G1 CYP2G1 is not expressed in humans but it is expressed in the olfactory mucosa of rodents and other animals. Numerous xenobiotics cause nasal cytotoxicity and cancer in rodents (reviewed in Jeffrey *et al.*, 2006). Along with other CYP enzymes that are highly expressed in olfactory mucosa, such as CYP2A5 and CYP2F2 in mice and CYP2A3 and CYP2F4 in rats, CYP2G1 is a potential contributor to the formation of reactive metabolites in this target of xenobiotic toxicity in rodents.

CYP2J2 CYP2J2 is of interest for a number of reasons. First, it is expressed in vascular epithelium and high levels are found in the heart and many other tissues. CYP2J2 is the most abundant CYP expressed in heart and left ventricular levels are ~1.5-fold higher in women than in men (Michaud *et al.*, 2010). Based on mRNA levels (which may not reflect protein levels), the expression of CYP2J2 is highest in small intestine followed by heart > skeletal muscle > kidney > salivary gland > lung > liver. Second, CYP2J2 metabolizes many of the same drugs that are substrates for CYP3A4 (although not always to the same metabolites) and it is inhibited by many of the same drugs that inhibit CYP3A4 (Lee *et al.*, 2010a, 2012). Various derivatives of terfenadine have been identified as selective competitive or metabolism-dependent inhibitors of CYP2J2 (Lafite *et al.*, 2006, 2007). However, given the relatively low levels of intestinal and hepatic CYP2J2 compared with CYP3A4, Lee *et al.* (2010a) concluded that the contribution of CYP2J2 to presystemic clearance of drugs is probably low compared with that of CYP3A4. Furthermore, in contrast to CYP3A4, CYP2J2 is not inducible by CAR/PXR agonists (Neat *et al.*, 2009).

The third notable aspect is that CYP2J2 is the major enzyme in vascular endothelial cells responsible for the epoxidation of arachidonic acid to 4 EETs (5,6-, 8,9-, 11,12-, and 14,15-epoxyeicosatrienoic acid) with a minor contribution from CYP2C8 and CYP2C9 (Liu *et al.*, 2006a; Spiecker and Liao, 2006; Deng *et al.*, 2011; Xu *et al.*, 2011). EETs are endothelin-derived hyperpolarizing factors (EDHFs) (ie, vasodilators) that possess anti-inflammatory properties and protect tissues from ischemic injury. Hydrolysis of EETs by sEH terminates their vasodilatory and anti-inflammatory effects (see the section "Epoxide Hydrolases") (Fretland and Omiecinski, 2000; Morisseau and Hammock, 2005; Imig and Hammock, 2009). The acute vascular inflammatory response to endotoxin in transgenic mice can be attenuated either by overexpressing CYP2J2 (or CYP2C8) or by deleting sEH (sEH knockout mice) (Deng *et al.*, 2011).

The fourth and final notable aspect is that CYP2J2 is overexpressed in many human cancers and cancer-derived cell lines (Chen *et al.*, 2011a; Xu *et al.*, 2011). In human-derived tumor cell lines, overexpression of CYP2J2 (or direct application of EETs) stimulates cell proliferation and inhibits apoptosis, whereas the opposite effects are achieved by inhibiting CYP2J2 with terfenadine-like inhibitors or silencing CYP2J2 expression with antisense oligonucleotides (Chen *et al.*, 2009, 2011a; Xu *et al.*, 2011). Inhibitors of CYP2J2 are under consideration as anticancer agents, but by blocking EET formation in vascular endothelial cells they

may potentially predispose to hypertension and CAD (Chen *et al.*, 2011a; Xu *et al.*, 2011), whereas inhibitors of sEH are under consideration as cardioprotective drugs, but by inhibiting the hydrolysis of EETs in cancer cells they may potentially predispose to tumor development and metastatic tumorigenesis (Imig and Hammock, 2009; Wang *et al.*, 2010c).

In addition to its role in arachidonic acid metabolism, CYP2J2 can also catalyze the 25-hydroxylation of vitamin D₁, D₂, and D₃, the first of 2 steps in the formation of the active metabolite 1 α ,25-dihydroxyvitamin D (Aiba *et al.*, 2006).

CYP2R1, 2S1, 2U1, and 2W1 CYP2R1, 2S1, 2U1, and 2W1 are 4 of the 8 members of the CYP1 and 2 families that are so well conserved from an evolutionary perspective that they have been given the same names across all mammalian species (the other members are CYP1A1, 1A2, 1B1, and 2E1). These enzymes have been conserved during evolution presumably because they perform an important but in some cases a poorly defined physiological function. The hepatic enzyme CYP2R1 was identified as a vitamin D 25-hydroxylating enzyme in 2004, but other CYP enzymes in human liver microsomes (CYP27A1, CYP2J2, and CYP3A4) have been implicated in catalyzing this first step in the activation of vitamin D to 1 α ,25-dihydroxyvitamin D (Cheng *et al.*, 2004; Schuster, 2011). However, based on an analysis of genetic determinants of vitamin D deficiency, 2 groups established that genetic polymorphism of CYP2R1 is associated with circulating 25-hydroxyvitamin D, which provides strong evidence that CYP2R1 is the main enzyme responsible for the critical first step in vitamin D activation (Ahn *et al.*, 2010; Wang *et al.*, 2010b).

CYP2U1 is highly expressed in brain and thymus and to a lesser extent in kidney, lung, and heart (Devos *et al.*, 2010). CYP2U1 metabolizes arachidonic acid, docosahexaenoic acid (DHA), and other long-chain fatty acids. CYP2U1 catalyzes the ω -1 and ω -hydroxylation of arachidonic acid 19- and 20-HETE. The latter metabolite, 20-HETE, is a powerful vasoconstrictor in kidney and brain, which suggests CYP2U1 may play a role in the regulation of blood flow in these tissues. However, several CYP4A and CYP4F enzymes can also catalyze the ω -1 and ω -hydroxylation of arachidonic acid to 19- and 20-HETE. Genetic polymorphisms in CYP2U1 have been identified but they do not appear to alter its function or expression (Devos *et al.*, 2010).

CYP2S1 and CYP2W1 are intriguing enzymes because they are expressed in certain tumors and because they have unusual catalytic properties. CYP2S1 is expressed in several extrahepatic tissues such as lung, trachea, stomach, small intestine, colon, spleen, bladder, and skin (Saarikoski *et al.*, 2005). It is also expressed in psoriatic skin, ovarian cancer, and colorectal tumors where its presence is associated with poor prognosis (Kumarakulasingham *et al.*, 2005). CYP2W1 is expressed in a large number of tumors including colorectal and adrenal tumors, but it does not appear to be expressed to a significant extent in normal (ie, noncancerous) hepatic or extrahepatic tissues (Karlgrén *et al.*, 2006). Both enzymes are induced by hypoxia, which may account for their upregulation in tumors. CYP2S1 is also inducible by AhR agonists and joins CYP1A1, CYP1A2, and CYP1B1 as a TCDD-inducible enzyme (Saarikoski *et al.*, 2005). There is some evidence to suggest that, at least in certain cell lines, CYP2W1 is also inducible by AhR ligands (Tan *et al.*, 2011).

There is considerable controversy surrounding the catalytic function of CYP2S1, but this controversy has been resolved (at least in part) by understanding the importance of oxygen tension in the function of CYP2S1. Under aerobic conditions, CYP2S1 can catalyze the oxidative metabolism of several carcinogens (PAHs and

their diol epoxides, aflatoxin B₁, naphthalene, and styrene) but only if these reactions are supported by lipid peroxides or hydrogen peroxide (by the peroxide shunt) and not if the enzyme is supported by NADPH/O₂ together with NADPH-cytochrome P450 reductase (Wu *et al.*, 2006; Bui and Hankinson, 2009; Bui *et al.*, 2009). However, under anaerobic conditions, CYP2S1 can efficiently use NADPH-cytochrome P450 reductase and NADPH to catalyze reductive reactions, as can CYP2W1 (discussed later in this section) (Nishida *et al.*, 2010). These reactions are inhibited by oxygen. The ability of CYP2S1-expressing cells to catalyze the oxidative metabolism of carcinogens is suspect of being due to the presence of intracellular lipid peroxides and hydrogen peroxide that support the peroxide shunt (Bui and Hankinson, 2009; Bui *et al.*, 2009).

CYP2W1 catalyzes the oxidative metabolism of a wide variety of PAHs and their diol epoxides, aflatoxin B₁, and indoline to cytotoxic/mutagenic metabolites (Wu *et al.*, 2006; Gomez *et al.*, 2010). CYP2W1 also hydroxylates and epoxidates a variety of lysophospholipids (Xiao and Guengerich, 2012). It is unusual, however, for being one of the few CYP enzymes to undergo glycosylation, which places CYP2W1 on the luminal side of the endoplasmic reticulum, which is the wrong side for an interaction with NADPH-cytochrome P450 reductase, which faces the cytoplasmic side (Gomez *et al.*, 2010). Nevertheless, CYP2W1 expressed in cells is functional, either because it uses lipid peroxides/hydrogen peroxide (as does CYP2S1) or because it can use electron donors other than NADPH-cytochrome P450 reductase. As a result of its luminal orientation in the endoplasmic reticulum (where it becomes glycosylated), approximately 8% of CYP2W1 is expressed on the plasma membrane (Gomez *et al.*, 2010).

Because of their presence and upregulation in hypoxic tumors, CYP2S1 and CYP2W1 have been targeted for their potential to activate anticancer drugs. AQ4N is a prodrug (a di-*N*-oxide) that undergoes *N*-oxide reduction to 4QA, a potent topoisomerase II inhibitor. The reaction is catalyzed by both CYP2S1 and CYP2W1 under anaerobic conditions. The reductive activation by CYP2S1 and CYP2W1 requires NADPH-cytochrome P450 reductase but the reaction is inhibited by oxygen.

Phortress (a prodrug) is representative of a new class of anticancer drugs that are derivatives of 2-(4-amino-3-methylphenyl)-5-fluorobenzothiazole, better known as 5F-203. Phortress is in clinical trials as an anticancer agent. It is an AhR agonist that induces CYP1A1 and induces its own activation to one or more cytotoxic metabolites (Brantley *et al.*, 2004). Like CYP1A1, CYP2W1 also activates 5F-203 (the active metabolite of Phortress) and the related fluorinated benzothiazole GW-610 to cytotoxic metabolites, whereas CYP2S1 converts 5F-203 and GW-610 to inactive metabolites (Tan *et al.*, 2011). 5F-203 and GW-610 are AhR agonists that induce CYP1A1, CYP2S1, and, in certain cell lines, CYP2W1 (Tan *et al.*, 2011).

CYP3A Enzymes In terms of the number of drugs it metabolizes, CYP3A4 is the most important CYP enzyme. Numerous drugs, herbals, and food constituents inhibit or induce CYP3A4, making the enzyme the center of many drug interactions. The high levels in the liver and small intestine (where it works in conjunction with P-glycoprotein [ABCB1] and BCRP [ABCG2]) allow CYP3A4 to play a key role in the presystemic elimination of drugs and other xenobiotics. CYP3A5 is a polymorphically expressed enzyme expressed in liver, small intestine, and kidney. It is unusual inasmuch as the CYP3A5*3 allele that gives rise to a common PM genotype is more prevalent than the wild-type enzyme (the *1 allele) in several ethnic groups such that most Caucasians, Asians, and Mexicans are CYP3A5 PMs. CYP3A5 plays a significant role in the disposition

of tacrolimus but few (if any) other drugs. CYP3A7 is expressed in fetal liver. It is also expressed in adult liver and the levels increase with age (Ohtsuki *et al.*, 2012). Like CYP3A5, CYP3A43 plays an important role in the disposition of a select few drugs.

The function and regulation of the CYP3A enzymes is fairly well conserved among mammalian species, with some notable exceptions. For example, rifampin is an inducer of the CYP3A enzymes in humans and rabbits but not rats or mice, whereas the opposite is true of PCN. In adult rats, the levels of CYP3A2 in males are much greater (>10-fold) than in females (Waxman and Holloway, 2009). In humans, men do not have higher levels of CYP3A4 than women; in fact, there is evidence to suggest that the reverse is true—that women have slightly higher levels of CYP3A4 than men, although it should be noted that CYP3A4 levels vary widely in both men and women (Parkinson *et al.*, 2004; Seldin *et al.*, 2011).

CYP3A4 CYP3A4 is abundantly expressed in liver and small intestine, where it biotransforms an extraordinary array of xenobiotics and endobiotics (such as steroid hormones, sterols, and vitamin D), including drugs from numerous therapeutic classes as shown in Table 6-13. CYP3A4 metabolizes over half of all drugs (Gonzalez *et al.*, 2011). A large number of clinically significant drug–drug, drug–herbal, and drug–food interactions involve the inhibition or induction of hepatic and/or intestinal CYP3A4. Three victim drugs whose clearance is mainly determined by CYP3A4, namely, terfenadine (Seldane), cisapride (Propulsid), and astemizole (Hismanal), have been withdrawn from the market because of their potential to cause ventricular arrhythmias (and on rare occasions heart attacks) when their metabolism by CYP3A4 was inhibited by drugs such as ketoconazole and erythromycin (Huang *et al.*, 2008; Zhang *et al.*, 2009). One perpetrator drug, namely, mibefradil (Posicor), has been withdrawn from the market because of its ability to cause marked and prolonged inhibition of CYP3A4 by virtue of its ability to cause MDI of CYP3A4 (which persists after the inhibitory drug is withdrawn and until new enzyme is synthesized) (Foti *et al.*, 2011).

Intestinal CYP3A4 contributes significantly to the presystemic elimination of drugs because drugs in the small intestine are recycled by P-glycoprotein (ABCB1) and BCRP (ABCG2) on the luminal surface of enterocytes, which delays absorption and increases the opportunity for xenobiotic biotransformation by CYP3A4 (Benet, 2009; Galetin *et al.*, 2010). Furanocoumarins in grapefruit juice inhibit intestinal but not hepatic CYP3A4 and yet grapefruit juice increases systemic exposure to felodipine and other drugs that undergo first-pass metabolism by CYP3A4 (Paine *et al.*, 2006). The impact of the CYP3A4 inhibitor ketoconazole on the disposition of the CYP3A4 substrate midazolam depends on whether midazolam is given orally or intravenously. When midazolam is given intravenously, such that its clearance is dependent only on hepatic metabolism, ketoconazole causes a 3- to 5-fold increase in the AUC. However, when midazolam is given orally, ketoconazole causes a 10- to 15-fold increase in AUC, the difference reflecting the significant role of intestinal metabolism to the presystemic clearance of midazolam. In rats, administration of the general CYP inhibitor 1-aminobenzotriazole (ABT) by the intravenous route (which inhibits only hepatic CYP enzymes) and the oral route (which inhibits both intestinal and hepatic CYP enzymes) can be used to assess the relative role of the intestine and liver to the first-pass metabolism of a drug or other xenobiotic (Strelevez *et al.*, 2006).

The induction of CYP3A4 is mediated by CAR and PXR, agonists for which include several antibiotics, such as rifampin and rifabutin, several EIAEDs, such as phenobarbital, phenytoin, carbamazepine, and felbamate, and the herbal St. John's wort

(active inducer hyperforin), as shown in Table 6-13 (a more complete list of CYP3A4 inducers is given in the section “Induction of Cytochrome P450—Xenosensors”). The induction of intestinal and hepatic CYP3A4 (and conjugating enzymes, as outlined in the sections “Glucuronidation and Formation of Acyl-CoA Thioesters” and “Sulfonation”) by these agents can result in a loss of therapeutic efficacy of oral contraceptive steroids, anti-HIV, and anti-organ rejection drugs. It is an important mechanism of drug–drug and drug–herbal interactions (Huang *et al.*, 2008). Prolonged induction of CYP3A4 also adversely impacts the metabolism of vitamin D, as discussed in the section “Induction of Cytochrome P450—Xenosensors.”

CYP3A4 metabolizes more drugs than any other xenobiotic-biotransforming enzyme, which is apparent from the large list of CYP3A4 substrates listed in Table 6-13. Like CYP2C8, CYP3A4 can metabolize large substrates, such as paclitaxel (Taxol®), which is a substrate for both enzymes. The active site of CYP3A4 is sufficiently large to bind 2 drugs simultaneously (Ekroos and Sjögren, 2006), and individual drugs tend to bind to discrete regions, which has several consequences. First, the binding of 2 substrates to CYP3A4 allows for homotropic activation (where a substrate stimulates its own metabolism, as in the case of testosterone and diazepam) and heterotropic activation (where one compound, such as α -naphthoflavone, stimulates the metabolism of another). These effects give rise to non-Michaelis–Menten or atypical enzyme kinetics, which is characteristic of the metabolism of several drugs by CYP3A4 (Atkins, 2005). The binding of one ligand (substrate, inhibitor, or activator) to CYP3A4 can cause conformational changes that increase the size of the active site by 80% or more, which allows additional ligands to bind, possibly in a stacked or side-by-side configuration (Ekroos and Sjögren, 2006). Second, substrates can bind to relatively discrete sites within the active site. Testosterone and midazolam appear to bind to distinct sites (called the steroid and benzodiazepine binding site, respectively); consequently, these 2 prototypical substrates only weakly inhibit each other's metabolism by CYP3A4 (Schrag and Wienkers, 2001; Galetin *et al.*, 2003). As a result of these different substrate-binding sites or orientations, it is possible for a drug to inhibit CYP3A4 in a substrate-dependent manner (Schrag and Wienkers, 2001; Galetin *et al.*, 2003). However, inhibitors that coordinate directly with the heme moiety of CYP3A4 will inhibit the metabolism of all CYP3A4 substrates, as will most metabolism-dependent inhibitors of CYP3A4 (see the section “Inhibition of Cytochrome P450”). Although the active site of CYP3A4 is sufficiently large to bind substrates in apparently discrete sites and to bind 2 molecules simultaneously, it nevertheless often catalyzes reactions with a high degree of regioselectivity and stereoselectivity. In the case of testosterone, for example, CYP3A4 catalyzes hydroxylation at several sites on the β -face of the molecule (eg, 1 β -, 2 β -, 6 β -, and 15 β -hydroxylation) but none on the α -face.

More than 25 SNPs have been identified in the CYP3A4 gene, some of which contribute to the large interindividual variation in CYP3A4 activity (Staat *et al.*, 2010). An individual with low CYP3A4 activity was found to be heterozygous for a null allele (CYP3A4*20) and was characterized as a genetically determined IM (Westlind-Johnsson *et al.*, 2006). The *20 variant was the first null allele identified for CYP3A4. A genetic polymorphism in intron 6 (CYP3A4*22; rs35599367, C > T) affects the expression and, hence, the activity of CYP3A4 such that individuals who are homozygous for the *1 allele (CC carriers) have 1.7 times more CYP3A4 activity than heterozygotes (*1/*22 or CT) and 2.5 times more CYP3A4 activity than individuals homozygous for the *22 allele (TT carriers) (Wang *et al.*, 2011a). Compared with *1/*1

(wild-type) carriers, individuals carrying 1 or 2 of the loss-of-function *22 alleles require lower doses (40%–80% less) of atorvastatin, simvastatin, and lovastatin for optimal lipid control (Wang *et al.*, 2011a). The same genetic polymorphism impacts the disposition of cyclosporine and tacrolimus (Elens *et al.*, 2011a,b). In individuals who lack CYP3A5 (the majority of Caucasians, for example), carriers of the *22/*22 (TT) genotype (low CYP3A4) and *1/*22 (TC) genotype (intermediate CYP3A4) have dose-adjusted concentrations of cyclosporine that are, respectively, 1.5- and 2.2-fold greater than in carriers of the *1/*1 (CC) genotype (high CYP3A4); in the case of tacrolimus they are 1.6- and 4.1-fold greater (Elens *et al.*, 2011b).

The most widely studied CYP3A4 allelic variant (392A > G) is designated CYP3A4*1B. This allelic variant encodes a functional CYP3A4 enzyme that is expressed to the same extent (or perhaps to a slightly greater extent) than the wild-type enzyme (CYP3A4*1). The prevalence of the *1B allele varies from one ethnic group to the next as follows: 2% to 9.6% in Caucasians, 35% to 67% in black Africans, 9.3% to 11% in Hispanics, and 0% in Asians. This polymorphism is linked to the *1 genetic polymorphism in CYP3A5 such that CYP3A5 EMs tend to express the CYP3A4*1B variant, as discussed in the next section.

CYP3A5 CYP3A5 is a polymorphically expressed enzyme whose role in drug metabolism is a matter of considerable debate. The relative role of CYP3A4 *versus* CYP3A5 in the disposition of drugs is not easy to ascertain from in vitro or in vivo studies. Both enzymes are inducible by the same drugs; both enzymes metabolize the same drugs, and both are inhibited by the same drugs, although the 2 enzymes may differ in the affinity with which they bind to substrates and inhibitors. For example, when evaluated as inhibitors of recombinant human CYP3A enzymes, 14 out of 14 compounds inhibited CYP3A4 more potently than they inhibited CYP3A5 by a factor of 3.9- to 142-fold (Ekins *et al.*, 2003). A large number of drugs are metabolized in vitro by both CYP3A4 and CYP3A5. Some drugs appear to be metabolized by CYP3A4 but not CYP3A5; however, no drug is known to be metabolized by CYP3A5 but not by CYP3A4. Accordingly, there is no in vitro or in vivo probe drug to selectively measure CYP3A5 activity.

Assessing the relative contribution of CYP3A4 and CYP3A5 to the metabolism of drugs is complicated by several factors. For example, studies with human liver microsomes are complicated by conflicting reports on the relative levels of CYP3A5 and CYP3A4; some reports indicate that the levels of CYP3A5 in human liver microsomes are uniformly low (Patki *et al.*, 2003; Westlind-Johnsson *et al.*, 2003), whereas others indicate that, in some liver samples, the levels of CYP3A5 can approach those of CYP3A4 (Lin *et al.*, 2002). Analysis of the specific content of CYP enzymes by mass spectrometry indicates that, on average, CYP3A4 levels are considerably higher (>10 times) than the levels of CYP3A5, as shown in Table 6-12, but in individual livers the levels of CYP3A5 can approach those of CYP3A4 (Ohtsuki *et al.*, 2012). There are also conflicting reports on the relative rate of drug and steroid metabolism by recombinant CYP3A5 and CYP3A4. Early studies with recombinant enzymes generally showed that CYP3A4 is considerably more active than CYP3A5 in the metabolism of a wide range of substrates. However, these studies were criticized later by Huang *et al.* (2004) on the basis that few of them were conducted with recombinant enzymes in the presence of both NADPH-cytochrome P450 reductase and cytochrome b_5 . Under such conditions, the catalytic activity of CYP3A5 can rival or even surpass that of CYP3A4. Of the 8 substrates examined by Huang *et al.* (2004), midazolam represented the extreme case: in the presence of both

NADPH-cytochrome P450 reductase and cytochrome b_5 , recombinant CYP3A5 was 3 times more active than CYP3A4 at catalyzing the 1'-hydroxylation of midazolam, based on estimates of in vitro intrinsic clearance (*ie*, V_{\max}/K_m). However, when this same group evaluated the metabolism of the same 8 substrates in 2 pools ($n = 10$) of human liver microsomes each with the same levels of CYP3A4 but with markedly different levels of CYP3A5 (to mimic the CYP3A5 genetic polymorphism), it was found that CYP3A5 contributed nothing to the metabolism of testosterone, carbamazepine, lidocaine, terfenadine, dextromethorphan, or itraconazole, but contributed 27%, 26%, and 35% to the metabolism of midazolam, erythromycin, and flunitrazepam, respectively.

Huang *et al.* (2004) demonstrated that, under certain in vitro conditions, the catalytic activity of CYP3A5 can surpass that of CYP3A4 in a substrate-dependent manner, and they further predicted that CYP3A5 contributes to the in vivo metabolism of midazolam, a drug whose disposition is known to be highly dependent on CYP3A-catalyzed metabolism in the liver and small intestine. However, 2 clinical studies have shown that CYP3A5 genotype has no influence on the disposition of midazolam in vivo (Goh *et al.*, 2002; Shih and Huang, 2002). Possible reasons for the discrepancy between the in vitro prediction of the contribution of CYP3A5 to drug metabolism and the in vivo observation have been reviewed by Williams *et al.* (2003a).

The relative role of CYP3A4 and CYP3A5 in the metabolism of the calcineurin inhibitors cyclosporine and tacrolimus has been studied in vitro (Staatz *et al.*, 2010). These 2 antiorgan rejection drugs have a narrow therapeutic index and factors that affect their disposition are of great clinical interest. Studies with recombinant CYP3A4 and CYP3A5 and studies with human liver microsomes that contain both CYP3A4 and CYP3A5 or that contain only CYP3A4 suggest that the metabolism of cyclosporine is predominantly catalyzed by CYP3A4, whereas the metabolism of tacrolimus is predominantly catalyzed by CYP3A5 when this enzyme is present in human liver microsomes. Estimates of in vitro intrinsic clearance suggest that CYP3A4 contributes 2.3-fold more to the metabolism of cyclosporine than CYP3A5, whereas CYP3A5 contributes 2.0-fold more to the metabolism of tacrolimus than CYP3A4. Although these in vitro studies suggest a role for CYP3A5 in the metabolism of tacrolimus and, to a lesser extent, cyclosporine, it should be remembered that identical studies by Huang *et al.* (2004) predicted a role for CYP3A5 in the metabolism of midazolam, a prediction that subsequent clinical studies proved to be false.

In the case of CYP3A5, 11 SNPs have been identified, one of which (the *3 allele) causes a complete loss of CYP3A5 expression and, hence, a complete loss of CYP3A5 activity (Staatz *et al.*, 2010). Individuals who are homozygous for the *3 allele can be classified as CYP3A5 PMs; they are genetically deficient in CYP3A5. Individuals with at least 1 wild-type allele (*1/*1 and *1/*3) are considered CYP3A5 EMs.

The *3 allele that gives rise to the CYP3A5 PM genotype is unusual in that it is more prevalent than the wild-type allele (*1), at least in most populations. The prevalence of the wild-type allele (CYP3A5*1) varies from one ethnic group to the next as follows: 5% to 15% in Caucasians, 55% to 73% in black Africans, ~25% in Mexicans, and 15% to 35% in Asians. In Caucasians, Mexicans, and Asians, most individuals are CYP3A5 PMs, which creates an atypical situation with respect to drug metabolism, one that contrasts sharply with genetic polymorphisms in other CYP enzymes where, to take CYP2D6 as an example, most Caucasians are EMs and only a minority (about 7%) are PMs. In the case of a drug that is largely cleared by CYP2D6, for example, the dose that confers

therapeutic benefit to the largest number of people is a relatively *high* dose because most individuals are EMs. In the small number of individuals who are PMs (such as the 7% of Caucasians who lack CYP2D6), this dose may be too high; it may cause extended pharmacological effects (as seen with debrisoquine and sparteine) or adverse side effects (as seen with perhexiline). However, in the case of a drug that is primarily cleared by CYP3A5, the dose that confers therapeutic benefit to the largest number of people (in most ethnic populations) is a relatively *low* dose because most individuals are PMs. In the small number of individuals who are EMs (such as the 5%–15% of Caucasians who are CYP3A5 EMs), this dose may be too low; it may fail to confer a therapeutic benefit, which is a major concern for an antiorgan rejection drug such as tacrolimus.

Several studies have shown linkage disequilibrium between the CYP3A4*1B allelic variant and the CYP3A5*1 wild-type allele, as evidenced by the observation that 67% of Caucasians and 100% of black Africans expressing the CYP3A4*1B variant allele also express the CYP3A5*1 wild-type allele (Staatz *et al.*, 2010). There is also evidence of linkage disequilibrium between the P-glycoprotein 3435C > T variant allele and the CYP3A5*3 variant allele. Such linkages underscore the need for caution in attributing an effect to one allelic variant when in fact the effect may be caused by another allele in close linkage.

Numerous studies have been conducted to assess the impact of genetic polymorphisms of CYP3A4 and CYP3A5 (as well as P-glycoprotein [ABCB1]) on the pharmacokinetics of cyclosporine and tacrolimus. These studies were extensively reviewed by Staatz *et al.* (2010), and their findings can be summarized as follows:

1. The CYP3A4*1B allele has no effect on the disposition of cyclosporine.
2. The CYP3A4*1B allele increases the metabolism of tacrolimus, but this association likely reflects its linkage with CYP3A5*1 (the EM genotype).
3. The CYP3A5*3 allele has no consistent effect on the disposition of cyclosporine; some studies suggest the lack of functional CYP3A5 actually increases the rate of metabolism of cyclosporine, but others show no effect or a slight decrease.
4. The CYP3A5*3 allele impairs the metabolism of tacrolimus. The dose-adjusted trough level of tacrolimus in CYP3A5 PMs (*3/*3) is roughly twice that in CYP3A5 EMs (*1/*1 and *1/*3). Accordingly, to achieve the same blood levels, the dose of tacrolimus administered to CYP3A5 EMs is twice that administered to CYP3A5 PMs.

Overall, the results establish that the disposition of tacrolimus, but not cyclosporine, is affected by genetic polymorphisms of CYP3A5. Individuals with 1 or 2 copies of the wild-type *1 allele (EMs) metabolize tacrolimus twice as quickly as individuals with 2 copies of the *3 allele (PMs). In contrast, genetic polymorphisms of CYP3A4 (such as the loss-of-function *22 allele) impact the disposition of both cyclosporine and tacrolimus, as outlined in the section “CYP3A4”.

CYP3A7 CYP3A7 is expressed in fetal liver where it may play a role in the activation of drugs and other xenobiotics to teratogenic metabolites (Li *et al.*, 1997; Pang *et al.*, 2012). This is a concern because the laboratory animals used in drug safety testing (rats, mice, dogs, and monkeys) do not express a fetal CYP3A enzyme, raising the possibility that teratogenic metabolites formed by CYP3A7 may go undetected during reproductive toxicity testing in animals. In the fetus CYP3A7 is also expressed in extrahepatic tissue such as intestine, endometrial, placenta, adrenal gland, prostate, and lung in the fetus.

CYP3A7 is also expressed in most adult human livers and the levels increase with age (Ohtsuki *et al.*, 2012). CYP3A7 shows high activity toward endobiotics such as dehydroepiandrosterone (DHEA), estrone, and retinoic acid but low activity toward the majority of drugs metabolized by CYP3A4 (Williams *et al.*, 2002; Pang *et al.*, 2012). The 16 α -hydroxylation of DHEA is catalyzed by CYP3A7 but not by CYP3A4. A null allelic variant (CYP3A7*3, caused by a thymidine insertion [4011insT] that prematurely terminates translation) has been identified in a Korean subject (Lee *et al.*, 2010b).

CYP3A43 CYP3A43 is expressed in human liver but higher levels are found in brain, testis, and ovary (Westlind *et al.*, 2001). It is upregulated in prostate, breast, and ovarian carcinomas. There are reports of an association between the loss-of-function CYP3A43*3 polymorphism (Pro₃₄₀Ala) and the risk of prostate cancer and the grade and size of benign prostatic hyperplasia but there is no association with breast cancer risk (Justenhoven *et al.*, 2010, and references therein). A genetic polymorphism (an intronic SNP) in CYP3A43 (rs472660) accounts for the long recognized ethnic difference in the metabolism of olanzapine, an antipsychotic drug associated with a high rate of discontinuation due to lack of efficacy or the prevalence of adverse effects. Although the functional consequences of the SNP remain to be determined, 67% of African Americans carry the A variant and have higher rates of olanzapine clearance than Caucasians, only 14% of whom carry the A variant. Among the AA carriers 89% are African Americans (compared with 11% of Caucasians), whereas 95% of GG carriers are Caucasians compared with only 5% of African Americans (Justenhoven *et al.*, 2010).

The expression CYP3A43 in brain impacts the metabolism of the anti-anxiety drug alprazolam (Agarwal *et al.*, 2008). In the liver, CYP3A4 mainly converts alprazolam to the pharmacologically inactive metabolite 4-hydroxy-alprazolam, whereas in the brain CYP3A43 converts alprazolam to both 4-hydroxy-alprazolam and the pharmacologically active metabolite α -hydroxy-alprazolam.

CYP4 Enzymes Humans express 11 members of the CYP4 family, namely, CYP4A11, 4A22, 4F2, 4F3, 4F8, 4F11, 4F12, 4F22, 4V2, 4X1, and 4Z1. CYP4B1 is often considered a 12th member but the human CYP4B1 gene, in contrast to that in other mammalian species, encodes a protein that does not incorporate heme; hence, human CYP4B1 is catalytically inactive (Baer and Rettie, 2006). For the most part, the CYP4 enzymes can be divided into 2 groups: a large group that is known to metabolize fatty acids and/or eicosanoids and a small group (CYP4A22 and CYP4X1) with no known function (so-called orphan enzymes), as shown in Table 6-10. The first group (CYP4A11, 4F2, 4F3, 4F8, 4F12, 4F22, 4V2, and 4Z1) is part of a larger group of fatty acid- and eicosanoid-metabolizing enzymes, which includes CYP2C8, 2C9, and 2J2. However, these latter enzymes are fatty acid/eicosanoid epoxidases; they oxidize arachidonic acid to 4 regioisomers of EETs, which are vasodilators. In contrast, the CYP4 enzymes hydroxylate the terminal methyl group (ω -hydroxylation) of fatty acids and eicosanoids. In the case of arachidonic acid, ω -hydroxylation by CYP4 enzymes produces 20-HETE, which is a vasoconstrictor. Hydroxylation of the terminal methyl group (ω -hydroxylation) by CYP4 enzymes is thermodynamically unfavorable compared with hydroxylation of a methylene group (eg, ω -1 hydroxylation), which some CYP4 enzymes also catalyze (Baer and Rettie, 2006; Kalsotra and Strobel, 2006; Johnston *et al.*, 2011). Following ω -hydroxylation, the terminal hydroxymethyl group can be further oxidized to convert the original fatty acid/eicosanoid to a dicarboxylic acid. These dicarboxylic acids are then catabolized by fatty acid β -oxidation (chain shortening) and eliminated.

Unlike other CYP families, the majority of CYP4 enzymes have a covalently attached heme moiety in which the heme forms an ester bond with a conserved glutamic acid residue (Ortiz de Montellano, 2008). However, CYP4F8 and CYP4F12 are exceptions (and CYP4X1 probably also lacks a covalent heme because it lacks the critical glutamate residue). It is noteworthy that CYP4F8 and CYP4F12 preferentially hydroxylate fatty acids in the ω -1 or ω -2 position, which are more energetically favorable than ω -hydroxylation but which do not lead to the formation of dicarboxylic acids (Stark *et al.*, 2005). It has been postulated that the purpose of the covalently bound heme in CYP4 ω -hydroxylases is to help restrict the orientation of the fatty acid in the active site to direct hydroxylation toward the ω -position (Ortiz de Montellano, 2008; Johnston *et al.*, 2011).

Several CYP4 enzymes have been shown to metabolize drugs and other xenobiotics, but in nearly all cases the drugs that are metabolized by the CYP4 enzymes are also metabolized more extensively by CYP1, 2, or 3 family members. A notable exception is the antiparasitic prodrug pafuramidine (DB-289), which is *O*-demethylated in human liver microsomes by CYP4F2 and CYP4F3 with negligible contribution from CYP enzymes in the 1, 2, or 3 family (Wang *et al.*, 2006). *O*-Demethylation converts pafuramidine (DB-289) to an amidoxime, which undergoes dehydroxylation by mARC/cytochrome b_5 /NADH-cytochrome b_5 reductase as shown for other amidoximes in Fig. 6-22. Other examples of CYP4-mediated drug metabolism include the CYP4F12-dependent hydroxylation of ebastine and terfenadine (Cauffiez *et al.*, 2004), and the CYP4F2-dependent ω -hydroxylation of fingolimod (FTY720, Gilenya), an FDA-approved immunosuppressive drug for the treatment of multiple sclerosis (Zollinger *et al.*, 2011).

Another notable exception is CYP4B1, which is expressed in a wide range of extrahepatic tissues and which activates several prototoxicants including the pneumotoxins ipomeanol and 3-methylindole, the bladder carcinogen 2-AF, as well as aromatic amines in animals (Baer and Rettie, 2006). However, CYP4B1 appears to be inactive in humans due to a mutation that interferes with heme incorporation; the mutation is located in the meander region and encodes for a serine residue at amino acid 427. This amino acid is an evolutionarily conserved proline in other species where CYP4B1 is known to be active including cow, mouse, rat, rabbit, and dog. Introducing a Pro₄₂₇Ser mutation into rabbit CYP4B1 interferes with heme incorporation, and reverting Ser₄₂₇ to the conserved proline in the human CYP4B1 gene yields a functional enzyme that incorporates heme (Zheng *et al.*, 1998). The Pro₄₂₇Ser mutation likely explains why attempts to express human CYP4B1 in a recombinant system have yielded inactive enzyme lacking heme.

CYP4F2 has been implicated in the clearance of both vitamins K and E (Parker *et al.*, 2004; Sontag and Parker, 2007; McDonald *et al.*, 2009). Both of these compounds have phytyl-derived, long alkyl chains attached to a polar moiety (which makes them roughly structurally analogous to fatty acids). Urinary metabolites of vitamins K and E that lack the phytyl chain likely arise from CYP4F2-catalyzed ω -hydroxylation followed by further oxidation to the carboxylic acid with subsequent chain shortening by β -oxidation. A genetic polymorphism in CYP4F2 (Val₄₃₃Met) that impairs the metabolism of vitamin K₁ is clinically relevant because individuals with this loss-of-function allelic variant require a higher warfarin dose to compete with the increased levels of the vitamin K₁ in the liver (McDonald *et al.*, 2009; Lurie *et al.*, 2010).

Genetic defects in CYP4V2 and CYP4F22 have been linked to diseases with symptoms possibly caused by disruption of fatty acid homeostasis and/or disruption of eicosanoid signaling. Mutations in CYP4V2 are linked to Bietti crystalline corneoretinal dystrophy

(Li *et al.*, 2004), a late-onset eye disease characterized by night blindness and eventually blindness caused by crystalline deposits in the retinal epithelium and cornea. Mutations in CYP4F22 are associated with autosomal recessive congenital ichthyosis (Lefèvre *et al.*, 2006), which is characterized by large dark scales on the skin without exfoliative dermatitis. CYP4F22 is likely involved in the metabolism of hepoxillins or trioxillins, signaling molecules that are part of the arachidonic acid cascade (Kelly *et al.*, 2011).

Activation of Xenobiotics by Cytochrome P450

Biotransformation by CYP does not always lead to detoxication, and several examples have been given previously where the toxicity or tumorigenicity of a chemical depends on its activation by CYP. The role of individual human CYP enzymes in the activation of selected procarcinogens and prototoxicants is summarized in Table 6-14 (adapted from Guengerich, 1991). A variety of CYP-dependent reactions are involved in the activation of the chemicals listed in Table 6-14. The conversion of PAHs to tumor-forming metabolites involves the formation of bay-region diol epoxides, as shown in Fig. 6-10, for the conversion of B[a]P to B[a]P 7,8-dihydrodiol-9,10-epoxide. Epoxidation generates hepatotoxic metabolites of chlorobenzene and coumarin (Fig. 6-43), and generates a hepatotumorigenic metabolite of aflatoxin B1 (Fig. 6-34).

The initial step in the conversion of aromatic amines and amides to tumor-forming metabolites involves *N*-hydroxylation, as shown for 2-amino-6-nitrobenzylalcohol (Fig. 6-12), 2-AF, and 2-AAF (Fig. 6-61). The aromatic amides phenacetin, a discontinued drug, undergoes *N*-hydroxylation by CYP (and peroxidases) to form a hydroxamic acid. Under acidic conditions (such as in urine), the hydroxamic acid can lose water to form reactive nitrenium ion, which is thought to contribute to the renal toxicity of phenacetin (Testa and Krämer, 2008, 2010). In the case of acetaminophen, activation to hepatotoxic metabolite involves dehydrogenation to NAPQI, as shown in Fig. 6-35. A similar reaction converts BHT to a toxic quinone methide, as shown in Fig. 6-36. The myelotoxicity of benzene depends on its conversion to phenol and hydroquinone (Fig. 6-32). The toxicity of several OP insecticides involves oxidative group transfer to the corresponding organophosphate, as shown for the conversion of parathion to paraoxon in Figs. 6-46 and 6-47. The hepatotoxicity of carbon tetrachloride involves reductive dechlorination to a trichloromethyl free radical, which binds to protein and initiates lipid peroxidation, as shown in Fig. 6-18. The hepatotoxicity and nephrotoxicity of chloroform involves oxidative dechlorination to phosgene (Fig. 6-18). Both oxidative and reductive dehalogenation play a role in the activation of halothane, although hepatotoxicity in rats is more dependent on reductive dehalogenation, whereas the immune hepatitis in humans is largely a consequence of oxidative dehalogenation, which leads to the formation of neoantigens (Pohl *et al.*, 1989). Formation of neoantigens (by covalent binding to CYP2C9) is also the mechanism by which the uricosuric diuretic drug, tienilic acid, causes immune hepatitis (Lecoeur *et al.*, 1994).

Some of the chemicals listed in Table 6-14 are activated to toxic or tumorigenic metabolites by mechanisms not mentioned previously. For example, *N*-nitrosodimethylamine, which is representative of a large class of tumorigenic nitrosamines, is activated to an alkylating electrophile by *N*-demethylation, as shown in Fig. 6-50. The activation of ethyl carbamate (urethane) involves 2 sequential reactions catalyzed by CYP (CYP2E1): dehydrogenation to vinyl carbamate followed by epoxidation, as shown in Fig. 6-50. CYP2E1 is one of several CYP enzymes that can catalyze the epoxidation of tetrachloroethylene. The rearrangement of this epoxide to a carbonyl is accompanied by migration of chlorine,

which produces the highly reactive metabolite, trichloroacetyl chloride, as shown in Fig. 6-50. The toxic pyrrolizidine alkaloids, such as senecionine, are cyclic arylamines that are dehydrogenated by CYP (CYP3A4) to the corresponding pyrroles. Pyrroles themselves are nucleophiles, but electrophiles are generated through the loss of substituents on the pyrrolizidine nucleus, as shown in Fig. 6-50. Cyclophosphamide and ifosfamide are examples of chemicals designed to be activated to toxic electrophiles for the treatment of malignant tumors and other proliferative diseases. These drugs are nitrogen mustards, which have a tendency to undergo intramolecular nucleophilic displacement to form an electrophilic aziridinium species. In the case of cyclophosphamide and ifosfamide, the nitrogen mustard is stabilized by the presence of a phosphoryl oxygen, which delocalizes the lone pair of nitrogen electrons required for intramolecular nucleophilic displacement. For this reason, formation of an electrophilic aziridinium species requires hydroxylation by CYP, as shown in Fig. 6-50 for cyclophosphamide. Hydroxylation of the carbon atom next to the ring nitrogen leads spontaneously to ring opening and elimination of acrolein. In the resultant phosphoramidate mustard, delocalization of the lone pair of nitrogen electrons to the phosphoryl oxygen is now disfavored by the presence of the lone pair of electrons on the oxygen anion; hence, the phosphoramidate undergoes an intramolecular nucleophilic elimination to generate an electrophilic aziridinium species. This reaction is catalyzed by CYP2B6 and CYP3A4. Activation of cyclophosphamide by CYP enzymes in the skin would generate a cytotoxic metabolite at the base of hair follicles, which may be the reason why hair loss is one of the side effects of cyclophosphamide treatment.

Many of the chemicals listed in Table 6-14 are also detoxified by CYP by biotransformation to less toxic metabolites. In some cases, the same CYP enzyme catalyzes both activation and detoxication reactions. For example, CYP3A4 activates aflatoxin B₁ to the hepatotoxic and tumorigenic 8,9-epoxide, but it also detoxifies aflatoxin B₁ by 3-hydroxylation to aflatoxin Q₁. Similarly, CYP3A4 activates senecionine by converting this pyrrolizidine alkaloid to the corresponding pyrrole, but it also detoxifies senecionine through formation of an *N*-oxide (a reaction mainly catalyzed by FMO3). Epoxidation of trichloroethylene by CYP2E1 is both an activation and detoxication pathway, as shown in Fig. 6-50. Rearrangement of trichloroethylene epoxide can be accompanied by migration of chlorine, which produces chloral (trichloroacetaldehyde), or hydrogen, which produces dichloroacetylchloride. Chloral is much less toxic than dichloroacetylchloride; hence, migration of the chlorine during epoxide rearrangement is a detoxication reaction, whereas migration of the hydrogen is an activation reaction. These few examples serve to underscore the complexity of factors that determine the balance between xenobiotic activation and detoxication.

Structural alerts (functional groups) for the bioactivation of xenobiotics to reactive metabolites by CYP include the following: acetylenes, activated aromatics, 3-alklyl indoles, anilines, cyclopropylamines, formamides, furans, hydrazines, polyaromatics, pyrroles, nitro aromatics, sulfonylureas, thiazolidinones, thioamides, thiophenes, and thioureas (Walsh and Miwa, 2011). As outlined more fully in Point 12 (see the section "Introduction"), the prominence of cytochrome P450 in converting xenobiotics to reactive and potentially harmful metabolites is illustrated by the widespread use of liver microsomes in the *in vitro* safety evaluation of drug candidates. Liver microsomes are used in (1) the Ames bacterial mutagenicity assay, (2) an assessment of the formation of reactive metabolites that bind covalently to protein or GSH (or a related nucleophile such as *N*-acetylcysteine [NAC]), and (3) an assessment of a drug candidate's potential to cause irreversible inhibition of the

major drug-metabolizing CYP enzymes. The latter application is the topic of the next section.

Inhibition of Cytochrome P450 Inhibition of CYP is a major cause of drug–drug interactions (and occasionally the withdrawal of regulatory approval), as illustrated by the examples cited earlier (terfenadine, cisapride, astemizole, cerivastatin, and mibefradil) in the sections "CYP3A4" and "CYP2C8" (Ogilvie *et al.*, 2008). The magnitude of the drug–drug interaction depends on the degree of CYP inhibition by the perpetrator drug and the fractional metabolism (*f_m*) of the victim drug by the affected enzyme. This principle is explained in Point 23 in the section "Introduction." In summary, complete inhibition of a CYP enzyme that contributed 50% to the clearance of Drug A (*f_m* = 0.5) and 90% to the clearance of Drug B (*f_m* = 0.9) would cause a 2-fold increase in systemic exposure (plasma AUC) to Drug A, and a 10-fold increase in exposure to Drug B. The concept of "maximum exposure," where 2 perpetrators inhibit 2 parallel pathways of clearance and cause dramatic increases in systemic exposure to the victim drug, was explained in Point 24 in the section "Introduction." Maximum exposure often occurs when a genetic polymorphism affects one pathway of clearance and a perpetrator drug inhibits a second, parallel pathway of clearance, as illustrated in Point 24 for the weak effect (~2-fold) of the CYP3A4 inhibitor ritonavir on voriconazole exposure in CYP2C19 EMs (individuals in whom CYP3A4 plays a minor role in voriconazole metabolism) and the dramatic (26-fold) increase in voriconazole AUC in CYP2C19 PMs (individuals who lack CYP2C19 and in whom CYP3A4 plays the major role in voriconazole clearance) (Collins *et al.*, 2006; Ogilvie and Parkinson, *in press*). A single drug can inhibit multiple CYP enzymes and thereby inhibit 2 or more parallel pathways of drug clearance. An exceptional case is the interaction between fluvoxamine and ramelteon. The 3 major enzymes involved in the clearance of ramelteon are CYP1A2, CYP2C19, and CYP3A4, all of which are inhibited by fluvoxamine. The product label for ramelteon (Rozerem, Takeda Pharmaceuticals, Osaka, Japan) describes a drug–drug interaction study in which fluvoxamine caused a 190-fold increase in the plasma AUC of ramelteon, which is the largest drug interaction reported. Interestingly, the magnitude of the interaction surpasses that predicted from *in vitro* studies (Obach and Ryder, 2010).

Inhibitory drug interactions generally fall into 2 categories: direct inhibition (which can be competitive, noncompetitive, and uncompetitive) and metabolism-dependent inhibition (MDI, which can be irreversible or quasi-irreversible). Direct inhibition can be subdivided into 2 types. The first involves competition between 2 drugs that are metabolized by the same CYP enzyme. The second type of direct inhibition is when the inhibitor is not a substrate for the affected CYP enzyme. The inhibition of dextromethorphan biotransformation by quinidine is a good example of this type of drug interaction. Dextromethorphan is *O*-demethylated by CYP2D6, and the clearance of dextromethorphan is impaired in individuals lacking this polymorphically expressed enzyme. The clearance of dextromethorphan is similarly impaired when this antitussive drug is taken with quinidine, a potent inhibitor of CYP2D6. However, quinidine is not biotransformed by CYP2D6, even though it binds to this enzyme with high affinity (*K_i* ~100 nM). Quinidine is actually biotransformed by CYP3A4, and is a weak competitive inhibitor of this enzyme (*K_i* >100 μM), although its effects are highly dependent on the CYP3A4 substrate employed.

As the name implies, MDI occurs when CYP converts a xenobiotic to a metabolite that is a more potent inhibitor than the parent compound. In some cases, the metabolite, once formed, functions as a potent, reversible inhibitor, as occurs when fluoxetine is

N-demethylated to norfluoxetine. The contribution of norfluoxetine to the inhibitory effects of fluoxetine illustrates a common finding that drug metabolites often function as reversible inhibitors of CYP and thereby contribute significantly to drug–drug interactions (Isoherranen *et al.*, 2009; Yeung *et al.*, 2011). In other cases, however, the metabolite functions as an irreversible inhibitor (which occurs when the metabolite alkylates the heme or apoprotein moiety of CYP) or a quasi-irreversible inhibitor (which occurs when the metabolite coordinates tightly but not covalently with the ferrous heme to form what is known as a metabolite-inhibitory complex [MIC]). Metabolism-dependent inhibitors that cause irreversible inactivation of CYP include 8-methoxypsoralen (CYP2A6), clopidogrel (CYP2B6), tienilic acid (CYP2C9), and ticlopidine (CYP2C19), all of which contain a furan or thiophene that is activated by CYP to a reactive metabolite that inactivates the enzyme (suicide inactivation). Metabolism-dependent inhibitors that form metabolite inhibitory complexes and cause quasi-irreversible inhibition include the CYP3A4 inhibitor troleandomycin, which contains a tertiary amine (R-N(CH₃)₂) that is converted by several successive oxidative reactions to a putative nitroso metabolite (R-N=O) that coordinately binds to the ferrous heme iron. This interaction resembles the binding of CO to the ferrous heme iron, and indeed compounds that form inhibitory metabolite complexes with CYP can be detected spectrophotometrically based on an absorbance peak at around 455 nm (which is similar to the peak at ~450 nm when CO binds to CYP). The chemical structures commonly associated with MDI of CYP are shown in Table 6-15.

In some cases, MDI involves metabolism by enzymes other than the affected CYP enzyme, which can give rise to system-dependent inhibition in *in vitro* studies (whereby the results obtained in human liver microsomes or recombinant enzymes do not predict as well as studies performed with human hepatocytes). For example, the inhibition of CYP2C8 by gemfibrozil requires the formation of gemfibrozil glucuronide by UGT, after which gemfibrozil glucuronide functions as a metabolism-dependent inhibitor of CYP2C8 (Ogilvie *et al.*, 2006). Likewise, the reduction of bupropion to erythrohydrobupropion and threo hydrobupropion is largely responsible for its ability to cause clinically relevant inhibition of CYP2D6 (Reese *et al.*, 2008). Experiments with human liver microsomes and recombinant CYP enzymes underpredict the inhibition of CYP2C8 by gemfibrozil and the inhibition of CYP2D6 by bupropion, whereas hepatocytes do not because they support the necessary glucuronidation and reduction pathways, respectively (Parkinson *et al.*, 2010). Conversely, experiments with human liver microsomes and recombinant CYP enzymes overpredict the inhibition of CYP3A4 by ezetimibe. In the clinic (and in hepatocytes) rapid glucuronidation of ezetimibe protects CYP3A4 from MDI by ezetimibe (Parkinson *et al.*, 2010). Other issues that can arise during the *in vitro* evaluation of drug candidates as metabolism-dependent inhibitors of CYP enzymes are described by Parkinson *et al.* (2011). An extensive database on drug–drug interactions is available at the University of Washington Metabolism and Transport Drug Interaction Database (<http://www.druginteractioninfo.org>).

There are cases where inhibition of CYP has proved advantageous, as in the case of certain combinations of anti-HIV drugs. For example, by inhibiting CYP3A4, the HIV protease inhibitor ritonavir improves the pharmacokinetic profile of saquinavir and lopinavir, protease inhibitors that are otherwise cleared so rapidly by CYP3A4 that blood levels easily fall below therapeutically effective concentrations.

Induction of Cytochrome P450—Xenosensors The induction (upregulation) of xenobiotic-biotransforming enzymes and

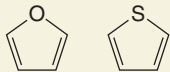

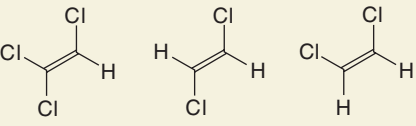

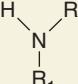

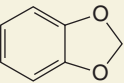

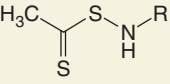

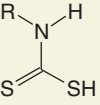

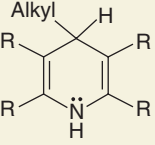

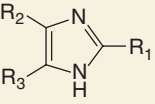

transporters is a receptor-mediated, adaptive process that augments xenobiotic elimination during periods of high xenobiotic exposure. It is not a toxicological or pathological response, but enzyme induction is often associated with liver enlargement (due to both hepatocellular hypertrophy and hyperplasia), and it may be associated with toxicological and pharmacological consequences, especially for the safety evaluation of drug candidates in laboratory animals and for clinical practice in humans. In animals and humans, enzyme induction may be associated with pharmacokinetic tolerance, whereby the xenobiotic induces its own elimination. Carbamazepine is one of many EIAEDs that induced its own metabolism. Because of autoinduction it is often necessary to increase the dose of carbamazepine at a rate of 200 mg every 1 to 2 weeks to achieve the desired seizure threshold. During safety testing in animals, autoinduction may require increasing dosages of drug candidate to achieve the same degree of systemic exposure. In rodents, lifetime exposure to enzyme inducers may be associated with liver or thyroid tumor formation, as discussed later in this section. In humans, enzyme induction may also be associated with pharmacokinetic tolerance (autoinduction). Long-term treatment of humans with enzyme inducers can cause osteomalacia due to increased inactivation of 1,25-(OH)₂-D₃, the active metabolite of vitamin D (discussed later in this section), but it is not associated with liver or thyroid tumor formation. However, in humans, enzyme induction by one drug (the perpetrator) can augment the clearance of a concomitantly administered drug (the victim), which is a cause of drug–drug interactions.

As an underlying cause of serious adverse events, enzyme induction is generally less important than enzyme inhibition because the latter can cause a rapid and profound increase in blood levels of a victim drug, which can cause an exaggerated pharmacological or toxicological effect. In contrast, enzyme induction lowers blood levels, which usually does not cause an exaggerated pharmacological or toxicological response to the drug. However, enzyme induction may be associated with a loss of therapeutic effectiveness, which is a particular concern when it compromises the therapeutic effectiveness of drugs that have a narrow therapeutic index and are being used to treat a life-threatening illness, such as anti-HIV drugs, antirejection drugs (such as cyclosporine and tacrolimus), and oral anticoagulants (such as warfarin), or when it is used with drugs that exhibit a quantal (all-or-nothing) dose–response relationship, such as oral contraceptive steroids (which either block or do not block ovulation and thereby provide or do not provide protection against pregnancy).

CYP induction does not necessarily enhance the biotransformation of the inducer, in which case the induction is said to be gratuitous. Consequently, lack of autoinduction cannot be taken as evidence that a xenobiotic does not cause enzyme induction. For example, in humans, omeprazole induces CYP1A2, even though the disposition of this acid-suppressing drug is largely determined by CYP2C19 and, to a lesser extent, CYP3A4. Some of the most effective inducers of CYP are polyhalogenated aromatic hydrocarbons (PHAHs), such as polychlorinated derivatives of dibenzo-*p*-dioxin (PCDDs), dibenzofurans (PCDFs), azobenzenes and azoxybenzenes, biphenyl (PCBs), and naphthalene. In general, highly chlorinated compounds are resistant to biotransformation and cause a prolonged induction of CYP and other enzymes. Some inducers are potent direct-acting or metabolism-dependent inhibitors such that they mask the activity of one or more of the enzymes they induce. Such dual-acting xenobiotics include macrolide antibiotics (eg, erythromycin and troleandomycin), methylenedioxy-containing compounds (eg, tadalafil [Cialis®], safrole, isosafrole), and imidazole antimycotics (eg, clotrimazole, ketoconazole, and

Table 6-15

Structures Associated With Metabolism-Dependent Inhibition of Cytochrome P450 (CYP) Enzymes

CHEMICAL GROUPS (EXAMPLES)	STRUCTURES
Terminal (ω) and ω -1 acetylenes (gestodene)	$R-C\equiv C-H$ $R-C\equiv C-R$
Furans and thiophenes (8-methoxypsoralen and tienilic acid)	
Epoxides (<i>R</i> -bergamottin-6',7'-epoxide)	
Dichloroethylenes and trichloroethylenes (1,2-dichloroethylene and trichloroethylene)	
Secondary amines (fluoxetine)	
Benzodioxoles (paroxetine)	
Isothiocyanates (phenethyl isothiocyanate)	$R-N=C=S$
Thioamides (methimazole)	
Dithiocarbamates (disulfiram)	
Conjugated structures (rhapontigenin)	
Terminal alkenes (tiamulin)	$R-CH=CH_2$
4-Alkyl-1,4-dihydropyridines (3,5-diethoxycarbonyl-1,4-dihydro-2,6-dimethyl-4-ethylpyridine [DDEP])

miconazole). In the case of dual-acting drugs (such as the induction/inhibition of CYP3A4 by ritonavir and several other HIV protease inhibitors, and the induction/inhibition of CYP2E1 by isoniazid), the initial effect—and often the effect observed during the period of drug treatment—is CYP inhibition, with induction becoming evident after prolonged drug treatment or following drug cessation. However, when ritonavir induces CYP3A4, for example, it also induces several other CYP enzymes, as well as conjugating enzymes and transporters that are regulated by CAR/PXR. Ritonavir does not inhibit all of the enzymes it induces. For

example, in the presence of 2 to 20 μ M ritonavir for 72 hours, CYP2B6 activity is increased by 4- to 6-fold in primary cultures of human hepatocytes, conditions that cause CYP3A4 inhibition (Faucette *et al.*, 2004). Some dual-acting xenobiotics, such as allyl-isopropylacetamide, cause certain types of porphyria (a disorder of heme synthesis) because they induce CYP enzymes and destroy the CYP heme moiety, which greatly increases the demand for heme synthesis (discussed later in this section).

In general, CYP induction is mediated by four ligand-activated receptors, namely, AhR, CAR, PXR, and PPAR α , as summarized in

Table 6-16

Receptors Mediating the Induction (or Suppression) of Cytochrome P450 Enzymes and Other Xenobiotic-Biotransforming Enzymes and Transporters

NUCLEAR RECEPTOR	RESPONSE ELEMENT(S)	RECEPTOR ACTIVATORS	REGULATED GENES*
AhR	XRE	PAHs, TCDD (other PHAHs), β -naphthoflavone, indigoids, tryptophan metabolites, omeprazole, lansoprazole	CYP1A1, 1A2, 1B1, 2S1, UGT1A1, UGT1A6, AKR1A1, AKR1C1-4
CAR	DR-3 DR-4 ER-6	Phenobarbital, phenytoin, carbamazepine, CITCO (human), TCPOBOP (mouse), clotrimazole, Yin Zhi Wang (many PXR agonists are also CAR agonists, and vice versa)	CYP2A6, 2B6, 2C8, 2C9, 2C19, 3A4, UGT1A1, SULT1A1, AKR1D1, ALAS, MRP2, MRP3, MRP4
PXR	DR-3 DR-4 ER-6 ER-8	Amprenavir, avasimibe, bosentan, bile acids, carbamazepine, clindamycin, clotrimazole, cortisol, cyproterone acetate, dicloxacillin, efavirenz, etoposide, dexamethasone, griseofulvin, guggulsterone, hyperforin (SJW), indinavir, lovastatin, mifepristone, nafcillin, nelfinavir, nifedipine, omeprazole, paclitaxel, PCBs, phenobarbital, phthalate monoesters, 5 β -pregnane-3,20-dione, rifabutin, rifampin, ritonavir, saquinavir, simvastatin, spironolactone, sulfapyrazole, TAO, tetracycline, topotecan, transnancolor, troglitazone, verapamil, vitamin E, vitamin K ₂	CYP2A6, 2B6, 2C8, 2C9, 2C19, 3A4, 3A7, 4F12, 7A1 \downarrow , CES2, SULT2A1, UGT1A1, 1A3, 1A4, 1A6, GSTA1, AKR1D1, PAPSS2, ALAS, MDR1, MRP2, AhR
PPAR α	DR-1	Fibrates, WY-14643, perfluorodecanoic acid	CYP4A, UGT1A9, 2B4
Nrf2	ARE	β -Naphthoflavone, oltipraz, phenolic antioxidants (eg, BHA and BHT), phenylisothiocyanate, and various glutathione depletors (diethyl maleate, phorone)	NQO1, mEH, AKR7A, UGTs, GSTA1, γ -GCL, MRP1
GR	GRE	Glucocorticoids (eg, dexamethasone)	CYP2C9, 2B6, 3A4, 3A5, CAR, PXR
FXR	IR-1	Bile acids, GW4064, AGN29, AGN31	BSEP, I-BABP, MDR3, UGT2B4, SULT2A1, OATP1B3, PPAR α , SHP
LXR α	DR-4	GW3965, T0901317, paxiline, F ₃ methylAA, [†] acetylpodocarpic dimer (APD)	LRH1, SHP, CYP7A, LXR α , CYP3A4 $\downarrow\downarrow$, 2B6 \downarrow
VDR	DR-3 ER-6 IR-0	1 α ,25-Dihydroxyvitamin D ₃ , lithocholate	CYP2B6, 2C9, 3A4, SULT2A1
HNF1 α	‡		OATP1B1, OATP1B3, CYP7A1, UGT1A6, 1A8, 1A9, 1A10, HNF4 α , PXR, kidney-specific expression of OAT1, OAT3, URAT1
HNF4 α	DR		CYP2A6, 2B6, 2C9, 2D6, 3A4, DD4, MDR1, PXR, CAR, FXR, PPAR α , HNF1 α
LRH-1	DR-4		CYP7A, ASBT
SHP	None		Targets of PPAR α \downarrow , AhR \downarrow , PXR \downarrow , CAR \downarrow , LRH-1 \downarrow , HNF4 α \downarrow , LXR α \downarrow , GR \downarrow

Data from Tirona and Kim (2005), Penning and Drury (2007), and Jin et al. (2011).

*A downward arrow indicates downregulation (suppression). All others are upregulated (induced).

[†][3-Chloro-4-(3-(7-propyl-3-trifluoromethyl-6-(4,5)-isoxazolyl)propylthio)-phenylacetic acid].

[‡]The HNF1 α consensus sequence is GTTAAATNATTAAC.

Table 6-16 (adapted from Tirona and Kim, 2005). These so-called xenosensors resemble other nuclear receptors, such as steroid and TH receptors, which has consequences for receptor interactions (cross-talk among xenosensors and cross-talk between xenosensors and other nuclear receptors), the role that some xenosensors play in responding to endobiotics and regulating their metabolism (eg, bilirubin, bile acids, fatty acids, and 1,25-(OH)₂-D₃), and the role

that some nuclear receptors (such as farnesoid X receptor [FXR], VDR, small heterodimer partner-1 [SHP], NF- κ B) play in inducing or suppressing the expression of xenobiotic-biotransforming enzymes and transporters, as discussed later in this section. Details of the nomenclature system of this superfamily of DNA-binding transcriptional factors have been reviewed (Germain et al., 2006). Xenosensors have a ligand-binding domain (LBD) and a highly

conserved cysteine-rich DNA-binding domain (DBD). In general, CYP induction involves the following steps (with steps 2 and 3 reversed in the case of AhR): (1) binding of ligand (xenobiotic) to the receptor, which triggers conformational changes that promote its dissociation from accessory proteins (such as corepressors, chaperones, and cytoplasm retention proteins) and promote its association with coactivators; (2) dimerization of the ligand-bound receptor with a partner protein to form a DNA-binding heterodimer (which is analogous to the two halves of a clothes peg coming together to form a functional unit); (3) translocation of the functional receptor heterodimer from the cytoplasm to the nucleus; (4) binding of the functional receptor heterodimer to discrete regions of DNA (response elements) that are typically located in the 5'-promoter region of the gene (which is analogous to a clothes peg being fastened to a clothes line); (5) recruitment of other transcription factors and coactivators (such as histone and RNA methyltransferases, histone and chromatin deacetylases, and histone remodeling helicases) and RNA polymerase to form a transcription complex; and (6) gene transcription, which leads to increased levels of CYP mRNA and protein (as well as other xenobiotic-biotransforming enzymes and transporters). As is the case with all nuclear receptors, the details of the process of activating a xenosensor to its transcriptionally active form are complex and multifaceted. Over 200 coactivators/coregulators of nuclear receptor function have been identified (Lonard and O'Malley, 2006), some of which are known to play a critical but undefined role in xenosensor activation.

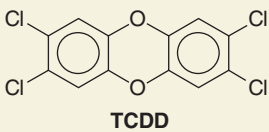

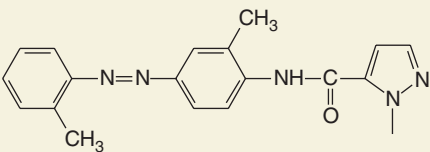

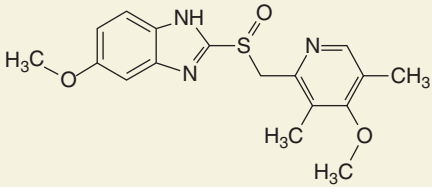

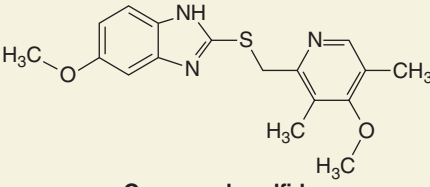

As shown in Table 6-16, the major ligand-activated receptors mediating CYP induction are (1) AhR, which partners with aryl hydrocarbon receptor nuclear translocator (ARNT) to induce CYP1A1, 1A2, 1B1, and 2S1; (2) CAR (aka the constitutively active receptor), which partners with RXR α (the retinoid X receptor, which binds 9-*cis*-retinoic acid) to induce several members of the CYP2A, 2B, 2C, and 3A subfamilies; (3) PXR (aka SXR, the steroid X receptor) that, like CAR, partners with RXR α and induces several members of the CYP2A, 2B, 2C, and 3A subfamilies; and (4) PPAR α , which partners with RXR α and induces CYP4A enzymes. The response elements (aka consensus sequences) to which xenosensors bind are generally a pair of hexanucleotide sequences in a direct repeat (DR), inverted repeated (IR), or everted repeat (ER) orientation, separated by a 0 to 8 nucleotide spacer. As shown in Tables 6-16 and 6-17, activation of a xenosensor leads to the induction of multiple enzymes, which is called a pleiotypic response. However, in terms of fold induction, CYP enzymes tend to be the most inducible and, consequently, the most studied enzymes (although activation of PPAR α has a more pronounced effect on the expression of peroxisomal enzymes involved in fatty acid oxidation). Like induction of CYP enzymes, induction of conjugating and other non-CYP enzymes is an important mechanism of drug–drug and drug–endobiotic interactions. For example, induction of various conjugating enzymes (both *SULT* and *UGT* enzymes) plays a key role in the metabolism of oral contraceptive steroids in humans, which is associated with a loss of therapeutic effect. In rodents induction of conjugating enzymes is responsible for increased metabolism of thyroid hormone, which is associated with thyroid follicular cell hyperplasia and tumor formation. As shown in Table 6-16, AhR, CAR, PXR, and PPAR α are not the only receptors that regulate CYP expression in response to xenobiotics (or certain endobiotics). Nuclear factor erythroid 2-related factor 2 (Nrf2) plays a key role in regulating the induction of several enzymes in response to electrophilic metabolites, oxidative stress, or GSH depletion, as discussed previously (see Point 9 in the section “Introduction” and sections “Epoxide Hydrolases” and “Quinone Reduction—NQO1 and NQO2”). The enzymes regulated by Nrf2

include several conjugating but few CYP enzymes (notable exceptions are CYP2C55 and 2U1 in mice), whereas those regulated by AhR, CAR, PXR, and PPAR α include both conjugating and CYP enzymes. A role for HNF1 α in the kidney-specific expression of drug transporters, OAT1, OAT3, and URAT1, has been documented (Jin *et al.*, 2011). Some of the other receptors listed in Table 6-16 are discussed later in this section. CYP induction can also involve mechanisms other than receptor-mediated transcriptional activation. Increased translation of mRNA is the mechanism by which several xenobiotics increase the levels of CYP2E1, and increased translational efficiency and protein stabilization play important roles in the induction of several CYP enzymes including CYP1A2, 2E1, and 3A enzymes (Gonzalez, 2007).

It might be assumed that xenobiotics can be divided into four categories of inducers represented by the xenosensors AhR, CAR, PXR, and PPAR α . This is largely true of rats where 3-methylcholanthrene, phenobarbital, PCN, and clofibrac acid are prototypical inducers of CYP1A, 2B, 3A, and 4A by virtue of their ability to activate AhR, CAR, PXR, and PPAR α , respectively. In fact, rats have 5 classes of inducible CYP enzymes with the fifth class represented by CYP2E1, which is inducible by the prototypical inducer isoniazid. However, the situation in other species (including rats) on a xenobiotic-by-xenobiotic basis is not so straightforward because (1) CAR and PXR have similar but not identical LBDs such that ligands that activate one receptor activate the other and vice versa (although they can do so with markedly different affinities) and (2) CAR and PXR have similar but not identical DBDs such that, once activated, CAR and PXR bind to some of the same response elements and induce the same enzymes. It was once thought that CYP2B induction was mediated only by CAR, and that CYP3A induction was mediated only by PXR. However, the PXR agonist dexamethasone can maximally induce both CYP2B10 and CYP3A11 in wild-type and CAR knockout mice, indicating that PXR can maximally induce both CYP2B and 3A enzymes in mice. Similarly, the CAR activator phenobarbital can maximally induce CYP2B10 and induce CYP3A11 (albeit submaximally) in wild-type and PXR knockout mice, indicating that CAR can also induce both CYP2B and 3A enzymes (Kodama and Negishi, 2006). The same is true of humans: PXR can maximally induce both CYP2B6 and CYP3A4, whereas CAR can maximally induce CYP2B6 and induce CYP3A4 submaximally due to its relatively weaker binding and functional activation of the CYP3A4 ER6 (Faucette *et al.*, 2006). Furthermore, there are species and strain differences in the LBDs, the DBDs, and the DNA-response elements that give rise to species and strain differences in enzyme induction, and even interindividual differences in humans. Some species differences in enzyme induction reflect differences in the catalytic activity of CYP enzymes. For example, although 7-methoxyresorufin and 7-ethoxyresorufin are useful substrates to study CYP1A enzyme induction in all mammalian species, 7-pentoxoresorufin is useful for studying CYP2B only in mouse and rat (not hamster, dog, monkey, or humans). However, many species, strain, and individual differences in enzyme induction reflect differences in xenosensor function, as discussed below (this section). The following descriptions of the individual xenosensors focus largely on the mouse and human receptors; studies of the latter have been driven by the desire to investigate drug–drug interactions, whereas studies of the former have been facilitated by the ability to create transgenic mice in which a particular xenosensor has been deleted (so-called knockout or null mice) or replaced with the human receptor (so-called humanized mice).

Aryl Hydrocarbon Receptor AhR and ARNT are cytosolic and nuclear transcription factors, respectively, that are expressed in

Examples of Agonists and Antagonists for the Receptors That Mediate Enzyme Induction (AhR, CAR, and PXR) and PXR/CAR Target Genes in Humans and Mice

*Data from Tolson and Wang (2010).

most tissues and many cell lines. The binding of an agonist such as TCDD (the structure of which is shown in Table 6-17) to AhR initiates a number of changes (such as dissociation from heat-shock protein [hsp90] and other chaperones, dissociation from proteins that retain the unbound receptor in the cytoplasm, phosphorylation by tyrosine kinase) that culminate in (1) the translocation of AhR to the nucleus, (2) the dimerization of AhR with ARNT (which is somewhat misnamed as the *aryl hydrocarbon receptor nuclear translocator* because it is a nuclear, not a cytoplasmic protein that complexes with AhR after it translocates to the nucleus), (3) the binding of AhR-ARNT to DNA-response elements known as XRE, and (4) the increased transcription of CYP1A1 and numerous other genes listed in Table 6-16. Whereas members of the nuclear receptor superfamily (such as CAR, PXR, and PPAR α) are “zinc finger” proteins, AhR and ARNT are “bHLH-PAS” proteins, so-named because they belong to the per-arnt-sim (PAS) class of receptors and they have a basic helix-loop-helix (bHLH) domain near their N-terminus, which is involved in protein-protein interactions.

TCDD is a high-affinity ligand for AhR (K_D values tend to be in the nanomolar-to-submicromolar range), and AhR mediates the toxicity of TCDD and related PHAHs (such as various chlorinated or brominated dibenzodioxins, dibenzofurans, and biphenyls), which is characterized by a wasting syndrome (progressive weight loss or cachexia resulting in death), immunosuppression (thymic atrophy), tumor promotion, fetal abnormalities (cleft palate and other teratogenic disorders), and, in some species, liver enlargement and a skin condition called chloracne. TCDD binds to AhR and induces CYP1A1 in all mammalian species, but it causes lethal cachexia in some species (such as guinea pig, where the LD_{50} is ~ 1 $\mu\text{g}/\text{kg}$) but not others (such as hamsters, where the LD_{50} exceeds 1000 $\mu\text{g}/\text{kg}$). This species difference in toxicity but not in CYP1A1 induction raised the possibility that AhR does not mediate the toxicity of TCDD, but several lines of evidence established that AhR does in fact mediate many, perhaps all, of the toxic effects of TCDD and related compounds. First, naturally occurring strain differences in the responsiveness of mice (such as so-called responsive C57 and nonresponsive DBA mice) and rats (such as responsive Long-Evans and nonresponsive Han/Wistar rats) to TCDD toxicity are associated with polymorphisms in AhR (Pohjanvirta *et al.*, 1999). Second, AhR knockout mice are resistant to TCDD-induced toxicity, whereas transgenic mice that express a constitutively active form of AhR (CA-AhR mice) spontaneously display numerous signs of TCDD toxicity (even though the CYP1A1 levels in the liver of CA-AhR mice are elevated to a lesser extent than those in TCDD-treated wild-type mice) (Brunnberg *et al.*, 2006). Third, the AhR antagonist CH-223191 (see Table 6-17) blocks the enzyme-inducing effects and various toxic effects of TCDD (Kim *et al.*, 2006). Nevertheless, it remains to be determined why prolonged activation of AhR by TCDD and related compounds causes an irreversible cachexia that leads to death after a certain time (after a latency period that varies from one species to the next but that cannot be shortened by administering “superlethal” doses of TCDD).

AhR agonists include PHAHs (such as TCDD), PAHs (such as 3-methylcholanthrene and B[a]P), flavonoids (such as β -naphthoflavone), and various acid-catalyzed condensation products or UV-induced derivatives of naturally occurring indoles (such as indole-3-carbinol and tryptophan). The indole derivative indirubin and indoxyl sulfate, the major metabolite of indole in mammals, and two metabolites of the indoleamine-2,3-dioxygenase pathway, namely, kynurenic acid and xanthurenic acid, are AhR agonists particularly of the human receptor (Omiecinski *et al.*, 2011b). In general, AhR agonists induce CYP1A1 and other enzymes across all mammalian and many nonmammalian species. A notable exception is a class of benzimidazole-containing compounds that includes the proton

pump inhibitors omeprazole and lansoprazole. These drugs are not typical AhR agonists for 2 reasons. First, they do not bind to the LBD of AhR but activate AhR either directly (by binding to a second site on AhR) or indirectly (by activating a tyrosine kinase that phosphorylates AhR). Second, they activate AhR and induce CYP1A enzymes in humans but not in rats or mice, which is 1 of the few species differences in AhR activation by xenobiotics (Diaz *et al.*, 1990). An endogenous AhR ligand is suspected to exist because AhR function is so well conserved from fish to humans and because of developmental abnormalities observed in AhR knockout mice. In addition to agonists and antagonists there is a third class of AhR ligands known as selective AhR modulators (SAhRMs) as exemplified by SGA360. In contrast to AhR agonists that induce both XRE-driven transcriptional activity and repression of acute-phase gene expression, SAhRMs are only capable of mediating repression of acute-phase genes (Murray *et al.*, 2010). The SAhRM-mediated suppression of acute-phase genes is a non-XRE-driven, cytoplasmic event. This process illustrates an emerging role of AhR in the regulation of inflammatory process and liver homeostasis. AhR influences T-cell differentiation and influences the balance of T_H1 and T_H2 cells, as was established through the use of an AhR agonist M50367 that preferentially promotes the production of T_H1 over T_H2 cells. Exposure of mice to M50367 leads to a decrease in IgE synthesis and peritoneal eosinophilia in allergic experimental models (Negishi *et al.*, 2005).

Several compounds can disrupt AhR signaling at a variety of levels. CH-223191 (Table 6-17) and α -naphthoflavone are receptor antagonists that bind to the LBD of AhR without activating the receptor. Omeprazole sulfide (which forms by reduction of the sulfoxide group in omeprazole [see Table 6-17]) antagonizes CYP1A1 induction by omeprazole by stabilizing AhR in an inactive conformation (Gerbal-Chaloin *et al.*, 2006). After AhR is activated, its translocation to the nucleus is blocked by 3'-methoxy-4-nitroflavone, its binding to XRE is blocked by salicylamide, and its ability to recruit transcription factors and initiate gene transcription is blocked by resveratrol (an antioxidant in red wine) (Gerbal-Chaloin *et al.*, 2006). The presence of exogenous (and perhaps endogenous) AhR antagonists is one of the many factors that are known or suspected of causing clinically observed interindividual differences in CYP1A induction. These factors have been reviewed by Ma and Lu (2003), who have documented that differences in the magnitude of CYP1A induction in humans can be attributed to (1) genetic polymorphisms in AhR, ARNT, or XRE; (2) altered levels or function of accessory proteins (some of which are associated with inflammation and other disease states that activate NF- κ B, as discussed later in this section); (3) gender differences in basal CYP1A2 activity (which tends to be lower in females compared with males); and (4) variation in the intracellular concentration of the inducing drug, as exemplified by variation in the metabolism of omeprazole. The clearance of omeprazole is largely determined by its rate of metabolism by the polymorphically expressed enzyme CYP2C19. Based on measurements of caffeine metabolism, a daily dose of 40 mg omeprazole causes CYP1A2 induction in CYP2C19 PMs but not in CYP2C19 EMs, which require higher doses (120 mg) to achieve CYP1A2 induction. In a clinical setting, the formation of omeprazole sulfide (an AhR antagonist) does not prevent CYP1A induction by omeprazole (an agonist). However, it is possible that the formation of rabeprazole sulfide, which occurs rapidly and extensively (by nonenzymatic means), explains why rabeprazole is one of the proton pump inhibitors that does not induce CYP1A.

Although strain differences in CYP1A inducibility have been linked to genetic polymorphisms in the mouse and rat AhR gene, species differences have been attributed either to the unusual interaction of AhR with benzimidazole-containing compounds such as omeprazole and lansoprazole or to species differences in the

location of XRE. For example, rat UGT1A6 and 1A7 are highly inducible (>20-fold) enzymes because these conjugating genes are under the control of XRE in rats but in few other species.

Increased expression of AhR is correlated with tumor invasiveness of cigarette-smoke-associated urothelial carcinoma cells in vitro, presumably due to enhanced expression of MMP-1 and MMP-9, matrix metalloproteinases involved in tumor invasion (Ishida *et al.*, 2010). The involvement of AhR signaling in tumor invasiveness is further supported by a positive correlation between nuclear localization of the receptor and histopathological characteristics of the neoplasm and long-term survival of urothelial carcinoma patients.

Constitutive Androstane Receptor and Pregnane X Receptor

CAR and PXR are members of the nuclear receptor family 1 (NR1I2 and NR1I3, respectively). In contrast to AhR, which is expressed in most tissues and numerous cell lines, CAR and PXR are expressed in relatively few organs—liver, small intestine, and colon—and in few cell lines. Both CAR and PXR are cytoplasmic nuclear receptors; both are activated by some of the same compounds, and both dimerize with RXR α to form DNA-binding proteins that recognize some of the same response elements, as shown in Tables 6-16 and 6-17. Consequently, there is considerable crosstalk between these two xenosensors, and it can sometimes be difficult to ascertain whether induction is mediated by CAR, PXR, or both receptors. Both humans and mice have drug-metabolizing enzymes and transporters that are regulated by CAR only, PXR only, and both xenosensors, but the enzymes/transporters are inducible in a species-dependent manner, as shown for humans and mice in Table 6-17 (Tolson and Wang, 2010).

As shown in Table 6-16, three factors combine to make CAR and PXR the most important human xenosensors in terms of drug–drug interactions. First, CAR and PXR regulate several CYP enzymes (eg, CYP2B6, 2C8, 2C9, 2C19, and 3A4), conjugating enzymes (several UGTs and SULTs), and transporters (such as *P*-glycoprotein [MDR1 or ABCB1], MRP2, and MRP4). Second, a large number of xenobiotics (drugs and the herbal preparations, St. John’s wort, and Yin Zhi Huang) and certain endobiotics (such as bilirubin, bile acids, and 1,25-(OH)₂-D₃) activate CAR and/or PXR. Third, some of the genes regulated by CAR and PXR encode proteins with broad substrate specificities, such as CYP3A4 and *P*-glycoprotein, such that the induction mediated by CAR and PXR impacts the disposition of a large number of xenobiotics and certain endobiotics (see Table 6-13). In terms of drug–drug interactions, human xenosensors can be rank-ordered (from most important to least) as follows: CAR/PXR > AhR > “CYP2E1” > PPAR α . PPAR α is ranked last because its activation in humans, in contrast to its activation in rodents, does not lead to induction of CYP4 enzymes (a family of enzymes that plays a limited role in drug metabolism compared with CYP1, 2, and 3 enzymes). CYP2E1 is an inducible enzyme in humans (by mechanisms that do not appear to involve any of the xenosensors listed in Table 6-16), but relatively few drugs are inducers of—or substrates for—CYP2E1. AhR is less important than CAR/PXR because there are relatively few drugs that activate AhR and because the major hepatic enzyme regulated by AhR, namely, CYP1A2, plays a more limited role in drug metabolism than the hepatic and intestinal CYP enzymes regulated by CAR/PXR, namely, CYP2B6, 2C8, 2C9, 2C19, 3A4, and other enzymes (see Tables 6-16 and 6-17).

The activation of PXR follows the canonical steps outlined above (this section), beginning with (1) ligand binding to LBD, (2) dissociation of PXR from cytoplasmic retention protein and corepressors (such as nuclear receptor corepressor [NCOR] and

silencing mediator for retinoid and thyroid hormone receptors [SMRT]), (3) association with coactivators (such as SRC1, GRIP-1, PGC-1, C/EBP α , and RAC3), (4) dimerization with RXR α , (5) translocation to the nucleus, and (6) binding to a set of core gene promoter elements within xenobiotic-responsive enhancer modules that typically contain DR-3 or ER-6 motifs, which culminates in transcriptional activation of multiple genes, as shown in Tables 6-16 and 6-17 (Chang and Waxman, 2006; Stanley *et al.*, 2006; Gao and Xie, 2010; Tolson and Wang, 2010; Omiecinski *et al.*, 2011a). Sequence variation in the LBD of PXR accounts for certain species differences in CYP3A induction. For example, PCN is a prototypical inducer of CYP3A in rats and mice, but not humans, whereas the opposite is true of rifampin. Transgenic mice with human PXR in place of mouse PXR (PXR-humanized mice) lose the ability to respond to PCN and gain the ability to respond to rifampin. Rifampin can also bind and activate rat PXR once the opening to the LBD is slightly widened (by changing a phenylalanine to a leucine residue). As shown in Table 6-17, rifampin, artemisinin, clotrimazole, nicardipine, and nifedipine are agonists for human PXR but not mouse PXR, which exemplifies why enzyme induction studies in rodents often fail to predict enzyme induction in humans. Some agonists bind to human PXR with relatively high affinity (with K_D values in the [sub]micromolar range), including rifampin and hyperforin, the inducing agent in St. John’s wort. In general, activation of CAR/PXR shows little or no stereospecificity, although the *C*-cyclopropylalkylamide known as S20 is a rare exception: (–)-C20 preferentially activates mouse PXR, whereas (+)-C20 preferentially activates human PXR. This difference further underscores the lack of predictability of rodent data to the human situation.

Tang *et al.* (2005) have reviewed the factors that give rise to differences in the magnitude of enzyme induction by PXR/CAR agonists in humans; such differences can be attributed to (1) genetic polymorphisms or splicing variation in PXR or CAR and/or polymorphism in their DNA-response elements; (2) altered levels or function of accessory proteins (some of which are associated with inflammation and other disease states that activate NF- κ B, as discussed later in this section); (3) gender differences in basal CYP3A4 activity (which tends to be lower in males compared with that in females); and (4) variation in the intracellular concentration of the inducing drug, as exemplified by variation in the metabolism of propafenone and celecoxib. Propafenone is metabolized by CYP2D6, 3A4, and 1A2. In CYP2D6 EMs, the clearance of propafenone is determined by CYP2D6, and treatment with rifampin causes no induction of propafenone metabolism. However, in CYP2D6 PMs, CYP3A4 plays a significant role in the clearance of propafenone, and treatment of CYP2D6 PMs with rifampin causes a doubling of propafenone clearance. The COX-2 inhibitor celecoxib is a PXR agonist whose in vivo clearance is largely determined by CYP2C9. At recommended clinical doses, celecoxib induces CYP3A4 in CYP2C9 PMs but not in CYP2C9 EMs due to the higher levels of celecoxib in the PMs (Rodriguez *et al.*, 2006).

The activation of CAR is considerably more complex than that of PXR (Chang and Waxman, 2006; Kodama and Negishi, 2006; Stanley *et al.*, 2006; Mutoh *et al.*, 2009; Tolson and Wang, 2010; Omiecinski *et al.*, 2011b; Osabe and Negishi, 2011). CAR is constitutively active, meaning that, in the absence of an exogenous ligand, it can complex with RXR α , translocate to the nucleus, bind to DNA-response elements (known as PBREM [for phenobarbital response elements] and containing DR4 and DR5 elements), and activate gene transcription, which is what generally happens when CAR is expressed in cell lines in vitro. In the in vivo situation (such as occurs in hepatocytes), CAR is prevented from

being transcriptionally active by its retention in the cytoplasm by cytoplasmic CAR retention protein (CCRP) and chaperones such as hsp90, and possibly by its binding to an endogenous reverse agonist such as androstanol (5α -androstan- 3α -ol) and androst-enol (5α -androst-16-en- 3α -ol), the androstanes for which CAR is named (reverse agonists are discussed later in this section). The retention of CAR in the cytoplasm is achieved by its phosphorylation (at threonine 38 in human CAR and threonine 48 in mouse CAR) by protein kinase C (PKC) (Mutoh *et al.*, 2009). Once phosphorylated, CAR complexes with P-ERK1/2, the phosphorylated (active) form of extracellular-signal-regulated kinase (also known as mitogen-activated protein kinase p42/p44), which binds to the so-called xenochemical response signal (XRS), a peptide sequence (313 LGLLAEL 319) near the C-terminus of the CAR receptor (Osabe and Negishi, 2011). Similar XRSs are present in RXR, VDR, peroxisome proliferator-activated receptors (PPARs), and estrogen receptor. Binding of P-ERK1/2 to XRS prevents the hydrolysis of the phosphate group at threonine 38 (human CAR) or threonine 48 (mouse CAR). The activation of CAR by xenobiotics involves the dephosphorylation of the threonine residue by protein phosphatase 2A, as evidenced by the observation that the protein phosphatase 2A inhibitor okadaic acid blocks CAR translocation in mouse hepatocytes (Mutoh *et al.*, 2009). How this dephosphorylation is triggered by xenobiotics is not fully understood and the situation is complicated by the fact that CAR activators can be divided into *direct activators*, which bind directly to the LBD of CAR, and *indirect activators*, which do not bind to CAR.

Because CAR is constitutively active but retained in the cytoplasm, ligands can function as agonists, reverse agonists, or antagonists. Agonists activate CAR by displacing endogenous reverse agonists (eg, androstanes) (Chang and Waxman, 2006; Kodama and Negishi, 2006; Stanley *et al.*, 2006; Mutoh *et al.*, 2009; Tolson and Wang, 2010; Omiecinski *et al.*, 2011b; Osabe and Negishi, 2011) or by promoting the dissociation of corepressors (such as P-ERK1/2 and NCOR) and the recruitment of coactivators (such as SRC-1, SP1, ASC-2, and PBP). Reverse agonists have the opposite effect: they promote the dissociation of coactivators and the recruitment of corepressors, and they may also decrease the transcriptional activity of CAR. Antagonists bind to the same LBD as agonists and reverse agonists; they neither activate nor deactivate CAR, but they block the binding of other ligands. Examples of agonists, reverse agonists, or antagonists of CAR are shown in Table 6-17.

Xenobiotics can function as CAR agonists or antagonists in a species-specific manner. For example, chlorpromazine and meclizine are agonists for mouse CAR, but they are inverse agonists for human CAR. TCPOBOP and CITCO are potent direct activators of CAR, but they function as CAR agonists in a species-specific manner: TCPOBOP is a potent agonist for mouse CAR, whereas CITCO is a potent agonist for human CAR (Table 6-17). These selective CAR agonists must be used in a species-specific manner, as underscored by the fact that the mouse CAR agonist TCPOBOP is *not* an agonist for human CAR but it *is* an agonist for human PXR. Phenobarbital is an indirect activator of mouse and human CAR, but it is also an activator of human PXR (but not mouse or rat PXR). In contrast, another enzyme-inducing antiepileptic drug phenytoin does not activate human PXR and, like CITCO, is a selective activator of human CAR. There are also species differences in the genes regulated specifically by CAR, specifically by PXR, and by both xenosensors, as shown for mouse and human in Table 6-17. These species differences in CAR, like those described earlier in this section for PXR, illustrate why, during the safety evaluation of drug candidates, enzyme induction studies in rodents are often of limited value in predicting enzyme induction in humans.

Alternative splicing of CAR mRNA gives rise to CAR2 and CAR3, which are not constitutively active but are ligand-activated forms of the receptor. CAR2 and CAR3 contain 4 and 5 amino acid inserts, respectively, within the LBD of the receptor. The inserts interfere with the ligand-binding pocket affinity of CAR2 but not CAR3. As a result, the ubiquitous plasticizer and environmental pollutant, di(2ethylhexyl)phthalate (DEHP), is a highly potent and selective CAR2 activator. Alternative splicing of CAR mRNA leads to the expression of tissue-specific variants, which can increase CAR's functional diversity and broaden the human receptor's repertoire of responses to xenobiotics (DeKeyser *et al.*, 2009, 2011). The splice variants detected for human CAR are not present in rats or mice, which further underscores why rodents may not be adequate to assess CAR-mediated events in humans.

Certain cofactors/enzymes are required for activation of CAR to its transcriptionally active form. For example, the coactivator PBP/MED1 (PPAR-binding protein/TRAP220/DRIP205/mediator subunit 1) is required for CAR activation (as well as PPAR α activation) (Pyper *et al.*, 2010), as is AMP-activated protein kinase (AMPK) (Rencurel *et al.*, 2006). The ability of phenobarbital to induce CYP2B10 and CYP3A11 is abolished in transgenic mice lacking CAR, PBP/MED1, or the α -subunit of AMPK. However, the role of AMPK in CAR activation is not clear. Phenobarbital activates the upstream kinase LKB1, which in turn phosphorylates and activates AMPK. Once activated, AMPK does not appear to phosphorylate CAR directly but it does phosphorylate transcriptional coactivators such as p300 (a nuclear phosphoprotein with histone acetylase activity), TORC2 (transducer of regulated cAMP response element-binding protein [CREB]), and peroxisome proliferator-activated receptor γ coactivator-1 α (PGC-1 α) (Blättler *et al.*, 2007; Shindo *et al.*, 2007). Metformin, a drug used to lower fasting blood glucose levels in patients with noninsulin-dependent (Type 2) diabetes, also activates AMPK, and metformin induces CYP2B6 and 3A4 in human hepatocytes (Rencurel *et al.*, 2006). 5-Amino-4-carboxamide-1- β -ribofuranoside (AICAR) is another activator of AMPK that induces CYP2B enzymes in human and mouse hepatocytes (Rencurel *et al.*, 2006). However, AICAR does not induce CYP2B in rat hepatocytes (Kanno *et al.*, 2010) and metformin does not induce CYP2B in vivo in mice or rats (Shindo *et al.*, 2007). Furthermore, metformin does not cause clinically significant CYP2B6 or CYP3A4 induction in humans (Blättler *et al.*, 2007). Collectively these results establish that activation of AMPK is necessary for CYP2B induction by CAR activators but AMPK activation alone is not sufficient.

AMPK is sensitive to energy charge; consequently, it is activated by an increase in the ratio of AMP to ATP, which occurs, for example, during fasting. AMPK, PGC-1 α , and CAR are all activated by fasting, which is associated with the induction of CYP2B10 and other CAR-regulated enzymes and transporters in mice (Ding *et al.*, 2006). Like metformin, phenobarbital also lowers glucose levels in patients with Type 2 diabetes and improves glucose tolerance and insulin sensitivity in mice (Rencurel *et al.*, 2006; Dong *et al.*, 2009). This glucose-lowering effect involves, at least in part, the following steps: (1) activation of AMPK by phenobarbital or metformin; (2) activation of CAR by dephosphorylation of threonine 38; (3) binding of activated CAR to forkhead box protein O1 (FOXO1), a transcription factor that binds to insulin-response sequences (IRS) in the promoter region of gluconeogenic genes such as phosphoenolpyruvate carboxykinase-1 (PEPCK1) and glucose-6-phosphatase (G6Pase); and (4) suppression of PEPCK1 and G6Pase leading to decreased gluconeogenesis (ie, decreased glucose synthesis) as a result of FOXO1 inactivation by CAR (Kodama and Negishi, 2006; Rencurel *et al.*, 2006). Consistent with this mechanism of action,

phenobarbital decreases glucose levels in wild-type mice but not in CAR knockout mice. PXR agonists can also suppress gluconeogenesis either by the binding of activated PXR to FOXO1, which impairs the ability of FOXO1 to activate IRS-regulated gluconeogenic enzymes such as PEPCK1 and G6Pase, or by the binding of activated PXR to phosphorylated CREB that prevents CREB-dependent transcription of G6Pase (Kodama *et al.*, 2004; Gao and Xie, 2010). In addition to suppressing gluconeogenic enzymes (PEPCK1 and G6Pase), CAR activators also induce hexokinase and glucose metabolism by the pentose phosphate pathway, which supports drug metabolism by generating the NADPH required by CYP, FMO, and certain other xenobiotic-biotransforming enzymes (Kodama *et al.*, 2004; Dong *et al.*, 2009).

The interaction between CAR and transcription factor FOXO1 has opposing effects on each other's transcriptional activity: CAR is a *corepressor* of FOXO1, whereas FOXO1 is a *coactivator* of CAR. Activation of FOXO1 by diabetes increases CYP2B and 3A expression in rats and mice, and this effect is reversed by insulin treatment (which stimulates the phosphorylation of FOXO1 and thereby decreases its activity). By inactivating FOXO1 (which removes a coactivator for CAR), insulin blunts the induction of CYP2B enzymes by phenobarbital and represses the gluconeogenic pathway (Kodama and Negishi, 2006; Moreau *et al.*, 2008). The interactions between CAR and FOXO1 have also been described for PXR and FOXO1 (Kodama *et al.*, 2004; Gao and Xie, 2010).

In addition to playing a role in glucose homeostasis (by suppressing gluconeogenic enzymes), CAR also plays a role in lipid homeostasis (largely by suppressing lipogenic enzymes). Multiple mechanisms have been identified that contribute to the suppression of lipogenesis by CAR activators (Gao and Xie, 2010). CAR activation and its associated activation of AMPK lead to the induction of Insig-1, a microsomal protein that, together with Insig-2, plays a key role in the control of hepatic triglyceride and cholesterol synthesis (Roth *et al.*, 2008). Induction of Insig-1 results in repression of sterol regulatory element-binding protein-1 (SREBP-1), which in turn results in the downregulation of lipogenic enzymes and, hence, a decrease in hepatic triglyceride and, to a lesser extent, cholesterol levels. In addition to Insig-1 induction, the mechanism of SREBP-1 repression may also occur by an indirect mechanism that involves induction of CAR-regulated SULT2B enzyme(s) that sulfonate and inactivate the oxysterols that function as agonists for the liver X receptor- α (LXR α), which is an inducer of SREBP-1. This indirect pathway may play a significant role in suppressing SREBP-1 expression based on the observation that the ability of CAR activators to suppress triglyceride/cholesterol synthesis is substantially impaired in SULT1B1b knockout mice (Dong *et al.*, 2009). In addition to suppressing lipogenesis, CAR activators also induce fatty acid β -oxidation. The mechanism is distinct from the induction of fatty acid β -oxidation by PPAR α agonists, which are the main regulators of lipid catabolism (discussed in the next section). CAR activators promote fatty acid β -oxidation by repressing the expression of acetyl-coenzyme A (acetyl-CoA) carboxylase (both ACC1 and ACC2; gene symbols ACACA and ACACB), which results in a decrease in the levels of malonyl-CoA, the initial intermediate in lipogenesis and an allosteric inhibitor of the carnitine-dependent transport of fatty acids into mitochondria for β -oxidation (Dong *et al.*, 2009). From the foregoing it can be appreciated that there is growing interest in CAR as a potential therapeutic target in Type 2 diabetes and fatty liver disease.

Just as activation of CAR suppresses lipogenesis so excess lipid in the liver suppresses CAR activity. Obesity, steatosis (fatty liver), and high-fat diets all suppress CAR activation and CYP2B induction (Blouin *et al.*, 1993; Gao and Xie, 2010). The effects are

mediated, at least in part, by suppression of CAR (and PXR) by the key lipogenic factors SREBP-1 and LXR α presumably by competition for nuclear receptor coactivators. Although CAR and PXR have the same effect on gluconeogenesis (both of them suppress glucose synthesis), these xenosensors have opposing effects on lipid homeostasis: activation of CAR leads to repression of lipogenesis, whereas activation of PXR leads to the promotion of lipogenesis (Gao and Xie, 2010). Transgenic mice expressing a constitutively activated PXR develop hepatomegaly with marked steatosis, as do PXR-humanized mice treated with rifampin, albeit to a lesser extent (Zhou *et al.*, 2006c). PXR activation causes fatty liver by inducing CD36 (a transporter of free fatty acids), PPAR γ (a lipogenic peroxisome proliferation activation receptor discussed in the next section), and several accessory lipogenic enzymes including stearoyl-CoA desaturase-1 (SDC-1) and long-chain fatty acid elongase and by suppressing enzymes involved in β -oxidation (Zhou *et al.*, 2006c). Both PXR and CAR agonists induce thyroid hormone-responsive spot 14 (gene symbol THRSP), the expression of which correlates with lipogenesis, which is consistent with the aforementioned role of PXR in lipogenesis and which suggests that the role of CAR in lipid homeostasis may be complex because paradoxically CAR appears to induce both lipid synthesis and catabolism. In the clinical setting, a number of PXR agonists (rifampin, nifedipine, and carbamazepine) and a number of CAR activators (phenobarbital, phenytoin, and valproic acid) have been shown to alter lipid homeostasis and/or cause steatosis (fatty liver) (reviewed in Zhou *et al.*, 2006c).

CAR and PXR are activated by certain endobiotics, and the enzymes regulated by these xenosensors play important roles in terminating the hormonal activity of 1,25-(OH) $_2$ -D $_3$ and attenuating the toxicity of high levels of bilirubin and bile acids. The active form of vitamin D, namely, 1,25-(OH) $_2$ -D $_3$, binds to the VDR to induce the synthesis of calbindin-D9K, a calcium-binding protein that facilitates the uptake of calcium from the intestinal lumen to blood. VDR also induces CYP enzymes that further hydroxylate and thereby inactivate 1,25-(OH) $_2$ -D $_3$, which establishes a negative feedback loop. Two VDR-inducible CYP enzymes have been shown to inactivate 1,25-(OH) $_2$ -D $_3$ by hydroxylating the active hormone in the 24-position and, to a lesser extent, the 23-position. The first is CYP24A1, which is expressed mainly in the kidney, and which catalyzes the 24 *R*-hydroxylation of 1,25-(OH) $_2$ -D $_3$. The second is CYP3A4, which is expressed mainly in intestine and liver, and which catalyzes the 24 *S*-hydroxylation of 1,25-(OH) $_2$ -D $_3$. The stereochemical differences in the 24-hydroxylation reaction helped to establish that CYP3A4 is the principal inactivator of 1,25-(OH) $_2$ -D $_3$ in the intestine, with little or no contribution from CYP24A1. These findings are important for two reasons. First, the ability of VDR to mimic PXR/CAR and induce CYP3A4 is an example of the crosstalk that can occur between a xenosensor and other nuclear receptors. Second, the key role played by CYP3A4 in the inactivation of 1,25-(OH) $_2$ -D $_3$ in the intestine provides an explanation for the clinical observation that long-term treatment of patients with rifampin, phenobarbital, phenytoin, or carbamazepine can lead to osteomalacia, a bone disorder that is symptomatic of vitamin D deficiency. These PXR/CAR agonists are thought to cause osteomalacia by inducing CYP3A4 in the intestine, which accelerates the inactivation of 1,25-(OH) $_2$ -D $_3$ and thereby impairs calcium absorption (Xu *et al.*, 2006; Zhou *et al.*, 2006a).

CAR plays an important role in detoxifying high levels of bilirubin, as might occur in patients with hemolytic anemia. Like phenobarbital, bilirubin is an indirect activator of CAR. When activated, CAR induces UGT1A1 and several SULTs, the major hepatic enzymes responsible for conjugating bilirubin, as well as transporters of bilirubin/bilirubin conjugates (MRP2 and MRP4).

When hemolytic anemia is induced by treating mice with phenylhydrazine, bilirubin levels rise to a greater extent in CAR knockout mice compared with wild-type mice, which demonstrates the important role CAR plays in responding to high levels of bilirubin. Phenobarbital was once used to treat neonatal jaundice, and the Chinese herbal Yin Zhi Huang is still used for this purpose. Phenobarbital and scoparone (6,7-dimethylscutellin), the active ingredient in Yin Zhi Huang, are CAR activators that, like bilirubin itself, induce the major bilirubin-conjugating enzyme UGT1A1 and related transporters (Chang and Waxman, 2006; Kodama and Negishi, 2006). In contrast, CAR appears to play a role in acetaminophen hepatotoxicity presumably by allowing acetaminophen to induce its own activation to a toxic quinoneimine. CAR knockout mice are relatively resistant to acetaminophen hepatotoxicity compared with both wild-type and CAR-humanized mice, which suggests early treatment with a CAR antagonist might be a useful adjunct treatment for acetaminophen overdose.

CAR, PXR, and the VDR appear to act as backup receptors to prevent bile acid accumulation and toxicity when the principal bile acid sensor, FXR, is overloaded. In the mouse ileum and colon, bile acid activation of FXR and, to a lesser extent, VDR and PXR promotes bile acid detoxication (by AKR1B7 and CYP3A11), intracellular binding (to ileal bile acid binding protein [IBABP]), and secretion (by organic solute transporters, OST α/β) (Ballatori *et al.*, 2009b; Degirolamo *et al.*, 2011; Schmidt *et al.*, 2011). FXR induces the expression of AKR1B7 in murine small intestine, colon, and liver by binding directly to a response element in the AKR1B7 promoter and this AKR metabolizes 3-keto bile acids to the corresponding 3 β -hydroxy bile acids, which are less toxic than their 3 α -hydroxy isomers. High concentrations of bile acids activate FXR, which suppresses the expression of CYP7A1, the cholesterol 7 α -hydroxylase that catalyzes the rate-limiting step in bile acid synthesis, and which induces the expression of bile acid conjugating enzymes (UGT2B4 and SULT2A1) and bile acid transporters (such as the bile salt export pump [BSEP]). When hepatocytes contain low concentrations of bile acids, FXR is inactive and the expression of CYP7A1 is stimulated by liver receptor homolog-1 (LRH-1), a constitutively active nuclear receptor. When hepatocytes contain high concentrations of bile acids, FXR is activated, and it inactivates LRH-1 by inducing the synthesis of small heterodimer partner-1 (SHP), so named because it lacks a DNA-binding domain (hence its small size) and because it forms heterodimers with LRH-1 and numerous other nuclear receptors including AhR, CAR, PXR, LXR α , HNF4 α , and the glucocorticoid receptor (GR). Because it lacks a DBD, SHP inactivates all of these receptors; in the case of LRH-1, this results in a loss of CYP7A1 expression and a decrease in bile acid synthesis, which represents a negative feedback loop. FXR knockout mice are more sensitive than wild-type mice to bile acid toxicity, and treatment with the FXR ligand GW4064 further protects wild-type mice against experimentally induced extrahepatic and intrahepatic cholestasis. Cholic acid is both an FXR and PXR agonist; it suppresses CYP7A1 expression by activating first FXR and then PXR. In contrast to the situation in wild-type or single receptor knockout mice, 1% dietary cholic acid is lethal to FXR/PXR double knockout mice. PXR and CAR play a similar role in attenuating the toxicity of lithocholic acid, which is both a PXR agonist and a substrate for many of the enzymes regulated by PXR, including CYP3A, SULT, and transporters involved in the hepatic uptake and efflux of lithocholic acid. In PXR/CAR double knockout mice, lithocholic acid causes lethal hepatotoxicity at doses that are well tolerated by wild-type mice. The mouse PXR agonist PCN can markedly suppress CYP7A1 expression and bile acid synthesis in mice, and the human PXR agonist rifampin

can markedly suppress CYP7A1 expression in human hepatocytes. The ability of PXR/CAR to function as a backup system for FXR may be compromised by the expression of SHP, which represses the activity of these xenosensors. This complex interplay is one of the likely reasons why there are some conflicting results from studies of the role of PXR/CAR in bile acid detoxication. The overall role of FXR is to provide protection against the toxic and tumorigenic effects of bile acids in the liver and colon; consequently, agonists of this receptor are being considered as potential colon cancer chemotherapeutic agents (Degirolamo *et al.*, 2011).

As the preceding examples in this section illustrate, there is a complex interplay between many of the nuclear receptors listed in Table 6-16. Some nuclear receptors, such as the hepatic nuclear factors HNF1 α and HNF4 α , and the coactivator PBP/MED1 (PPAR-binding protein/TRAP220/DRIP205/mediator subunit 1) play a critical permissive role in gene regulation by CAR, PXR, and other receptors, whereas others, such as SHP, play a widespread role in suppressing nuclear receptor activity. HNF1 α is instrumental for the expression of high levels of CYP2E1 mRNA in liver, although it is not the only factor because disruption of the β -catenin gene in mice greatly reduces CYP2E1 mRNA levels in the liver in the absence of changes in HNF1 α expression (Gonzalez, 2007). Interestingly, the cross-talk between transcription factors, particularly between HNF4 α , CAR, and PXR, is markedly increased in tissues from patients with severe viral hepatitis with pronounced inflammation and fibrosis (Congiu *et al.*, 2009).

The glucocorticoid receptor (GR) plays an important role in inducing the synthesis of CAR and PXR (and individual xenobiotic-biotransforming enzymes such as CYP2C9). The role of GR in regulating the synthesis of xenosensors and the interplay among nuclear receptors are instrumental to the mechanism by which infections and inflammatory diseases suppress the expression and blunt the induction of xenobiotic-biotransforming enzymes and, conversely, the mechanism by which PXR agonists cause immunosuppression.

The expression and induction of xenobiotic-biotransforming enzymes by AhR, CAR, PXR, and PPAR α are all suppressed by infection (viral, bacterial, and parasitic), vaccination, inflammation, and treatment with endotoxin (lipopolysaccharide or LPS) or inflammatory cytokines such as interleukin-1 β (IL-1 β) and IL-6. The suppression involves (1) an increase in proinflammatory cytokines, (2) a decrease in the levels of PXR and CAR due to a decrease in GR activity, and (3) a decrease in the activity of GR, PXR, CAR, AhR, PPAR α , and several other nuclear receptors including the androgen, estrogen, and mineralocorticoid receptors (De Bosscher *et al.*, 2006; Pascual and Glass, 2006; Zhou *et al.*, 2006b). The decrease in receptor activity is caused by NF- κ B, which is activated during infection and inflammatory disease, and which induces the synthesis of COX-2, TNF α , ICAM-1, and several interleukins. NF- κ B binds to the DBD of RXR α and thereby decreases the transcriptional activity of all nuclear receptors that form heterodimers with RXR α (such as PXR, CAR, PPAR α , GR, etc.). It also decreases the transcriptional activity of AhR even though AhR forms heterodimers with ARNT, not RXR α . By lowering the levels and/or inhibiting the activity of the major xenosensors and numerous other nuclear factors, NF- κ B mediates the widespread suppression of xenobiotic-biotransforming enzymes associated with infection and inflammatory disease. However, the converse is also true inasmuch as certain nuclear receptors, when activated, can complex NF- κ B and thereby repress the expression of NF- κ B-regulated genes (COX-2, TNF α , ICAM-1, interleukins). This is the basis, at least in part, for the immunosuppressive effect of corticosteroids, which activate GR, and the immunosuppressive effect of PXR ligands such as rifampin and mifepristone (RU-486). PXR plays a role in suppressing NF- κ B activity in the

small intestine. PXR knockout mice show signs of inflammation of the small intestine, and certain genetic polymorphisms and splicing variants of PXR are associated with inflammatory bowel disease. Common environmental AhR agonists can suppress the response to bacterial LPS, through downregulation of IL-6. This suppression occurs at the level of IL-6 gene transcription and may be regulated by NF- κ B (Jensen *et al.*, 2003). The AhR can also attenuate cytokine-mediated induction of acute-phase response genes in liver in a XRE-independent manner. This function of the receptor suggests its role in maintaining liver homeostasis during inflammation. The role of PXR in regulating NF- κ B activity, responding to high levels of bile acids, and terminating the actions of 1,25-(OH) $_2$ -D $_3$, the role of CAR in responding to high level of bilirubin, and the role of CAR and PXR in glucose and lipid (energy) metabolism all illustrate that these so-called xenosensors do not simply respond to xenobiotics but play key roles in endobiotic homeostasis.

Peroxisome Proliferator-Activated Receptor-Alpha An increase in the size and number of rat hepatic peroxisomes was first observed in response to the hypolipidemic drug, clofibrate. Peroxisome proliferation is accompanied by hepatomegaly, induction of fatty acid oxidation in peroxisomes, mitochondria, and microsomes, and with long-term administration of hypolipidemic drugs, hepatocarcinogenicity. Induction of microsomal fatty acid oxidation is due to the induction of CYP4A enzymes that play a limited role in xenobiotic biotransformation but that convert fatty acids to dicarboxylic acids by ω -hydroxylation (see the section “CYP4 Enzymes”). Numerous xenobiotic “peroxisome proliferators” have been identified including hypolipidemic fibrate drugs (eg, clofibrate, fenofibrate, ciprofibrate, bezafibrate, nafenopin, methylcofenapate), various NSAIDs, aspirin, leukotriene receptor antagonists (MK-0571 and RG 7512), organic solvents (trichloroacetic acid), phthalate ester plasticizers, herbicides (haloxyfab, lactyofen, 2,4-dichlorophenoxyacetic acid [2,4-D]), perfluorodecanoic acid, nicotinic acid, cinnamyl anthranilate, and the potent and widely used experimental peroxisome proliferator-activated receptor α (PPAR α) agonist Wy-14643 (Lake, 2009). Peroxisome proliferation by some of these xenobiotics occurs stereoselectively. The receptor that mediates peroxisome proliferation by these xenobiotics is the PPAR α . PPAR α (NR1C1) is one of a family of three nuclear receptors; the other members are PPAR β/δ (NR1C2) and PPAR γ (NR1C3). All three are Type II nuclear receptors that reside in the nucleus (in contrast to AhR, CAR, and PXR, which reside in the cytoplasm) (Pyper *et al.*, 2010).

The distinction between xenobiotic- and endobiotic-sensing functions is particularly blurred in the case of PPAR α , which is activated by the aforementioned xenobiotics and by several endogenous fatty acids (eg, notably the acyl-CoA and enoyl-CoA derivatives of long-chain fatty acid), dicarboxylic acids (such as those formed by CYP4-dependent ω -hydroxylation of long-chain fatty acids and arachidonic acid [HETEs]), LTB $_4$, products formed by fatty acid synthase (such as 1-palmityl-2-oleoyl-*sn*-glycerol-3-phosphocholine [16:0/18:1-GPC]), and DHEA sulfate. From this list of endogenous ligands it is apparent that fatty acids (generally in the form of acyl-CoA thioesters) can activate PPAR α and induce their own metabolism. All three receptors play an important role in lipid (energy) metabolism. In general, PPAR α and PPAR β/δ are regulators of fatty acid catabolism (catabolic energy metabolism) that are highly expressed in liver, heart, kidney, brown adipose tissue, muscle, and the small and large intestines (Issemann and Green, 1990; Braissant *et al.*, 1996; Bookout *et al.*, 2006). PPAR γ , which is expressed in at least three forms (eg, PPAR γ 1, PPAR γ 2, and PPAR γ 3), regulates lipid synthesis and is abundant

in white and brown adipose tissues (Tontonoz *et al.*, 1994; Fajas *et al.*, 1998). The pattern of tissue expression of PPAR α is similar in rodents and humans (Bookout *et al.*, 2006). PPAR α exerts a dominant role in regulating fatty acid catabolism and ketone body synthesis in the liver. PPAR β/δ also participates in the regulation of fatty acid oxidation, but its effects are more prominent in muscle and heart; however, PPAR β/δ also regulates certain lipid-metabolizing enzymes in the liver (Sanderson *et al.*, 2009). PPAR α functions as the major xenobiotic and lipid sensor to regulate fatty acid catabolism, hepatic steatosis, lipoprotein synthesis, inflammation, and hepatocarcinogenesis; hence, this xenosensor is the major focus of discussion here.

Activation of PPAR α follows the canonical steps outlined earlier in this section. Binding of ligands to the LBD of PPAR α results in (1) dissociation of corepressors (such as NCOR and SMRT), (2) dimerization with RXR α , (3) association with coactivators (p300, SRC/p160 family members, PBP/MED1, PGC-1 α , and many others), and (4) binding of activated PPAR α to response elements (PPREs) that usually reside in the promoter (5'-region) of target genes. The PPRE is a direct repeat (DR1) composed of two copies of the consensus hexamer sequence AGG(A)TCA separated by a single base pair. PPAR α activity is increased by phosphorylation of serine residues 12 and 21. Insulin stimulates the phosphorylation and, hence, the transcriptional activity of PPAR α . The expression of PPAR α is increased by fasting/starvation to provide energy through the oxidation of fatty acids released from adipose tissue. During starvation, PPAR α is essential for the upregulation of the genes necessary for fatty acid oxidation, although PPAR β/δ can also upregulate some of the same enzymes independently of PPAR α (Sanderson *et al.*, 2009). The β -oxidation of fatty acids produces acetyl-CoA that either enters the mitochondrial tricarboxylic acid cycle or undergoes condensation reactions to form ketone bodies that are released into blood for energy (ATP) production in extrahepatic tissues. PPAR α is also regulated by stress, growth hormone, leptin, and glucocorticoids. Direct binding of glucose to PPAR α may be an important mechanism of stimulating fatty acid oxidation during uncontrolled diabetes (Pyper *et al.*, 2010).

Once activated, PPAR α induces the expression of key enzymes involved in the oxidation of fatty acids in peroxisomes, mitochondria, and endoplasmic reticulum (the three major organelles involved in lipid catabolism). Oxidation of fatty acids in peroxisomes and mitochondria involves β -oxidation, whereas their oxidation in microsomes involves ω - and ω -1 hydroxylation by CYP (especially CYP4 enzymes). Peroxisomal β -oxidation targets very long straight-chain fatty acids, 2-methyl branched fatty acids, prostanoids, and dicarboxylic acids. The latter are formed by the ω -hydroxylation of fatty acids by CYP4 enzymes. Compared with their precursors (monocarboxylic acids), dicarboxylic acids are highly toxic; hence, the coordinate induction of microsomal ω -hydroxylation and peroxisomal β -oxidation is an important function of PPAR α . There are two peroxisomal β -oxidation systems: system 1 targets long-chain fatty acids and is inducible by PPAR α , with the initial step being catalyzed by the highly inducible enzyme peroxisomal acyl-coenzyme A oxidase 1 (ACOX1). The second is a noninducible system that targets 2-methyl-branched fatty acids (with the initial step catalyzed by ACOX2). Peroxisomal β -oxidation of long-chain fatty acids (C $_{20+}$) produces chain-shortened fatty acids (approximately C $_{10}$) that are transported to mitochondria for further β -oxidation. The three enzymes involved in peroxisomal β -oxidation of long-chain fatty acids, namely, ACOX1, the bifunctional enzyme L-PBE/MFP1 (enoyl-CoA hydratase/3-hydroxyacyl-CoA dehydrogenase), and PTL (3-ketoacyl-CoA thiolase), are all inducible by PPAR α . PPAR α also induces mitochondrial carnitine

palmitoyl transferase-1, which facilitates the entry of fatty acyl carnitine into mitochondria, and long-chain acyl-CoA synthetases, which initiate β -oxidation of fatty acids.

Fatty liver is the most common liver disease. It encompasses steatosis and steatohepatitis, diseases that can progress to cirrhosis and hepatocellular carcinoma. Fatty liver disease is divided into *alcoholic fatty liver disease* (due to excessive alcohol consumption) and *nonalcoholic fatty liver disease* (due to obesity, which may occur with or without insulin resistance). During fasting PPAR α knockout mice develop steatosis, hyperlipidemia, hypoketonemia, hypoglycemia, and hypothermia because they are unable to induce the peroxisomal, mitochondrial, and microsomal enzymes required to metabolize lipids released from adipose tissue. PPAR α knockout mice also develop severe steatohepatitis if fed a choline- and methionine-deficient diet. Ethanol-fed PPAR α knockout mice develop marked hepatomegaly, steatohepatitis, hepatocellular proliferation, and cell death. In wild-type mice and humans ethanol impairs PPAR α function, which is thought to contribute to the mechanism by which alcohol causes alcoholic fatty liver disease (Pyper *et al.*, 2010).

In addition to playing a key role in protecting the liver against fatty liver disease, PPAR α plays an important role in reducing inflammation. The proinflammatory eicosanoid LTB $_4$ is an activator of PPAR α and induces its own metabolism by β - and ω -oxidation. PPAR α ligands significantly reduce the levels of other proinflammatory cytokines/enzymes including interleukin-1 (IL-1), tumor necrosis factor- α (TNF α), COX-2, and inducible nitric oxide synthase (NOS-2) by inhibiting NF- κ B and by decreasing phosphorylation of the c-Jun subunit of AP-1 (Pyper *et al.*, 2010).

Paradoxically, in addition to inducing peroxisomal, mitochondrial, and microsomal enzymes involved in fatty acid catabolism, PPAR α can upregulate the expression of hepatic lipogenic genes by activating SREBP-1 and liver X receptor α (LXR α) (Browning and Horton, 2004; Hebbachi *et al.*, 2008). The situation is analogous to CAR that also upregulates lipid synthesis and catabolism (see the preceding section). The upregulation of lipogenic genes by PPAR α is possibly a fail-safe mechanism to save fatty acids by incorporating them into triglycerides during starvation.

Species differences in PPAR α and peroxisome proliferation are a complex issue. Activation of human PPAR α in humans and other primates (and guinea pigs) is generally considered to cause little or no induction of microsomal CYP4A enzymes and minimal peroxisome proliferation (Lake, 2009). However, peroxisome proliferation does occur in rhesus and cynomolgus monkeys treated with supertherapeutic doses of ciprofibrate. The lack of hepatomegaly and peroxisome proliferation in humans administered PPAR α agonists is attributed to dose and the levels of hepatic PPAR α , which are about an order of magnitude lower in humans compared with those in rodents. PPAR α -humanized mice (ie, mice harboring human PPAR α instead of the mouse receptor) are resistant to peroxisome proliferation but the overexpression of human PPAR α in mice restores peroxisome proliferation, the pleiotropic induction response, and cell proliferation (Pyper *et al.*, 2010). These findings are pertinent to the risk of hepatocellular carcinogenesis posed by fibrate drugs and other PPAR α agonists, which is discussed in the next section.

Enzyme Induction and Chemical Carcinogenesis In humans, induction of CYP2E1 and the associated increased activation of acetaminophen to *N*-acetylbenzo-*p*-quinoneimine (NAPQI) is one of the mechanisms by which alcohol consumption and fasting potentiate acetaminophen hepatotoxicity (other contributing mechanisms include the impaired conjugation of acetaminophen

due to lowered levels of UDPGA and PAPS and the impaired detoxication of NAPQI due to lowered levels of GSH). By analogy, induction of CYP enzymes would be expected to increase the activation of procarcinogens to DNA-reactive metabolites, leading to increased tumor formation. However, contrary to expectation, treatment of rodents with a CYP inducer prior to treatment with a known proximate carcinogen (tumor initiators such as aflatoxin, various nitrosamines, or PAHs) is generally associated with a decrease, not an increase, in tumor incidence (Parkinson and Hurwitz, 1991; Nebert and Dalton, 2006; Shimada, 2006; Ma and Lu, 2007). The route of exposure to the carcinogen can affect the impact of enzyme induction; it protects against orally administered drugs but may increase the tumorigenicity of carcinogens applied directly to their site of action (Nebert *et al.*, 2004). Although treatment of rats and mice with a CYP inducer *before* treatment with an initiator (a genotoxic carcinogen) generally decreases tumor incidence, treatment with a CYP inducer *after* the initiator (such as diethylnitrosamine) generally increases tumor incidence because CYP inducers generally function as tumor promoters in rodents.

Phenobarbital is representative of a large number of compounds that appear to promote liver tumor formation in mice and, to a lesser extent, in rats by an epigenetic mechanism, including phenytoin, carbamazepine, chlordecone, butylated hydroxytoluene, DDT, dieldrin, hexachlorocyclohexane, certain polychlorinated and polybrominated biphenyls, loratadine, doxylamine, lansoprazole, musk xylene, and fenbuconazole (Williams and Iatropoulos, 2002; Juberg *et al.*, 2006). Although the exact mechanism of tumor formation remains unknown, it is critically dependent on CAR activation, as evidenced by the finding that phenobarbital and related compounds do not function as tumor promoters in CAR knockout mice (Gonzalez and Yu, 2006). Replicative DNA synthesis and possibly inhibition of apoptosis are mechanistically important. Phenobarbital does not function as a tumor promoter in Syrian hamsters (even following treatment with a genotoxic agent such as DMN, DEN, or methylazoxymethanol acetate). Phenobarbital is a CYP2B inducer in hamsters but it does not induce replicative DNA synthesis and does not inhibit apoptosis in hamster hepatocytes (either spontaneous or transforming growth factor- β 1 [TGF- β 1]-induced apoptosis) (Lake, 2009). In mice and rats phenobarbital and related compounds only cause liver tumors at doses that cause liver enlargement due to an increase in cell number (hepatocellular hyperplasia) and cell size (hepatocellular hypertrophy). The liver changes induced by phenobarbital, including an increase in DNA synthesis within 24 hours, a wave of mitotic activity after 1 to 3 days, enzyme induction (eg, CYP2B enzymes), and a progressive increase in liver weight, all exhibit nonlinear dose-response relationships, suggesting that there is a threshold dose below which no activation of CAR and no liver tumor promotion occur.

Although induction of CYP2B enzymes (and other xenobiotic-biotransforming enzymes and transporters) is a common feature of phenobarbital and related tumor-promoting chemicals, the two events do not appear to be mechanistically linked (Williams and Iatropoulos, 2002). Activation of CAR is critical to liver tumor development in mice, although upregulation of xenobiotic-biotransforming enzymes is less important than other xenosensor-dependent events, such as, in the cases of the indirect (phenobarbital) or direct mouse CAR-activator (TCPOBOP), altered DNA methylation of numerous genes, upregulation of GADD45B (an antiapoptotic factor) and Mdm2 (a negative regulator of the tumor suppressor p53), and the downregulation of gap junctional proteins (connexin 32), which diminishes cell-cell communication (Omicinski *et al.*, 2011b). Although phenobarbital and other CAR activators induce CYP2B6 in human hepatocytes (both in vitro and in vivo), they

neither cause replicative DNA synthesis nor inhibit spontaneous or TGF- β 1-induced apoptosis (Lake, 2009).

Prolonged treatment of rodents with clofibrate, fenofibrate, ciprofibrate, bezafibrate, nafenopin, methylcofenapate, Wy-14643, DEHP, DEHA, cinnamyl anthranilate, or trichloroethylene is associated with hepatic peroxisome proliferation and liver tumor (adenoma and/or carcinoma) formation (Lake, 2009). PPAR α plays a critical role in tumor formation by peroxisome proliferators as evidenced by the finding that Wy-14643 does not function as a tumor promoter in PPAR α knockout mice (Gonzalez and Yu, 2006). Furthermore, there is excellent agreement between the potency with which agonists activate PPAR α and the potency (in terms of latency period and tumor incidence) with which they promote liver tumor formation in rodents (which in turn is correlated with their ability to induce the proliferation of peroxisomes, induce peroxisomal enzymes involved in the β -oxidation of fatty acids, and induce microsomal CYP4A enzymes). Like CAR agonists, PPAR α agonists are considered epigenetic (nongenotoxic) tumorigens because they are not mutagenic and they are not known to be converted to mutagenic metabolites. Another similarity with CAR agonists is that, in rodents, PPAR α agonists cause replicative DNA synthesis in association with hepatomegaly (due to early hyperplastic and hypertrophic growth of hepatocytes) and they inhibit apoptosis. Just as it is sensitive to the enzyme-inducing/endoplasmic reticulum proliferative effects but not the tumor-promoting effects of CAR agonists, so the Syrian hamster is sensitive to the enzyme-inducing/peroxisome proliferating effects of PPAR α agonists but is resistant to their tumor-promoting effects (Lake, 2009). PPAR α agonists cause replicative DNA synthesis and inhibit apoptosis in rat and mouse hepatocytes but not in hepatocytes from hamsters, guinea pigs, monkeys, and humans (Lake, 2009). Treatment of mice with Wy-14643 represses the expression of let-7C microRNA, which results in increased expression (derepression) of c-myc oncogene expression (Shah *et al.*, 2007). Interestingly, suppression of let-7C miRNA does not occur in PPAR α -humanized mice treated with Wy-14643 (Yang *et al.*, 2008).

Although PPAR α agonists are not genotoxic, the dramatic (>20-fold) induction of peroxisomal ACOX1 by Wy-14643 and other peroxisome proliferators (dramatic when compared with the modest [2- to 5-fold] induction of peroxisomal catalase) leads to increased production of hydrogen peroxide, which can cause oxidative stress and DNA damage that possibly play a role in some of the downstream events leading to tumor promotion (Pyper *et al.*, 2010). Oxidative DNA damage is evident from the fact that treatment of rodents with PPAR α agonists leads to the induction of long-patch base excision DNA repair, the principal pathway for removing oxidized DNA bases (Rusyn *et al.*, 2004).

Activation of PPAR α is required but apparently not sufficient to lead to liver tumor formation. Other key events include increased oxidant production (such as increased peroxisomal H₂O₂ production), increased cell proliferation (which fixes mutations), and suppression of apoptosis (which prevents the removal of genetically damaged cells and permits clonal expansion) (Klaunig *et al.*, 2003; Lai, 2004; Bosgra *et al.*, 2005). Kupffer cells appear to play an important role in liver tumor formation by releasing mitogenic cytokines and possibly by contributing to oxidative stress by releasing superoxide anion, although it is not clear how PPAR α agonists trigger these events. Inhibition of gap junctional intercellular communication plays an important role in liver tumor formation by PPAR α agonists, just as it does in the promotion of liver tumors by phenobarbital-type inducers.

Epidemiological studies designed to assess the human cancer risk posed by PPAR α agonists have produced inconclusive results.

Clofibrate has been reported to cause a statistically significant increase in cancer mortality rate during a 5- to 8-year treatment period. However, there was no significant increase in cancer rate in a follow-up study, which included a posttreatment period (Lai, 2004). Three compelling lines of evidence suggest that PPAR α agonists will not cause liver tumors in humans. First, PPAR α agonists do not cause peroxisome proliferation and microsomal CYP4A induction in human hepatocytes in vitro or in primates in vivo at therapeutic doses. Second, PPAR α agonists do not cause replicative DNA synthesis or inhibit apoptosis in human hepatocytes (or in hepatocytes from hamsters and guinea pigs, two species that are resistant to the hepatocarcinogenic effects of PPAR α agonists). Third, treatment of PPAR α -humanized mice (transgenic mice with human PPAR α in place of mouse PPAR α) with Wy-14643 or fenofibrate neither results in the hepatocellular proliferation characteristic of wild type nor results in the repression of let-7C miRNA and the upregulation of the c-myc oncogene (Gonzalez and Yu, 2006; Yang *et al.*, 2008; Lake, 2009; Pyper *et al.*, 2010).

The mechanism of thyroid tumor formation is better understood. In rodents, CAR activators (as well as PXR and PPAR α agonists) induce UGT and SULT enzymes and transporters that accelerate the conjugation and elimination of thyroid hormones, which triggers a compensatory increase in thyroid stimulating hormone (TSH). T4 is a substrate for UGT1A enzymes, whereas T3 is a substrate for UGT2B2 and an as yet unidentified UGT enzyme (van Raaij *et al.*, 1993; Visser *et al.*, 1993; Richardson and Klaassen, 2010). Induction of T3 glucuronidation, rather than induction of T4 glucuronidation, is strongly associated with a compensatory increase in TSH and thyroid follicular hyperplasia. The PXR agonist PCN induces T3 glucuronidation in both Sprague-Dawley rats and UGT2B2-deficient Fischer 344 rats, which establishes that at least two PCN-inducible UGTs are involved in T3 glucuronidation (Richardson and Klaassen, 2010).

Sustained stimulation of the thyroid gland by TSH leads to the development of thyroid follicular tumors, the development of which can be blocked by administering T4, which blocks the release of TSH and thereby abrogates the hormonal stimulation of the thyroid gland. It is not clear why sustained stimulation of the thyroid gland by TSH results in tumor formation in rodents, but such tumors develop in other rodent organs following prolonged hormonal stimulation: LH causes Leydig cell tumors, gastrin causes stomach tumors, and corticosteroids cause pancreatic tumors. In addition, just as proliferation of the hepatic endoplasmic reticulum and peroxisomes by phenobarbital and Wy-14643 is associated with liver tumor formation, so the proliferation of hepatic lysosomes by Ponceau S and the proliferation of mitochondria by methapyrilene are also associated with liver tumor formation (Grasso *et al.*, 1991).

Epidemiological studies of epileptic patients treated for more than 35 years with phenobarbital or phenytoin have established that chronic liver microsomal enzyme induction in humans does not increase the incidence of thyroid tumor formation (Singh *et al.*, 2005). Prolonged elevation of TSH in humans does not lead to tumor formation but causes goiter, a reversible enlargement of the thyroid gland associated with iodide deficiency and treatment with drugs that block TH synthesis. In humans and monkeys, circulating T4 is largely bound to thyroxine-binding globulin (TBG). This high-affinity binding protein is not present in rodents, for which reason T4 is rapidly conjugated and excreted in bile in rodents. Accordingly, the plasma half-life of T4 in rats (12–24 hours) is considerably shorter than in humans (5–9 days). Similar differences are observed for T3. To compensate for the increased turnover of thyroid hormones, the rat pituitary secretes more TSH. Whereas baseline plasma TSH levels in humans are ~2.2 μ U/mL, TSH levels

in rats range from 55.5 to 65 $\mu\text{U}/\text{mL}$ in males and 36.5 to 41 $\mu\text{U}/\text{mL}$ in females (Hill *et al.*, 1989). It is estimated that rats require a 10-fold higher rate of T4 production (on a per kilogram body weight basis) than do humans to maintain physiological T4 and T3 levels. These differences in plasma half-life, protein binding, thyroid hormone metabolism, and TSH secretion between rats and humans are thought to be reasons for the greater sensitivity of rats to developing hyperplastic and/or neoplastic nodules in response to chronic TSH stimulation (Capen, 1997).

Enzyme Induction and Porphyria Due to the increased demand for heme, persistent induction of CYP can lead to porphyria, a disorder characterized by excessive accumulation of intermediates in the heme biosynthetic pathway. In 1956, widespread consumption of wheat contaminated with the fungicide hexachlorobenzene caused an epidemic of porphyria cutanea tarda in Turkey. Another outbreak occurred in 1964 among workers at a factory in the United States manufacturing 2,4,5-trichlorophenoxyacetic acid (the active ingredient in several herbicides and in the defoliant, Agent Orange). The outbreak of porphyria cutanea tarda was caused not by the herbicide itself but by a contaminant, namely, TCDD. Drugs that cause P450 induction have not been shown to cause porphyria cutanea tarda under normal circumstances, but phenobarbital, phenytoin, and alcohol are recognized as *precipitating factors* because they cause episodes of porphyria in individuals with an inherited deficiency in the heme-biosynthetic enzyme, uroporphyrinogen decarboxylase. Studies conducted in mice suggest that the use of fluorane-based anesthetics, such as enflurane and isoflurane, which affect heme metabolism, should be avoided in porphyria patients (Sampayo *et al.*, 2009).

Enzyme Suppression The suppression (downregulation) of drug-metabolizing enzymes and transporters is an adaptive process that reduces xenobiotic elimination during periods of inflammation, infection, and postvaccination or in response to certain therapeutic proteins. The phenomenon may be associated with pharmacological and toxicological consequences, especially in case of drugs with a narrow therapeutic index, and it can be a manifestation of a drug–disease interaction. Suppression of xenobiotic-biotransforming enzymes, a consequence of influenza infection, resulted in severe toxicity of theophylline, a CYP1A2 substrate with a narrow therapeutic index. A number of children infected with the influenza virus and receiving theophylline, a prophylactic asthma treatment, experienced convulsions and cardiac conduction anomalies associated with elevated plasma levels of the drug (which increased up to 5-fold in association with a prolongation of plasma half-life from 4 to up to 20 hours) (Kraemer *et al.*, 1982). Suppression of xenobiotic-biotransforming enzymes, as a result of vaccination or treatment with certain therapeutic protein, may cause drug–drug interactions involving a small drug molecule as victim and the biological drug as perpetrator. Blood trough levels of tacrolimus, a narrow therapeutic index immunosuppressant and a substrate of CYP3A4/5, increased by 63% in patients treated with basiliximab, a chimeric monoclonal antibody to the interleukin-2 (IL-2) receptor (Sifontis *et al.*, 2002). Similar effects of basiliximab on the calcineurin inhibitor cyclosporine A were observed in children following kidney transplantation. Within the first 10 days following transplantation, substantially less cyclosporine was required in the basiliximab treatment group than in controls, but it resulted in higher trough concentrations and was associated with liver enzymes and kidney toxicity (Strehlau *et al.*, 2000). The proposed mechanism of these interactions is an IL-2-mediated suppression of CYP3A4. This mechanism is in agreement with CYP suppression initiated by proinflammatory cytokines, such as IL-1 β , IL-6,

interferon γ (INF- γ), or TNF α , released in response to infection or inflammation. These proinflammatory cytokines, in turn, modulate expression and activity of transcription factors and specific nuclear receptors determining the levels of CYP mRNA (Morgan, 2009). In the liver proinflammatory cytokines can induce NOS-2 and the increased production of NO can directly inhibit CYP enzymes. Accordingly infection and inflammation can both suppress and inhibit CYP enzymes (Morgan *et al.*, 2008; Zhou and Mascelli, 2011). Therapeutic proteins that are cytokines or cytokine modulators deserve special scrutiny during the drug development process because they can suppress CYP enzymes without stimulating the release of endogenous cytokines. All the major drug-metabolizing CYP enzymes, including the noninducible CYP2D6, are subject of suppression by cytokines (IL-1, IL-2, IL-6, IL-10, INF- α , INF- α -2b, INF- β , TNF α) or cytokine modulators (tocilizumab, basiliximab, muromonab-CD3) (Huang *et al.*, 2010). By reversing the disease process—such as lessening the inflammation associated with rheumatoid arthritis—some biologics, for example, tocilizumab (a humanized monoclonal antibody against the interleukin-6 receptor), can reverse the suppression of drug-metabolizing enzymes and restore their activity to normal levels (Morgan, 2009; Schmitt *et al.*, 2011).

CONJUGATION

Conjugation reactions include glucuronidation, sulfonation (often called sulfation), acetylation, methylation, conjugation with glutathione (GSH; mercapturic acid synthesis), and conjugation with Coenzyme A (CoA) followed by conjugation with amino acids such as glycine, taurine, and glutamine. The cofactors for these reactions, which are shown in Fig. 6-51, react with functional groups that are either present on the xenobiotic or introduced/exposed during oxidation, reduction, or hydrolysis. With the exception of methylation and acetylation, conjugation reactions result in a large increase in xenobiotic hydrophilicity and total polar surface area (TPSA), so they greatly promote the excretion of foreign chemicals (see Point 6 in the section “Introduction”). Because of their high water solubility, most xenobiotic conjugates cannot readily diffuse across the plasma membrane; hence, their exit from hepatocytes, for example, generally involves transport across the canalicular membrane into bile (for elimination in feces) or the sinusoidal membrane into blood (for elimination in urine) (see Point 6 in the section “Introduction”). Glucuronidation, sulfonation, acetylation, and methylation involve reactions with activated or “high-energy” cofactors, whereas conjugation with amino acids or GSH involves reactions with activated xenobiotics. Most conjugation enzymes are located in the cytosol; a notable exception is the UDP-glucuronosyltransferases (UGTs), which are microsomal enzymes (Table 6-1).

Glucuronidation and Formation of Acyl-CoA Thioesters

Glucuronidation is a major pathway of xenobiotic biotransformation in mammalian species except for members of the cat family (lions, lynxes, civets, and domestic cats) (Tukey and Strassburg, 2000). It requires primarily the cofactor UDP-glucuronic acid (UDPGA), but can also use UDP-glucose, UDP-xylose, and UDP-galactose. The reaction is catalyzed by UGTs, which are located predominantly in the endoplasmic reticulum of liver and other tissues, such as the kidney, gastrointestinal tract, lungs, prostate, mammary glands, skin, brain, spleen, and nasal mucosa (Fig. 6-52). Examples of xenobiotics that are

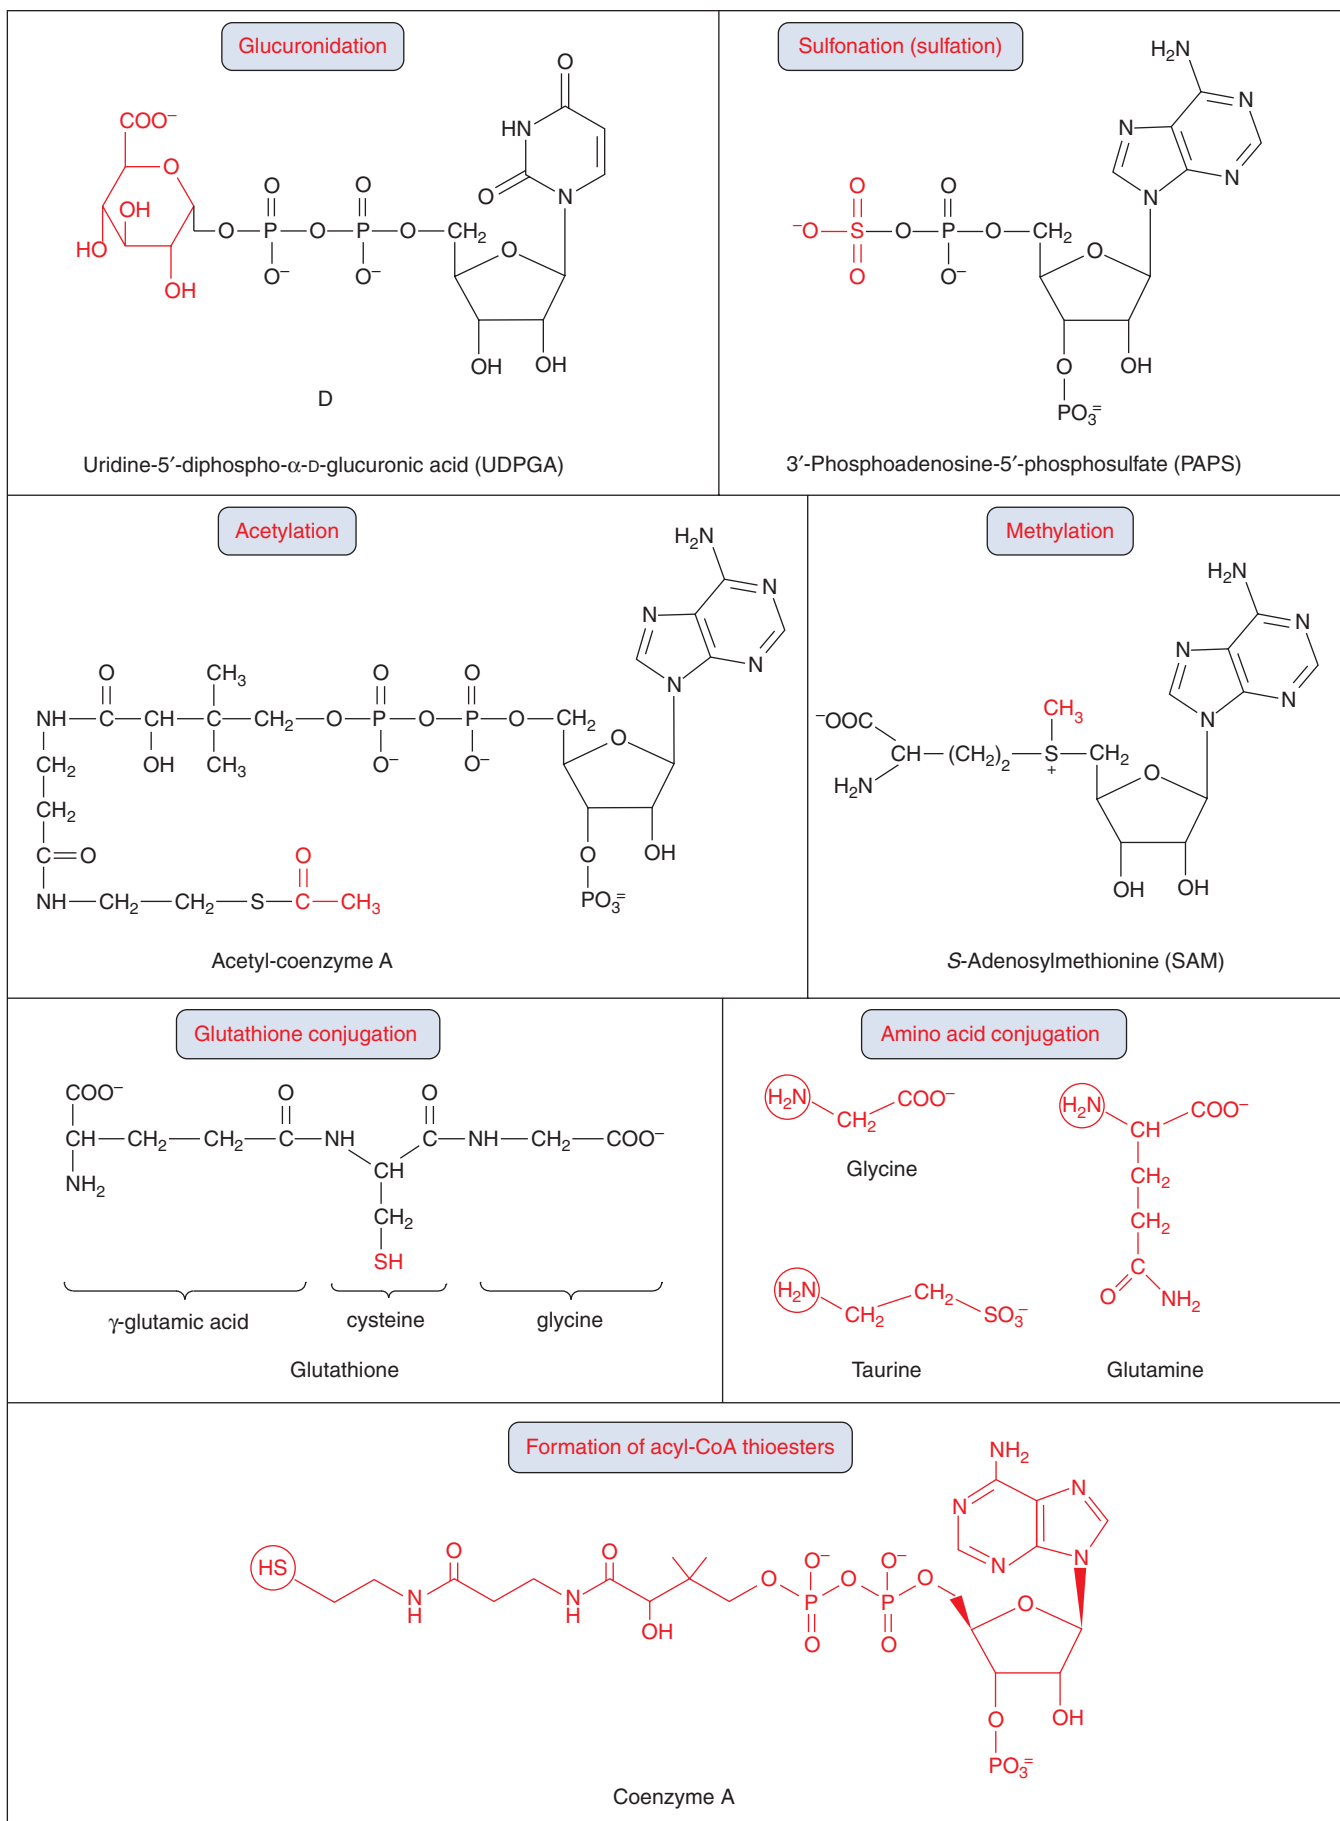

Figure 6-51. Structures of cofactors for conjugation reactions. The functional group that reacts with or is transferred to the xenobiotic is shown in red.

Figure 6-52. Synthesis of UDP-glucuronic acid and inversion of configuration ($\alpha \rightarrow \beta$) during glucuronidation of a phenolic xenobiotic (designated RO^-).

glucuronidated are shown in Fig. 6-53. The site of glucuronidation is generally an electron-rich (nucleophilic) O, N, or S heteroatom. Glucuronidation reactions mediated by UGTs are $\text{S}_{\text{N}}2$ substitution reactions where the nucleophilic heteroatom of the substrate attacks the C_1 atom of UDPGA which results in a xenobiotic glucuronide in the β -configuration (Yin *et al.*, 1994). Therefore, substrates for glucuronidation are typically small lipophilic compounds that contain functional groups such as aliphatic alcohols and phenols (which form *O*-glucuronide acetals), carboxylic acids (which form acyl glucuronides), primary and secondary aromatic and aliphatic amines (which form *N*-glucuronides), and free sulfhydryl groups (which form *S*-glucuronides). In humans and monkeys (but in few other species), numerous tertiary amines (including tripeleminamine, cyclobenzaprine, and imipramine) are substrates for *N*-glucuronidation, which leads to the formation of positively charged quaternary glucuronides, some of which may be carcinogenic (see below in this section) (Hawes, 1998). Certain xenobiotics, such as phenylbutazone, sulfapyrazone, suxibuzone, ethchlorvynol, Δ^6 -tetrahydrocannabinol, and feprazone, contain carbon atoms that are sufficiently nucleophilic to form *C*-glucuronides. Coumarin and certain other carbonyl-containing compounds are glucuronidated to form arylenol-glucuronides.

In addition to the typical conjugation reactions above, UGTs can form unusual conjugates: (1) bisglucuronides (eg, bilirubin and morphine), where two different functional groups on the same molecule are glucuronidated; (2) diglucuronides (eg, 5α -dihydroxytestosterone; *DHT*), where two glucuronides are attached in tandem to a single site; (3) *N*-carbamoyl glucuronides (eg, sertraline and varenicline), where carbonate is incorporated in the glucuronide; and (4) glycosidation with UDP-sugars other

than UDPGA (eg, glucosidation of barbiturates). Two examples are shown in Fig. 6-54. These reactions will be covered in greater detail later in this section. In addition to numerous xenobiotics, substrates for glucuronidation include several endogenous compounds, such as bilirubin, steroid hormones, and thyroid hormones (THs). Table 6-18 provides examples of marker substrates for the major human UGTs. A listing of over 350 UGT substrates is available at <http://arjournals.annualreviews.org/doi/suppl/10.1146/annurev.pharmtox.40.1.581> (Tukey and Strassburg, 2000). Reviews by Radominska-Pandya *et al.* (1999), Kiang *et al.* (2005), and Miners *et al.* (2010) also provide extensive descriptions of UGT substrates, K_{m} and V_{max} values, and specificity of substrates and inhibitors for individual UGT enzymes.

The cofactor for glucuronidation, UDPGA, is synthesized from glucose-1-phosphate, and the linkage between glucuronic acid and UDP has an α -configuration, as shown in Fig. 6-52. This configuration protects the cofactor from hydrolysis by β -glucuronidase. However, glucuronides of xenobiotics have a β -configuration. This inversion of configuration occurs because glucuronides are formed by nucleophilic attack by an electron-rich atom (usually O, N, or S) on UDPGA, and this attack occurs on the opposite side of the linkage between glucuronic acid and UDP, as shown in Fig. 6-52. In contrast to the UDPGA cofactor, xenobiotics conjugated with glucuronic acid are substrates for β -glucuronidase. Although present in the lysosomes of some mammalian tissues, considerable β -glucuronidase activity is present in the intestinal microflora. The intestinal enzyme can release the aglycone, which can be reabsorbed and thereby enter a cycle called *enterohepatic circulation*, which delays the elimination of xenobiotics. In general, *N*-glucuronides are hydrolyzed

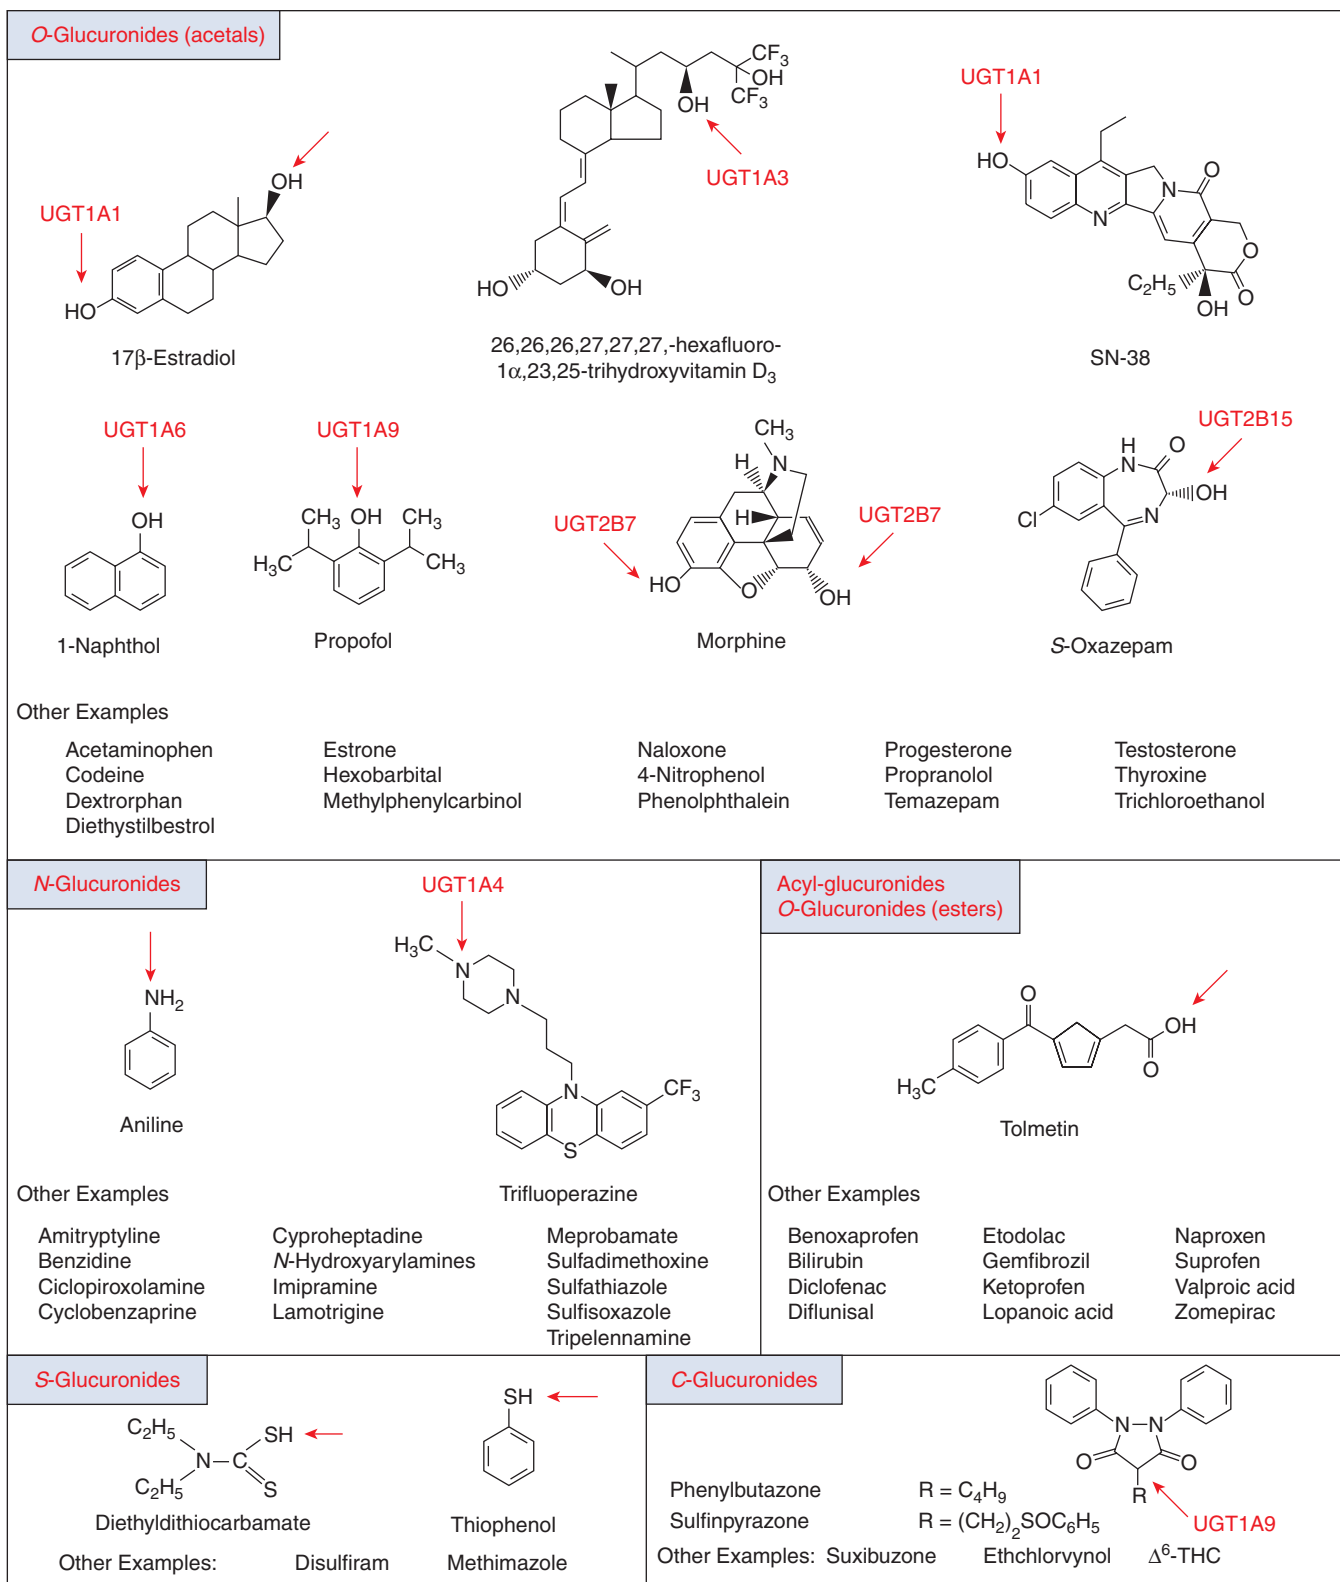

Figure 6-53. Examples of xenobiotics and endogenous substrates that are glucuronidated. The arrow indicates the site of glucuronidation, with the UGT enzyme if selective.

relatively slowly by β -glucuronidase (with some *N*-glucuronides being resistant to hydrolysis by β -glucuronidase) but some *N*-glucuronides undergo hydrolysis in acidic conditions (hence, some *N*-glucuronides are hydrolyzed in urine, which can give the impression that the parent compound was eliminated in urine

unchanged). In contrast, acyl glucuronides are stable under acidic conditions; unless the samples are acidified (to pH \sim 5), acyl glucuronides in plasma and other biological matrices can isomerize or hydrolyze to a significant extent. The instability of *N*-glucuronides under acidic conditions has implications for the tumorigenicity of

Figure 6-54. Examples of unusual glucuronide conjugates.

N-glucuronides of compounds such as benzidine (discussed later in this section).

Glucuronide conjugates of xenobiotics and endogenous compounds are polar (typically anionic with a $\text{p}K_a$ of approximately 4), water-soluble metabolites that are eliminated from the body in urine or bile. Whether glucuronides are excreted from the body in bile (following their canalicular transport by MRP2) or urine (following their sinusoidal transport into blood by MRP3) depends, in part, on the size of the aglycone (ie, the parent compound or its unconjugated metabolite). In rat, glucuronides are preferentially excreted in urine if the molecular weight of the aglycone is less than 250, whereas glucuronides of larger molecules (aglycones with molecular weight >350) are preferentially excreted in bile. Molecular weight cutoffs for the preferred route of excretion vary among mammalian species. Yang *et al.* (2009) conducted a statistical analysis of the molecular weight cutoff for biliary excretion of anionic, cationic, zwitterionic, and neutral compounds and concluded that, for anionic compounds, the molecular weight cutoff was approximately 400 and 475 Da in rats and humans, respectively. The carboxylic acid moiety of glucuronic acid ($\text{p}K_a$ 3–3.5), which is ionized at physiological pH, promotes excretion because (1) it increases the aqueous solubility and TPSA of the xenobiotic and (2) it is recognized by the biliary and renal organic anion transport systems, which enable glucuronides to be secreted into urine and bile. Furthermore, as anions, glucuronides generally bind extensively to albumin, which, in addition to their large TPSA, confines glucuronides to plasma (although some glucuronides are actively taken up by the liver, as described below).

As discussed above, glucuronide metabolites are often substrates of transmembrane transport proteins that mediate the vectorial transport of conjugates into systemic circulation or into bile for fecal excretion or enterohepatic circulation. These transport proteins efflux the glucuronide either across the canalicular membrane for biliary excretion or across the sinusoidal membrane into the blood for excretion in urine. Transport of glucuronides across the sinusoidal membrane into the blood is mediated largely by MRP3 (ABCC3) and, to a lesser extent, by MRP1 (ABCC1) and MRP4 (ABCC4). The transport of glucuronides across the canalicular

membrane into bile is largely mediated by MRP2 (ABCC2) and, to a lesser extent, by BCRP (ABCG2). Glucuronides can also be taken up by hepatocytes through the action of OATP1B1 (SLCO1B1) and OATP1B3 (SLCO1B3) on the sinusoidal membrane (Giacomini and Sugiyama, 2006; Giacomini *et al.*, 2010).

Bilirubin monoglucuronide and diglucuronide, certain steroid conjugates (such as estradiol-17 β -glucuronide), and certain bile acids are also substrates for MRP2 and MRP3, although bile acids are mainly effluxed into bile by the bile salt export pump (BSEP). The important role of MRP2 in transporting conjugated bilirubin into bile is evident from the observation that rats deficient in MRP2 (such as TR $^-$ /GY and EHBR rats) have high plasma levels of monoconjugated and diconjugated bilirubin. In humans, a deficiency of MRP2 also leads to conjugated hyperbilirubinemia, and this inherited disease is called Dubin–Johnson syndrome. When MRP2 function is impaired (due to a genetic deficiency or due to drug-induced cholestasis or bile duct ligation), MRP3 levels increase. In this way, when the biliary efflux of xenobiotics and endobiotics by MRP2 is impaired, their efflux into blood is increased (as if the back door is opened wider when the front door is closed). The upregulation of MRP3 in response to a loss of MRP2 augments the basolateral efflux of drug, steroid and bilirubin conjugates, and certain bile acids during cholestasis. MRP2 can be highly effective at transporting glucuronides and anionic compounds into bile as evidenced by bile-to-blood concentration ratios greater than 1 (and commonly between 10 and 1000) (Brauer, 1959). However, the elimination of drug conjugates in bile may not result in the elimination of the drug in feces because the conjugates may be hydrolyzed in the gut and the parent drug may be reabsorbed or eliminated in feces. For orally administered drugs, the former process (biliary excretion of conjugates, hydrolysis in the gut, and reabsorption of the parent drug) gives rise to the phenomenon of enterohepatic circulation, whereas the latter process (biliary excretion of conjugates, hydrolysis in the gut, and elimination of the parent drug in feces) can give the impression of incomplete intestinal absorption.

The mammalian UGT gene superfamily contains 4 families, UGT1, UGT2, UGT3, and UGT8. To date, at least 22 human UGT enzymes have been identified. The current UGT nomenclature may

Table 6-18

Major Human UDP-Glucuronosyltransferase Enzymes

UGT	PRESENT IN LIVER? (SPECIFIC CONTENT*)	TISSUE	EXAMPLE SUBSTRATES
1A1	Yes (33.2 pmol/mg)	Liver, small intestine, colon	Bilirubin, 17β-estradiol (3-glucuronidation), etoposide, tranilast, raloxifene, ethinyl estradiol, carvedilol, levothyroxine, acetaminophen, SN-38 (active metabolite of irinotecan)
1A3	Yes (17.3 pmol/mg)	Liver, small intestine, colon	Hexafluoro-1α,23(s),25-trihydroxyvitamin D₃, R-lorazepam, beviramat, 17 β -estradiol, zolozartan, ketotifen, naproxen, ketoprofen, ibuprofen, fenoprofen, valproic acid, ezetimibe, chenodeoxycholic acid, norbuprenorphine, tertiary amines, antihistamines
1A4	Yes	Liver, small intestine, colon	Trifluoperazine, 1'-hydroxymidazolam, tertiary amines, antihistamines, lamotrigine, amitriptyline, cyclobenzaprine, olanzapine
1A5	Yes	Liver	Unknown
1A6	Yes (114 pmol/mg)	Liver, small intestine, colon, stomach	1-Naphthol, serotonin, deferiprone, 4-nitrophenol, 4-methylumbelliferone, ibuprofen, acetaminophen, SN-38 (active metabolite of irinotecan), diclofenac
1A7	No	Esophagus, stomach, lung	Octylgallate, arylamines, 4-hydroxybiphenyl, 4-hydroxystrone, mycophenolic acid, SN-38 (active metabolite of irinotecan)
1A8	No	Colon, small intestine, kidney	Entacapone, troglitazone, anthraquinone, 8-hydroxyquinoline, furosemide, raloxifene, niflumic acid, ciprofibrilic acid, clofibrilic acid, valproic acid, mycophenolic acid, diflunisal, furosemide
1A9	Yes (25.9 pmol/mg)	Liver, colon, kidney	Propofol, mycophenolic acid, phenylbutazone, sulfapyrazone, thyroid hormones, entacapone, salicylic acid, scopoletin, fenofibrate, acetaminophen, ketoprofen, ibuprofen, fenoprofen, naproxen, furosemide, diflunisal, diclofenac, bumetanide
1A10	No	Stomach, small intestine, colon	Dopamine, 1-naphthol, mycophenolic acid, raloxifene, troglitazone, furosemide
2A1	No	Olfactory	Valproic acid, ibuprofen
2A2	Unknown	Unknown	Unknown
2A3	Yes	Liver, small intestine, colon, adipose tissue	Bile acids
2B4	Yes	Liver, small intestine	Hyodeoxycholate, estriol, codeine, androsterone, carvedilol
2B7	Yes (84.3 pmol/mg)	Kidney, small intestine, colon	Zidovudine (AZT), morphine (6-glucuronidation[†]), carbamazepine, epirubicin, hydroxyprogesterone (6 α - and 21-), ibuprofen, ketoprofen, diclofenac, opioids, oxazepam, carvedilol, clofibrilic acid, naloxone, valproic acid, tiaprofenic, zomepirac, benoxaprofen, other NSAIDs, denopamine
2B10	Yes	Liver, ileum, prostate	Cotinine, imipramine, amitriptyline, levomedetomidine
2B11	Yes	Mammary, prostate, others	4-Nitrophenol, naphthol, estriol, 2-aminophenol, 4-hydroxybiphenyl
2B15	Yes (61.8 pmol/mg)	Liver, small intestine, prostate	S-Oxazepam, S-lorazepam, androgens, flavonoids, 4-hydroxytamoxifen, estriol, entacapone, SN-38 (active metabolite of irinotecan), tolcapone, diclofenac
2B17	Yes	Liver, prostate	Androgens, eugenol, scopoletin, galangin, ibuprofen
2B28	Yes	Liver, mammary	17 β -Estradiol, testosterone

Bold text represents selective substrates (or reactions) for hepatic UGTs. These compounds may be glucuronidated in extrahepatic tissues by other UGT enzymes. Data from Miners et al. (2006, 2010), Kaivosari et al. (2011), Ohtsuki et al. (2012), Kiang et al. (2005), Williams et al. (2004), Fisher et al. (2000), and Court et al. (2008).

*Specific content of UGT enzymes (pmol/mg protein) was determined in pooled human liver microsomes (n = 17) by LC-MS/MS (Ohtsuki et al., 2012).

[†]UGT2B7 also catalyzes the 3-glucuronidation of morphine, but this reaction is also catalyzed by other UGTs.

Figure 6-55. Structure of the human *UGT1* locus that encodes multiple forms of UDP-glucuronosyltransferase. Note that these microsomal enzymes face the lumen of the endoplasmic reticulum.

be found at <http://som.flinders.edu.au/FUSA/ClinPharm/UGT/index.html>. Families 1 and 2 preferentially utilize UDPGA as the cofactor, but may use other UDP-sugars such as UDP-glucose and UDP-xylose (Mackenzie *et al.*, 2005). UGT3A1 and 3A2 were identified in the human genome, and are ~30% similar to UGT1 and 2 sequences but prefer *N*-acetylglucosamine as a cofactor (Mackenzie *et al.*, 2005; Meech and Mackenzie, 2010). UGT8A1 utilizes UDP-galactose and is involved in the synthesis of membrane components, which is beyond the scope of this chapter.

The major xenobiotic-metabolizing human UGT enzymes are products of either a single *UGT1A* gene locus (see Fig. 6-55) or multiple individual *UGT2* genes (with the exception of *UGT2A1* and *2A2*, see below). The human *UGT1A* locus encodes 13 potential UGT enzymes (namely, *UGT1A1*, *1A2*, *1A3*, *1A4*, *1A5*, *1A6*, *1A7*, *1A8*, *1A9*, *1A10*, *1A11*, *1A12*, and *1A13*), 9 of which are expressed *in vivo*; the 4 transcripts that are not expressed are *UGT1A2*, *1A11*, *1A12*, and *1A13*, which are pseudogenes because they lack an open reading frame (Mackenzie *et al.*, 2005). Each of the *UGT1A* enzymes is encoded by 5 exons, 4 of which (exons 2-5) are the same and encode the cofactor-binding site. Because of the cassette nature of the *UGT1A* locus, the individual *UGT1A* enzymes differ in only the first exon, which encodes the substrate-binding site. Because they share 4 out of 5 exons, all the *UGT1A* enzymes share extensive amino acid sequence identity. The *UGT2* genes expressed in humans are *UGT2A1*, *2A2*, *2A3*, *2B4*, *2B7*, *2B10*, *2B11*, *2B15*, *2B17*, and *2B28*. Human *UGT2B24* to *27* and *2B29* are pseudogenes. The *UGT2* genes are made up of 6 exons each, which are not shared between subfamily members, with the exception of *UGT2A1* and *2A2*, and these two genes are >70% similar (Mackenzie *et al.*, 2005). *UGT2A1* and *2A2* share 5 exons with a variable first exon, similar to the *UGT1A* enzymes.

Meech and Mackenzie (2010) reviewed *UGT3A* expression, function, and cofactor preference (sugar donor). The *UGT3* genes expressed in humans are *UGT3A1* and *3A2*. *UGT3A1* mRNA is expressed in liver and, to a lesser extent, in kidney, stomach, duodenum, colon, and testes. *UGT3A2* mRNA is expressed at high levels in kidney and testes. *UGT3A1* utilizes *N*-acetylglucosamine as a sugar donor and is implicated in the formation of *N*-acetylglucosamide conjugates of various steroidal substrates, such as steroid hormones and bile acids.

The C-terminus of all UGTs contains a membrane-spanning domain that anchors the enzyme in the endoplasmic reticulum. The enzyme faces the lumen of the endoplasmic reticulum, which places UGTs on the opposite side of the endoplasmic reticulum from CYP. As outlined in Point 6 in the section "Introduction," biotransformation of xenobiotics by CYP generally results in a modest increase in TPSA and hydrophilicity; hence, metabolites formed by cytochrome can generally diffuse through the lipid bilayer of the endoplasmic reticulum to access UGTs on the luminal side of the membrane. The luminal orientation of UGT poses a problem because UDPGA is a water-soluble cofactor synthesized in the cytoplasm. Several nucleotide sugar transporters (NSTs) have been postulated to shuttle UDPGA from the cytoplasm to the lumen of the endoplasmic reticulum, and they may also shuttle UDP (the by-product of glucuronidation) back into the cytoplasm for synthesis of UDPGA, as shown in Fig. 6-52.

Historically, studies on the ontogeny and inducibility of various UGT enzyme activities in rats contributed considerably to our understanding of the multiplicity of UGT enzymes. These studies predated widespread gene sequencing and genomic analysis and they were reviewed in previous versions of this chapter. Today we know that the genes encoding the xenobiotic-metabolizing UGT enzymes in rats are organized like those in humans: multiple *UGT1A* enzymes are encoded in cassette fashion by a single gene locus and multiple *UGT2B* enzymes are encoded by numerous individual genes. Three historical findings in rats are worth noting. First, in contrast to the situation in humans, some of the rat UGT enzymes are highly inducible. For example, AhR ligands such as TCDD and 3-methylcholanthrene cause more than a 10-fold induction of *UGT1A6* and *1A7* in rats but not in humans because the human UGT genes lack the XRE activated by AhR. Second, activators of rat PXR, such as dexamethasone and PCN, cause more than a 10-fold induction of a UGT enzyme that conjugates digitoxigenin monodigitoxoside (dt_1), a metabolite of digitoxin (dt_3) formed by CYP3A (see Fig. 6-48). The specific rat *UGT1A* enzyme responsible for glucuronidating dt_1 has not been identified. Third, all *UGT1A* enzymes are deficient in Gunn rats. In this hyperbilirubinemic rat, a mutation at codon 415 introduces a premature stop signal, so that all forms of UGT encoded by the *UGT1* locus are truncated and functionally inactive. The UGTs known to be encoded

by the rat UGT1 locus include the 3-methylcholanthrene-inducible enzyme that conjugates planar molecules such as 1-naphthol (UGT1A6 and UGT1A7), the phenobarbital- and clofibrac acid-inducible enzyme that conjugates bilirubin (UGT1A1), and the PCN-inducible enzyme that conjugates dt_1 . Whereas Gunn rats are genetically defective in all UGT1A enzymes, LA rats are selectively defective in UGT2B2, which allowed this enzyme to be identified as the principal enzyme responsible for glucuronidating androsterone and triiodothyronine (T_3) in rats (Burchell, 1999).

A summary of the current understanding of the tissue distribution and substrate specificity of the human UGT1 and UGT2 enzymes can be found in Table 6-18. Suffice it to say that these enzymes are expressed in a wide variety of tissues, and some enzymes—including UGT1A7, 1A8, 1A10, and 2A1—are expressed only in extrahepatic tissues, which has implications for the common practice of using human liver microsomes to investigate the role of glucuronidation in drug metabolism. Of the hepatically expressed UGT enzymes, UGT1A1, 1A3, 1A4, 1A6, 1A9, 2B7, 2B10, and 2B15 are considered to be the UGT enzymes most important for hepatic drug metabolism because UGT1A5, 2B4, 2B11, 2B17, and 2B28 are reported to have low or negligible activity toward xenobiotics (Miners *et al.*, 2006, 2010; Kaivosaaari *et al.*, 2011). UGT1A7, 1A8, and 1A10 expressed in the gastrointestinal tract may also be important for prehepatic elimination of various orally administered drugs. Numerous UGT1 and UGT2 enzymes are expressed throughout the gastrointestinal tract, where they contribute significantly to the first-pass (presystemic) elimination of numerous xenobiotics. UGT2A1 is primarily expressed in nasal epithelia, whereas UGT2A3 is a polymorphic enzyme expressed in the liver, GI tract, and kidneys (Jedlitschky *et al.*, 1999; Court *et al.*, 2008). Several UGT2B enzymes are expressed in steroid-sensitive tissues, such as prostate and mammary gland, where they presumably terminate the effects of steroid hormones. The tissue distribution of human UGTs (largely based on mRNA levels) and the levels (specific content) of selected UGT enzymes in human liver microsomes (as determined by mass spectrometry) are described in Table 6-18.

Probe drugs have been identified for most but not all of the human UGTs, including UGT1A1 (bilirubin, etoposide, and 17β -estradiol 3-glucuronidation), UGT1A3 (hexafluoro- $1\alpha,25$ -trihydroxyvitamin D_3 , *R*-lorazepam, and beviramat), UGT1A4 (trifluoperazine and 1'-hydroxymidazolam), UGT1A6 (serotonin, desferiprone, and 1-naphthol), UGT1A9 (propofol and mycophenolic acid), UGT2B7 (morphine 6-glucuronidation and zidovudine [AZT]), and UGT2B15 (*S*-oxazepam) (Miners *et al.*, 2010; Kaivosaaari *et al.*, 2011). The glucuronidation of morphine by UGT2B7 involves conjugation of the phenolic 3-hydroxyl and the alcoholic 6-hydroxyl group in a 7:1 ratio. The 6-*O*-glucuronide is 600 times more potent an analgesic than the parent drug, whereas the 3-*O*-glucuronide is devoid of analgesic activity. UGT2B7 is present in the brain, where it might facilitate the analgesic effect of morphine through formation of the 6-*O*-glucuronide, which presumably does not readily cross the blood-brain barrier and may be retained in the brain longer than morphine (Tukey and Strassburg, 2000). Only UGT2B7 catalyzes the 6-glucuronidation of morphine, whereas several UGTs including UGT1A1, 1A3, 1A6, 1A8, 1A9, 1A10, as well as 2B7 can catalyze the 3-glucuronidation (Stone *et al.*, 2003). Whereas UGT1A4 catalyzes quaternary *N*-glucuronide formation with low affinity, UGT2B10 catalyzes *N*-glucuronidation of tertiary amines with high affinity; consequently, CYP2B10 is primarily responsible for the *N*-glucuronidation of some tricyclic antidepressants (eg, imipramine and amitriptyline) at low, pharmacologically relevant substrate concentrations (Zhou *et al.*, 2010a;

Kaivosaaari *et al.*, 2011). Selective probe inhibitors have only been characterized for a few UGT enzymes. Those include UGT1A1 (erlotinib), UGT1A4 (hecogenin), 1A9 (niflumic acid), 2B7 (fluconazole), and 2B10 (nicotine) (Liu *et al.*, 2010; Miners *et al.*, 2010).

Despite their broad and overlapping substrate specificities, some generalities can be made regarding the types of substrates conjugated by certain UGT enzymes. For instance, UGT1A4 and 2B10 are largely responsible for glucuronidating tertiary amines (Kaivosaaari *et al.*, 2011). For UGT1A1 and 1A4, the site of glucuronidation is always adjacent to a hydrophobic region of the substrate, with another hydrophobic region 6 to 8 Å from the site of glucuronidation (Smith *et al.*, 2004). UGT1A9 is similar, except that the distal hydrophobic region also contains a hydrogen-bond acceptor (Smith *et al.*, 2004). UGT1A6 prefers to glucuronidate less bulky phenolic substrates. Specifically, rat UGT1A6 enzyme has restricted selectivity toward planar phenols with a molecular thickness <4 Å and a total length of <6.3 Å (Smith *et al.*, 2004). In a series of 24 *para*-substituted phenols, a methyl or ether in any position increased the rate of glucuronidation in human liver (in vitro) compared with phenol itself (Temellini *et al.*, 1991). A hydrogen bond acceptor 10 Å from the nucleophile is common to UGT2B4 substrates (Sorich *et al.*, 2004). The *C*-glucuronidation of the enolic form of phenylbutazone is catalyzed specifically by UGT1A9 (Nishimura and Naito, 2006). Additionally, Sorich *et al.* (2008) reviewed a number of pharmacophores and their importance as determinants in enzyme-specific glucuronidation with in silico modeling.

Kaivosaaari *et al.* (2011) reviewed *N*-glucuronidation of drugs and xenobiotics. Historically, UGT1A4 was considered the major UGT enzyme responsible for the formation of *N*-glucuronides of primary, secondary, and tertiary amines but it is now known that several UGT enzymes including UGT1A3, 1A9, 2B4, 2B7, and 2B10 can also form *N*-glucuronides (Zhou *et al.*, 2010a; Kaivosaaari *et al.*, 2011). UGT1A4 and UGT2B10 are considered low- and high-affinity enzymes specific for *N*-glucuronidation in liver, especially for tertiary amines, which are converted to positively charged quaternary ammonium glucuronides. In vitro, many tertiary amine substrates, such as imipramine and amitriptyline, exhibit biphasic kinetics with UGT2B10 as the high-affinity, low-capacity component and UGT1A4 as the low-affinity, high-capacity component (Zhou *et al.*, 2010a). Many in vitro studies that previously identified other UGT enzymes as key enzymes involved in *N*-glucuronidation may have overlooked the role of UGT2B10 because they employed substrate concentrations several times higher than those observed in vivo. *N*-Glucuronidation can be divided into 4 categories based on the structure of the aglycone: (1) primary amines and hydroxylamines, (2) amides and sulfonamides, (3) tertiary amines, and (4) aromatic *N*-heterocycles. In the case of primary amines, hydroxylamines, amides, and sulfonamides, UGT1A4 is the primary *N*-glucuronidating enzyme, with other enzymes such as UGT1A1, 1A3, 1A9, 1A10, and 2B7 playing a secondary role. In the case of tertiary amines and *N*-heterocycles, UGT2B10 and UGT1A4 are the primary high- and low-affinity enzymes, respectively, whereas several other enzymes have the potential to form *N*-glucuronides with these substrates, namely, UGT1A1, 1A3, and 2B7 (Kaivosaaari *et al.*, 2011).

Kaivosaaari *et al.* (2011) also summarized species differences in *N*-glucuronide formation based on the structure of the aglycone. Most species are capable of *N*-glucuronidating primary amines and hydroxylamines, although rats preferentially acetylate these compounds. Primary amine *N*-glucuronides are generally labile under acidic conditions and can undergo hydrolysis in urine (discussed in more detail later in this section). There are marked species differences in the *N*-glucuronidation of tertiary amines. Formation of

quaternary *N*-glucuronides is observed in humans and higher primates but is generally not observed in rats, mice, guinea pigs, and dogs, presumably due to the negligible contribution of UGT1A4 (a pseudogene in rodents). *N*-Glucuronidation of *N*-heterocycles is variable between species. For instance, the pyridine derivative nicotine is *N*-glucuronidated in humans > rhesus and cynomolgus monkeys > guinea pigs >> undetectable levels in dogs, rats, mice, and rabbit. In most cases, heterocyclic amines form *N*-glucuronides in humans and certain higher primates but are highly variable among all other species, particularly rats and dogs, two species that are commonly used to conduct safety toxicology studies for new drug candidates.

N-Carbamoyl glucuronidation has been reported for relatively few primary amines, or the demethylated metabolites of secondary and tertiary amines, and includes drugs such as sertraline (Fig. 6-54), carvedilol, varenicline, mofegiline, garenoxacin, tocainide, and sibutramine (Gipple *et al.*, 1982; Tremaine *et al.*, 1989; Beconi *et al.*, 2003; Hayakawa *et al.*, 2003; Link *et al.*, 2006; Obach *et al.*, 2006). Marked species difference have been found in the formation of *N*-carbamoyl glucuronides, and humans have only been found to produce these conjugates from even fewer drugs, including sertraline, varenicline, and mofegiline. To form this type of conjugate in vitro, the incubation must be performed under a CO₂ atmosphere, in a carbonate buffer. Although not directly demonstrated, it has been hypothesized that a transient carbamic acid intermediate is formed by the interaction of the amine with the dissolved CO₂, followed by glucuronidation (Obach *et al.*, 2005). Because the intermediate is not stable, the hypothesis that UGT also catalyzes the formation of the carbamic acid cannot be disproved. However, in the case of sertraline and varenicline, it is predominantly UGT2B7 that forms the *N*-carbamoyl glucuronide, which also conjugates various carboxylic acids (Obach *et al.*, 2005, 2006). Given that the in vitro formation of *N*-carbamoyl glucuronides occurs only under special incubation conditions that are not typically employed, it is possible that many other primary and secondary amines or their oxidative metabolites can be converted to such conjugates but have not been detected because of the unusual incubation conditions required to support the formation of *N*-carbamoyl glucuronides.

As mentioned above and as shown in Fig. 6-54, UGTs can form unusual conjugates including bisglucuronides, diglucuronides, *N*-carbamoyl glucuronides, *N*-glucosides, and other glycoside conjugates. Bisglucuronides (ie, a glucuronide in which two separate functional groups on the aglycone are glucuronidated) are more common than diglucuronides, and include the bisglucuronides of bilirubin, morphine, octylgallate, diosmetin, phenolphthalein, and hydroxylated PAHs (such as hydroxylated chrysene and B[a]P) (Murai *et al.*, 2006). A diglucuronide is a glucuronide in which a single functional group on the aglycone is conjugated twice resulting in two glucuronosyl groups in tandem (Murai *et al.*, 2006). Diglucuronides of the xenobiotics nalmefene and 4-hydroxybiphenyl and of the endogenous steroids androsterone, DHT, 17 β -estradiol, estriol, estrone, and testosterone have previously been detected in dogs. Rat liver microsomes do not form diglucuronides of these steroids, whereas monkey liver microsomes form detectable levels of the DHT, testosterone, and 17 β -estradiol diglucuronides, with human liver microsomes forming only the diglucuronide of DHT (see Fig. 6-54) (Murai *et al.*, 2005). In all cases, it is the 2-hydroxyl group of the first glucuronide moiety that is subject to additional glucuronidation. In the case of DHT, only human UGT1A8 (an intestinal UGT) has been found to produce the diglucuronide from DHT itself, although UGT1A4, 2B15, and 2B17 can produce the monoglucuronide, and UGT1A1 and 1A9 can produce the diglucuronide when the monoglucuronide is the substrate (Murai *et al.*, 2006). Human intestinal microsomes form

the diglucuronide more efficiently than human liver microsomes, reflecting the fact that UGT1A8, an extrahepatic UGT, is the predominant enzyme involved in the diglucuronidation of DHT.

Although human UGTs typically are highly selective in the use of UDPGA as a sugar donor, they can accommodate the use of other sugar donors such as UDP-glucose, UDP-galactose, and UDP-xylose in an aglycone-dependent manner, as mentioned previously (Tang and Ma, 2005). For instance, recombinant human UGT1A1 can utilize UDPGA, UDP-xylose, or UDP-glucose to form glycosides, but only with bilirubin (Tang and Ma, 2005). Recombinant human UGT2B7 can glycosidate Compound A [(+)-(5*S*,6*R*,7*R*)-2-isopropylamino-7-[4-methoxy-2-((2*R*)-3-methoxy-2-methylpropyl)-5-(3,4-methylenedioxyphenyl)cyclopenteno[1,2-*b*]pyridine 6-carboxylic acid], an endothelin ET_A receptor antagonist, with UDPGA, UDP-glucose, and UDP-galactose, but can glycosidate diclofenac with only UDPGA (Tang and Ma, 2005). In the case of AS-3201, an aldose reductase inhibitor, Toide *et al.* (2004) found that UGT2B4, 2B7, and especially 2B15 all *preferentially* utilize UDP-glucose over UDPGA. Several other compounds have been found to be glucosidated in mammals, including 5-aminosalicylic acid, bromfenac, pranoprofen, pantothenic acid, hydoxycholeic acid, mycophenolic acid, sulfamididine, sulfamerazine, sulfamethoxazole, and various barbiturates (eg, phenobarbital and amobarbital) (Tang and Carro-Ciampi, 1980; Nakano *et al.*, 1986; Arima, 1990; Kirkman *et al.*, 1998; Toide *et al.*, 2004; Picard *et al.*, 2005). In the case of the carboxyl-containing amine, bromfenac, the aglycone was observed in rat bile after base hydrolysis, and it was concluded that it was formed by hydrolysis of an acyl glucuronide (Kirkman *et al.*, 1998). In later studies to characterize the stability of the putative acyl glucuronide, an *N*-glucoside was detected (Kirkman *et al.*, 1998). 5-Aminosalicylic acid is structurally similar to bromfenac in that both NSAIDs contain a primary amine near the carboxyl group, and both are converted to *N*-glucosides (Kirkman *et al.*, 1998). In the human metabolism of barbiturates, *N*-glucosides are the major metabolites found in urine, and glucuronides have not been detected. Accordingly, it was theorized that enzymes other than UGTs may be involved in the conjugation of barbiturates in humans (Toide *et al.*, 2004). This theory is interesting because liver homogenates from cats, which lack UGT activity, can *N*-glucosidate amobarbital (however, it should be noted that glucose conjugates can sometimes form nonenzymatically) (Carro-Ciampi *et al.*, 1985). However, Toide *et al.* (2004) have demonstrated that the *N*-glucosidation of amobarbital in human liver microsomes correlates highly with the *N*-glucosidation of AS-3201, but not its *N*-glucuronidation, indicating that UGT2B15 is probably the predominant human UGT responsible for the glucosidation of amobarbital.

In general, in vivo hepatic clearance is often estimated from kinetic parameters (K_m and V_{max}) determined in vitro with human hepatocytes, liver microsomes or S9 fraction. The process is commonly used for in vitro–in vivo extrapolation (IVIVE). However, for drugs that are primarily eliminated by glucuronidation, these in vitro studies conducted with liver microsomes and, to a lesser extent, hepatocytes consistently underpredict UGT-mediated clearance in vivo (Miners *et al.*, 2010). There are several intrinsic factors that influence the clearance of glucuronidated compounds in vitro, such as: (1) the permeability of the microsomal membranes to allow access of both the aglycone substrate and cofactor UDPGA, (2) the influence of long-chain unsaturated fatty acids released in microsomal incubations, and (3) the homodimerization and heterodimerization of UGT proteins in the ER membranes. Additionally, the kinetic properties of UGTs vary in vitro with changes in the incubation conditions (extrinsic factors), such as the concentration of cofactor, membrane composition, nonspecific binding to

microsomes, type of buffer, ionic strength, pH, organic solvents (used for the addition of substrates), β -glucuronidase activity, and the stability of the glucuronide in the incubation buffer (Miners *et al.*, 2010). Many of these extrinsic factors are minimized with appropriate experimental conditions. For instance, cofactor availability is overcome with saturating concentrations of UDPGA, typically 2 to 5 mM. However, Fujiwara *et al.* (2008) reported that UDP, the by-product of glucuronidation reactions, is a competitive inhibitor that blocks binding of UDPGA. Therefore, for in vitro experiments, the concentrations of cofactor must be maintained at very high levels (up to 20 mM UDPGA) to overcome competitive inhibition of the UDPGA binding site by free UDP produced during the incubation, especially for high-turnover UGT substrates such as 1-naphthol. Other common in vitro conditions for microsomal assays include the addition of the pore-forming peptide alamethicin or zwitterionic detergent CHAPS (described below), the addition of saccharic acid-1,4-lactone to inhibit β -glucuronidase, and the acidification (pH 5-6.8) of the organic solvent used to stop reactions when acyl glucuronide formation is expected (Miners *et al.*, 2010).

In vitro intrinsic clearance (CL_{int}) values (measured as V_{max}/K_m) for zidovudine (AZT) glucuronidation in human liver microsomes were shown to vary 6-fold depending on incubation conditions, but even under conditions that produced the greatest CL_{int} , the in vivo clearance rate was underpredicted by 3- to 4-fold (Miners *et al.*, 2006). This in vitro underprediction of the in vivo rate of clearance of drugs that are glucuronidated is typical when human liver microsomes are used to assess CL_{int} , and is likely due to a number of factors including the presence or absence of albumin, the effects of long-chain unsaturated fatty acids, correction for nonspecific binding, atypical in vitro kinetics, active uptake into hepatocytes, and significant extrahepatic expression of various UGTs (Miners *et al.*, 2010). The prediction of the in vivo clearance of drugs that are glucuronidated by hepatocytes is generally more accurate than predictions made with microsomes, but underprediction is still the common outcome. Zidovudine is an exception to this rule because its in vivo clearance is accurately predicted from in vitro studies with hepatocytes (Miners *et al.*, 2006). The use of either microsomes or recombinant UGT2B7 also underpredicts the in vivo magnitude of the *inhibitory* interaction between fluconazole and zidovudine by 5- to 10-fold (Miners *et al.*, 2006). However, when 2% bovine serum albumin (BSA) is added to either systems, there is a decrease in the K_i value of 85% which results in a much improved prediction of the in vivo interaction (Miners *et al.*, 2006). The effect of BSA is not due to nonspecific binding but rather the sequestration of inhibitory fatty acids released from membranes during the incubation. The BSA or "albumin" effect is also observed with fatty-acid-free human serum albumin (HSA-FAF) added to incubations. The K_m values of reactions catalyzed by UGT1A9 and 2B7 are markedly influenced by the presence of free fatty acids released from microsomal membranes (notably arachidonic, linoleic, and oleic acids) and albumin serves as a fatty acid scavenger. Similarly, the addition of intestinal fatty-acid binding protein (IFABP) to microsomal incubations decreased the K_m values for zidovudine glucuronidation, a UGT2B7 substrate (Rowland *et al.*, 2009). Unsaturated long-chain fatty acids are potent competitive inhibitors of some, but not all, UGT enzymes and can lead to overestimation of K_m values and, therefore, underprediction of CL_{int} . Furthermore, the effect of fatty acids varies depending on the membrane composition of the enzyme source (recombinant vs microsomes vs hepatocytes) inasmuch as kinetic constants for a specific reaction may vary based on the test system. Unlike UGT1A9 and 2B7, fatty acids have little to no effect on reactions catalyzed by UGT1A1, 1A4, and 1A6 (Miners *et al.*, 2010).

The glucuronidation of xenobiotics by liver microsomes in vitro displays a property known as latency inasmuch as it can be stimulated by detergents (eg, CHAPS and Brij-58) and the pore-forming peptide alamethicin, which disrupt the lipid bilayer of the endoplasmic reticulum and allow UGTs free access to UDPGA. High concentrations of detergent, especially nonionic detergents such as Brij, can inhibit certain UGTs, presumably by disrupting their interaction with phospholipids, which are important for catalytic activity (Fisher *et al.*, 2000). Treatment of microsomes with detergents also virtually eliminates CYP activity; hence, detergents cannot be used to study the possible coupling of oxidation reactions catalyzed by CYP with conjugation reactions catalyzed by UGT. This is not a limitation of alamethicin which does not inhibit CYP. Furthermore, in contrast to certain detergents, alamethicin increases V_{max} without affecting K_m . From a review of the literature, Miners *et al.* (2006) report that alamethicin and nonionic detergents such as Brij-58 generally result in the highest UGT activity and that alamethicin is the preferred activator because the effects of detergents are not reproducible between substrates. However, in incubations designed strictly to measure UGT activity (and not both UGT and CYP activity), the zwitterionic detergent, CHAPS, can activate certain UGT activities to a comparable or even greater extent than alamethicin.

The kinetic properties of UGTs are possibly influenced by the formation of homodimers and heterodimers among UGT enzymes and by the formation of heterodimers with other microsomal enzymes such as various CYP enzymes, NADPH-cytochrome P450 reductase, or epoxide hydrolase (Ishii *et al.*, 2010). For instance, it has been demonstrated that the ratio of morphine-3-glucuronide to morphine-6-glucuronide formed by UGT2B7 is altered by the presence of CYP3A4. The K_m of UGT2B7-catalyzed formation of morphine-3-glucuronide was increased 9.8-fold (0.38 to 3.7 μ M) when coexpressed with CYP3A4 (Takeda *et al.*, 2005; Ishii *et al.*, 2010). Fremont *et al.* (2005) reported that UGT1A1, 1A6, and 2B7 coimmunoprecipitated with CYP3A4 in solubilized human liver microsomes. If there are functional consequences to the associations between different UGT enzymes and/or the association between UGT and CYP enzymes, then such associations would have implications for studies with recombinant UGT enzymes, which are invariably expressed individually. Additionally, there is historically no universally accepted method to quantify the amount (specific content) of UGTs in human liver microsomes and recombinant enzyme preparation, which precludes a meaningful comparison of rates of glucuronidation between these two in vitro systems as is done with CYP enzymes (through the application of relative activity factors [RAF] or intersystem extrapolation factors [ISEF]). However, advances in mass spectrometry have enabled the quantification of UGT proteins in samples of human liver microsomes and cultured hepatocytes (Table 6-18) (Ohtsuki *et al.*, 2012). The role of heteromeric or homomeric expression of UGTs in vivo is largely undefined. Several publications have investigated the coexpression of UGT enzymes in vitro with cell lines overexpressing various UGTs with mixed results: enhancement of some activities and impairment of others (Ishii *et al.*, 2010). Finally, posttranslational modifications to UGTs that occur in vivo in humans (eg, phosphorylation and *N*-glycosylation) may not occur in the cell expression system chosen to produce the recombinant UGTs (ie, bacterial systems), which can impact activity in a substrate-dependent manner (Miners *et al.*, 2006). All of these findings suggest that the use of recombinant human UGT enzymes may not provide accurate indications of the extent to which a given UGT can glucuronidate a given substrate.

Glucuronidation can be impaired by cofactor availability, polymorphisms, drug-drug interactions, or the effects of endogenous

or dietary compounds, any of which can result in toxicities due to decreased elimination of certain compounds (eg, bilirubin). Cofactor availability can limit the rate of glucuronidation of drugs that are administered in high doses and are conjugated extensively, such as aspirin and acetaminophen. In experimental animals, the glucuronidation of xenobiotics can be impaired *in vivo* by factors that reduce or deplete UDPGA levels, such as diethyl ether, borneol, and galactosamine. The lowering of UDPGA levels by fasting, such as might occur during a severe toothache or oral cancer, is thought to predispose individuals to the hepatotoxic effects of acetaminophen, although even then hepatotoxicity only occurs with higher-than-recommended doses of this analgesic (Whitcomb and Block, 1994; Rumack, 2004).

Drug–drug interactions that are at least partly due to inhibition of UGTs have been reported. For instance, plasma levels of indomethacin are increased about 2-fold upon coadministration of diflunisal, and *in vitro* studies indicate that this interaction is due in part to inhibition of indomethacin glucuronidation in the intestine (Gidal *et al.*, 2003; Mano *et al.*, 2006). Valproic acid coadministration increases the AUC of lorazepam and lamotrigine by 20% and 160%, respectively (Williams *et al.*, 2004). In contrast to the situation with CYP enzymes, there are fewer inhibitory drug–drug interactions caused by the inhibition of UGT enzymes, and AUC increases are rarely greater than 2-fold (Williams *et al.*, 2004), whereas dramatic AUC increases have been reported for CYP enzymes, such as the 190-fold increase in AUC reported for the CYP1A2 substrate ramelteon (Rozerem™) upon coadministration of fluvoxamine (Obach and Ryder, 2010). The low magnitude of UGT-based inhibitory interactions is partly due to the fact that most drugs that are primarily cleared by glucuronidation are metabolized by several UGTs. However, administration of drugs that inhibit UGT enzymes, particularly the bilirubin conjugating enzyme UGT1A1, can lead to toxicities by inhibiting clearance of endogenous substrates. For example, administration of the protease inhibitors atazanavir and indinavir to HIV patients is proposed to result in reversible hyperbilirubinemia caused by the inhibition of UGT1A1 (Zhang *et al.*, 2005). Drug–drug interactions due to induction of UGT enzymes have also been observed. Rifampin coadministration increases mycophenolic acid clearance by 30%, and increases the AUC of its acyl glucuronide (formed by UGT2B7) and its 7-*O*-glucuronide (formed by various UGT1 enzymes) by more than 100% and 20%, respectively (Naesens *et al.*, 2006). Similarly, rifampin coadministration in humans causes a decrease in the systemic AUC of some UGT substrates, including raltegravir (UGT1A1; decreases AUC by 40%) and zidovudine (UGT2B7; decreases AUC 30%–50%) (Gallicano *et al.*, 1999; Wenning *et al.*, 2009). Coadministration of other drugs, such as the enzyme-inducing antiepileptics (eg, phenobarbital), and certain physiological conditions (eg, increased levels of estrogens during pregnancy) can cause an increase of hepatic UGT enzymes and, therefore, the clearance of some UGT substrates. In general, the magnitude of drug–drug interactions due to UGT enzyme induction is less than those reported for CYP-mediated induction.

Human UGT1A6 glucuronidates acetaminophen. This reaction is enhanced by cigarette smoking and dietary cabbage and Brussels sprouts, which suggests that human UGT1A6 is inducible by PAHs and derivatives of indole 3-carbinol, but not to the extent observed in rats (Bock *et al.*, 1994). Ligands for AhR, such as those present in cigarette smoke, induce CYP1A2, which would be expected to enhance the hepatotoxicity of acetaminophen. Increased acetaminophen glucuronidation may explain why cigarette smoking does not enhance the hepatotoxicity of acetaminophen. Conversely, decreased glucuronidation may explain why some individuals with

Gilbert syndrome are predisposed to the hepatotoxic effects of acetaminophen (de Morais *et al.*, 1992). Low rates of glucuronidation predispose newborns to jaundice and to the toxic effects of chloramphenicol; the latter was once used prophylactically to prevent opportunistic infections in newborns until it was found to cause severe cyanosis and even death (gray baby syndrome).

Some glucuronide conjugates have been found to act as substrates for further biotransformation by oxidation or even by further conjugation. For instance, in male Wag/Rij rats, estradiol 17 β -glucuronide can be sulfonated by one or more sulfotransferases (SULTs) to estradiol 3-sulfate-17 β -glucuronide (Sun *et al.*, 2006). In addition, the acyl glucuronide of 4-hydroxydiclofenac can be formed either by a combination of 4'-hydroxylation followed by acyl glucuronidation or by a combination of acyl glucuronidation followed by 4'-hydroxylation. In the former case, the 4'-hydroxylation of diclofenac is catalyzed by CYP2C9, whereas in the latter case the 4'-hydroxylation of diclofenac acyl glucuronide is catalyzed by CYP2C8 (Kumar *et al.*, 2002). Glucuronidation converts several other CYP2C9 substrates into CYP2C8 substrates or inhibitors. For instance, CYP2C8 catalyzes the oxidation of several glucuronides, the aglycones of which are CYP2C9 substrates, including estradiol 17 β -glucuronide and the acyl glucuronides of naproxen, the PPAR α /agonist MRL-C, and gemfibrozil (Delaforge *et al.*, 2005; Kochansky *et al.*, 2005; Ogilvie *et al.*, 2006). In the case of gemfibrozil, the CYP2C8-mediated hydroxylation of its 1-*O*- β -glucuronide to the formation of a reactive product, presumably a benzyl radical intermediate, that alkylates the γ -meso position of the heme and causes irreversible inhibition of this enzyme (Baer *et al.*, 2009). The inactivation of CYP2C8 by gemfibrozil glucuronide is responsible for drug–drug interactions between gemfibrozil and CYP2C8 substrates such as repaglinide and cerivastatin (Ogilvie *et al.*, 2006). Similar to its inhibition of CYP2C8, gemfibrozil and its glucuronide are inhibitors (and substrates) of the organic anion transporter OATP1B1 on the sinusoidal membrane of hepatocytes. Inhibition of OATP1B1 by gemfibrozil and gemfibrozil glucuronide accounts, at least in part, for the pharmacokinetic drug–drug interaction between gemfibrozil and several statin drugs whose systemic clearance is predominately through OATP-mediated hepatic uptake, namely, pravastatin and rosuvastatin (Tornio *et al.*, 2008). Although inactivation of CYP2C8 by gemfibrozil glucuronide is the only known example of CYP inactivation by the glucuronide of a clinically used drug, Kazmi *et al.* (2010) identified a carbamoyl-glucuronide of a drug candidate that caused irreversible metabolism-dependent inhibitor (MDI) of CYP2C8 *in vitro*, the clinical significance of which is unknown.

Glucuronidation is important for the conversion of atorvastatin acid to its pharmacologically inactive lactone form at physiological pH; however, the formation of atorvastatin lactone is also associated with dose-limiting toxicities (Riedmaier *et al.*, 2011). Atorvastatin (Lipitor) is administered as a free acid but is found in systemic circulation at levels similar to its pharmacologically inactive lactone based on plasma AUC. The major cause of adverse events associated with atorvastatin therapy is myopathy (skeletal muscle toxicity) which, in severe cases, can result in rhabdomyolysis and fatal kidney failure. *In vitro* studies with the acid and lactone forms of atorvastatin in primary skeletal muscle cells established that the lactone form is 14 times more potent than the acid form at inducing cell death. Both atorvastatin acid and lactone can undergo oxidative metabolism by CYP3A4 and CYP3A5 to form *ortho*- and *para*-hydroxylated metabolites. Atorvastatin acid also undergoes glucuronidation to form atorvastatin acyl glucuronide. The conversion of atorvastatin acid to its pharmacologically inactive lactone occurs nonenzymatically at low pH (eg, intestine) or enzymatically at physiological pH (7.4); the latter is dependent on formation of the acyl glucuronide

(Riedmaier *et al.*, 2011). The glucuronide moiety is a good leaving group and is lost during the lactonization reaction. Based on in vitro and in vivo studies Riedmaier *et al.* (2010) identified UGT1A3 as the enzyme largely responsible for the lactonization of atorvastatin and further demonstrated that the paraoxonases PON1 and PON3 are responsible for the hydrolysis of atorvastatin lactone back to the acid form. Taken together, UGT1A3, PON1, and PON3 are important determinants of the atorvastatin acid–lactone ratio in vivo and, hence, the potential for atorvastatin myopathy and rhabdomyolysis.

Kumar and colleagues demonstrated that failure to take into account the formation of the acyl glucuronide of 4'-hydroxydiclofenac leads to an underestimation of hepatic clearance of diclofenac. It may also be that oxidation of glucuronide metabolites can lead to toxicity. A case report described the formation of an IgM antibody that bound erythrocytes, but only in the presence of the 4-hydroxydiclofenac acyl glucuronide in a patient who developed hemolysis (hemolytic anemia) during diclofenac treatment (Shipkova *et al.*, 2003). A determination of the absolute amount of diclofenac acyl glucuronide formed in vivo relative to the amount of 4-hydroxydiclofenac formed in vivo would be confounded by the rapid hydrolysis of the glucuronide to the aglycone, and it would therefore be likely that detection of 4-hydroxydiclofenac acyl glucuronide would be attributed to oxidative metabolism occurring prior to conjugation. Two recent reports suggest that direct glucuronidation with subsequent oxidation (by a combination of UGT2B7 and CYP2C8 in humans) may be the major determinants of diclofenac clearance in humans (possibly as high as 75%) and monkeys (>90%) (Kumar *et al.*, 2002; Prueksaritanont *et al.*, 2006), as opposed to earlier in vivo data that suggested oxidative metabolism by CYP2C9 alone is the major determinant of clearance (Stierlin and Faigle, 1979; Stierlin *et al.*, 1979). Prueksaritanont *et al.* (2006) further note that there are no clinical reports that implicate pharmacokinetic interactions between diclofenac and potent CYP2C9 inhibitors or inducers. Taken together, these observations suggest that the CYP-mediated oxidation of glucuronide metabolites has implications not only for the prediction of in vivo drug–drug interactions from in vitro data (ie, gemfibrozil) but also for the prediction of in vivo clearance (ie, diclofenac), and possibly also toxicity, as in the case of immune-mediated toxicity of diclofenac.

In humans, Crigler–Najjar syndrome (type I and II) and Gilbert disease are congenital defects in bilirubin conjugation. The diseases have historically been differentiated largely on the basis of the severity of symptoms and total plasma concentrations of bilirubin (eg, Crigler–Najjar Type I: 310–855 μM , Crigler–Najjar Type II: 100–430 μM , and Gilbert disease: 20–100 μM). The major bilirubin-conjugating enzyme in humans is UGT1A1. Genetic polymorphisms in exons 2 to 5 (which affect all enzymes encoded by the UGT1A locus), in exon 1 (which affect only UGT1A1), in the promoter regions, and in introns 1 and 3 have been identified in patients with Crigler–Najjar syndrome or Gilbert disease. More than 60 genetic polymorphisms are associated with these diseases. A current list of all UGT polymorphisms and phenotypes (when known) can be found at <http://galien.pha.ulaval.ca/alleles/alleles.html>. Some polymorphisms cause the introduction of a premature stop codon in one of the UGT1A common exons 2 to 5 (which causes a loss of all UGT1A enzymes, analogous to the Gunn rat) and are associated with type I Crigler–Najjar syndrome, a severe form of the disease characterized by a complete loss of bilirubin-conjugating activity and marked hyperbilirubinemia. Type I Crigler–Najjar syndrome is also associated with various frameshifts and deletions in exons 1 to 5, and in at least three cases with changes in introns 1 and 3 that affect splice donor or acceptor sites. Other polymorphisms are associated with the less severe type II Crigler–Najjar syndrome (ie, UGT1A1*7-9, 12, 26, 30, 33-38, 42, 48, 51, 52, 59, and 64).

Individuals with Gilbert disease have an occasionally transient, and generally mild, hyperbilirubinemia that is often caused by the addition of one “TA” segment in the TATA promoter region (ie, UGT1A1*28: A(TA)₆TAA \rightarrow A(TA)₇TAA). There is some overlap between Crigler–Najjar Type II and Gilbert disease, not only in terms of the plasma concentrations of bilirubin but also in the type of polymorphism that underlies the disease. In addition to the *28 allele, the *6, *27, *29, *60, and *62 alleles are associated with Gilbert disease, and some of these polymorphisms affect coding regions of the UGT1A1 gene. In addition, the UGT1A1*37 allele produces a A(TA)₈TAA promoter defect that results in Crigler–Najjar Type II. A Korean individual heterozygous for three UGT1A1 alleles associated with Gilbert disease (ie, likely *6, *28, and *60) was found to have total bilirubin concentrations as high as 193 μM (Seo *et al.*, 2007), which is a concentration typically associated with Crigler–Najjar Type II. Crigler–Najjar Type II and Gilbert disease (in contrast to Crigler–Najjar Type I) typically respond to some extent to phenobarbital treatment, which stimulates bilirubin conjugation presumably by inducing UGT1A1. Type I Crigler–Najjar syndrome is also associated with impaired glucuronidation of propofol, ethinylestradiol, and various phenolic substrates for UGT1A enzymes. Polymorphisms that might affect the other UGT1A enzymes have not been thoroughly characterized in vivo, but there are data to suggest that polymorphisms in these enzymes may modify the risk of developing certain types of cancer (Nagar and Rimmel, 2006).

The UGT1A1*28 allele has received widespread attention in recent years due to the impact this variant has on the toxicity of the topoisomerase I inhibitor, irinotecan, which is used primarily to treat colorectal cancer. The disposition of irinotecan is complex. Irinotecan (a prodrug) is administered intravenously with hydrolysis to the active metabolite, SN-38, occurring mainly by tissue carboxylesterases, namely, CES2, and hydrolytic enzymes in plasma. The active metabolite SN-38 is subsequently glucuronidated in the liver primarily by UGT1A1 after which the glucuronide conjugate is excreted into bile. Other UGT enzymes that contribute to glucuronidation, at least in part, include hepatic UGT1A6 and 1A9 and intestinal UGT1A7 and 1A10 (Nagar and Blanchard, 2006; Wallace *et al.*, 2010). The UGT1A1*28 variant has now been referenced in the Camptosar[®] prescribing information, which notes that patients with reduced UGT1A1 activity have a higher exposure to SN-38 (which is 50–100 times more toxic than the glucuronide), and that the dose of irinotecan should be adjusted downward accordingly (Nagar and Blanchard, 2006). The toxicity of SN-38 primarily manifests as severe diarrhea and myelosuppression (in the form of leucopenia, severe thrombocytopenia, severe anemia, or grade 3–4 neutropenia) (Nagar and Blanchard, 2006). Several studies have demonstrated grade 3 to 4 neutropenia and/or grade 3 to 4 diarrhea upon irinotecan administration in patients with at least one UGT1A1*28 or *27 allele, and one study implicated *high*-activity variants of UGT1A7 and 1A9 with diarrhea (Nagar and Blanchard, 2006).

Wallace *et al.* (2010) reported that inhibition of bacterial β -glucuronidase is a potential pharmacological approach to overcome the severe diarrhea associated with irinotecan (CPT-11) chemotherapy. Hydrolysis of SN-38-*O*-glucuronide (SN-38G) by bacterial β -glucuronidase in the gastrointestinal tract releases the pharmacologically active SN-38 into the intestinal lumen where it can be reabsorbed and cause dose-limiting diarrhea. The β -glucuronidase enzyme responsible for hydrolysis of SN-38G in the gut is found in the symbiotic microflora. Wallace *et al.* (2010) identified 4 compounds that potently (K_i values in the nanomolar range) and specifically inhibit *E. coli* β -glucuronidase, but not human β -glucuronidase activity, by targeting a 17-residue loop in the bacterial enzyme that is not present in mammalian forms. Inhibition of

E. coli-specific β -glucuronidase protected mice from the GI toxicity of irinotecan (Wallace *et al.*, 2010). Taken together, these results suggest that β -glucuronidase may be a potential pharmacological target to limit pharmacokinetic or toxicological concerns associated with hydrolysis of glucuronides in the GI tract, which may lead to reabsorption of, and prolonged exposure to, the aglycone.

Polymorphisms have been identified in UGT2B4, 2B7, 2B10, 2B15, 2B17, and 2B28. For example, oxazepam is glucuronidated by UGT2B15, which preferentially glucuronidates *S*-oxazepam over its *R*-enantiomer. Ten percent of the population appear to be poor glucuronidators of *S*-oxazepam, and one study has implicated the low-activity UGT2B15*2 allele as a possible determinant of such variation (Nagar and Rimmel, 2006). Such polymorphisms also appear to be the underlying cause of alterations in hydroxycholesterol glucuronidation in gastric mucosa (Tukey and Strassburg, 2000). Glucuronidation of dihydrotestosterone, testosterone, and androsterone by UGT2B17 terminates androgen signaling in prostate and other androgen target cells. The UGT2B17 gene is deleted in some individuals and the role of this genetic polymorphism on circulating testosterone levels has gained importance in many areas, such as sports doping and some instances of an increased risk of prostate cancer, among others (Guillemette *et al.*, 2010).

In some cases, glucuronidation represents an important event in the toxicity of xenobiotics. For example, the aromatic amines

that cause bladder cancer (such as benzidine, 2-aminonaphthalene, and 4-aminobiphenyl) undergo *N*-hydroxylation in the liver ($aryl-NH_2 \rightarrow aryl-NHOH$) followed by *N*-glucuronidation (not *O*-glucuronidation) of the resultant hydroxylamine. Direct *N*-glucuronidation (prior to *N*-hydroxylation) also occurs, and is a competing pathway of hepatic metabolism. In the case of 4-aminobiphenyl, the competing pathways of ring hydroxylation and *O*-esterification (ie, *O*-glucuronidation, *O*-sulfonation, or *O*-acetylation) are detoxication pathways, whereas *N*-esterification catalyzed by UGTs, SULTs, or NATs represent activating pathways (see the section “Acetylation”) (Cohen *et al.*, 2006). Benzidine and 2-aminonaphthalene are particularly tumorigenic. The risk of bladder cancer may increase by up to 100-fold in workers exposed to these substances in the course of their occupation in various manufacturing processes (Al-Zoughool *et al.*, 2006). The *N*-glucuronides of such carcinogens, which accumulate in the urine of the bladder, are unstable in acidic pH and thus are hydrolyzed to the corresponding unstable, tumorigenic hydroxylamines, as shown in Fig. 6-56. Under acidic condition, hydroxylamines can produce highly electrophilic aromatic nitrenium ions ($aryl-NHOH + H^+ \rightarrow aryl-N^+ + H_2O$) that can bind to DNA and other macromolecules, or they can be converted to reactive acetoxy metabolites directly in the bladder epithelium by NAT-mediated *O*-acetylation ($aryl-NH-O-CO-CH_3$), which also leads to the formation of aromatic nitrenium ions

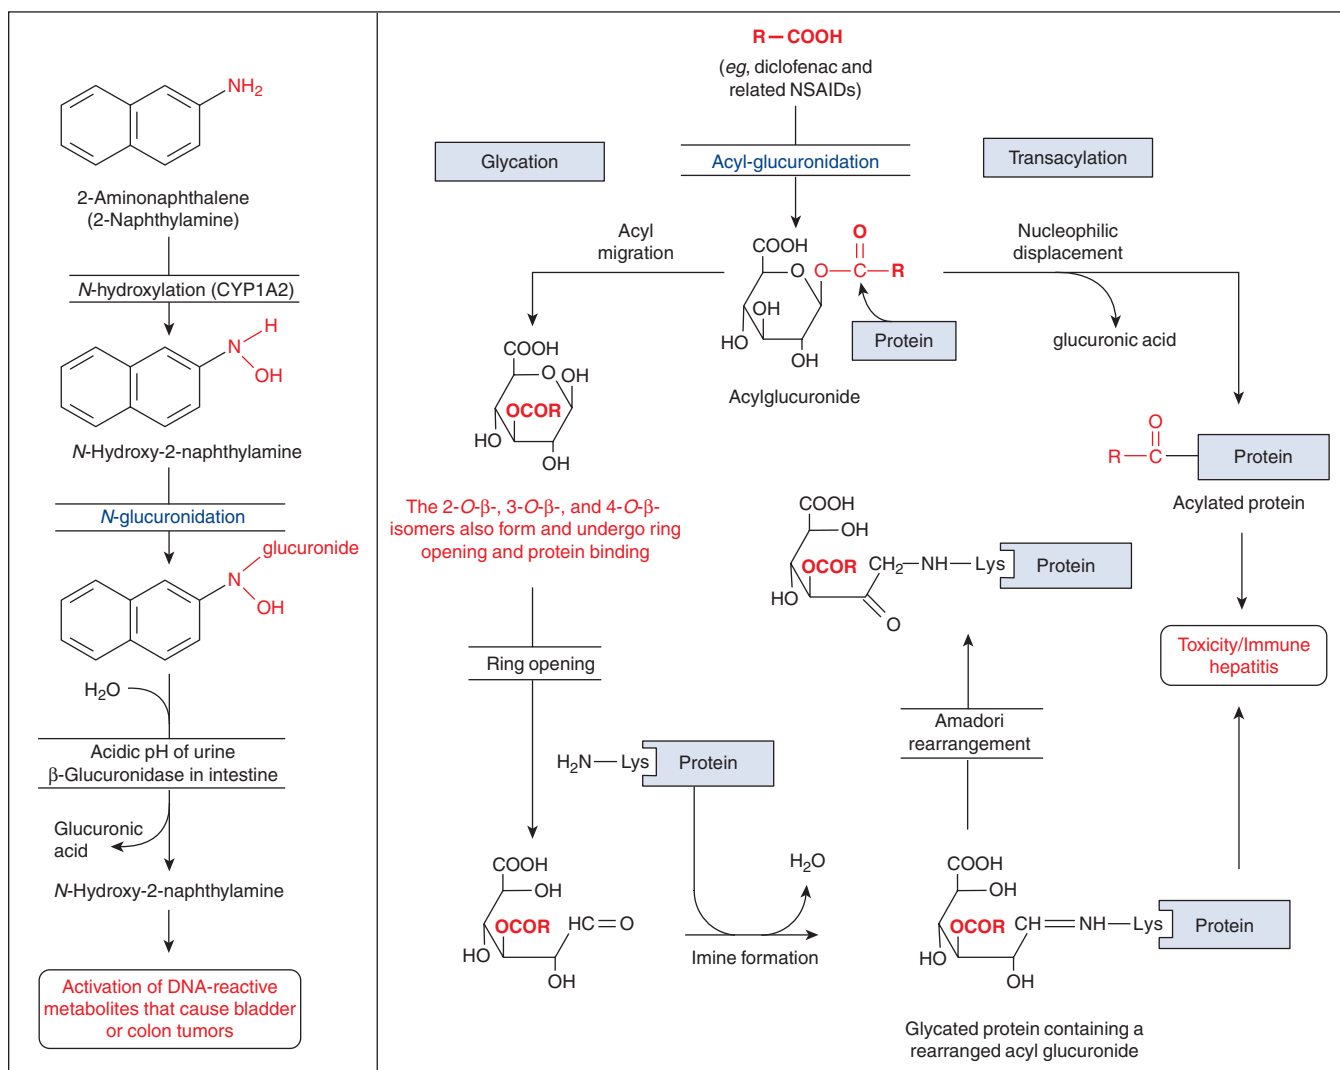

Figure 6-56. Role of glucuronidation in the activation of xenobiotics to toxic metabolites.

(Al-Zoughool *et al.*, 2006). Because *N*-glucuronidation of aromatic amines can also occur directly without a prior oxidation, this reaction competes with oxidation, and therefore a decrease in UGT activity in the liver would favor *N*-hydroxylation, with subsequent *O*-acetylation by NAT and spontaneous formation of aromatic nitrenium ions in the liver, rather than the bladder. In contrast, decreased acetylation with normal UGT activity would lead to a greater accumulation of *N*-glucuronides (of the parent aromatic amine and its hydroxylamine) in the bladder with increased bladder tumor formation. Concordant with this scenario, benzidine induces predominantly liver tumors in rats (fast acetylators) but bladder cancer in dogs (poor acetylators) (Al-Zoughool *et al.*, 2006). In humans, there are sex differences in aromatic amine carcinogenicity. Irrespective of ethnicity or race, men are 2.5 to 5 times more likely to develop bladder cancer than women in general, and in particular male smokers, hairdressers, and dye and textile workers who are exposed to aromatic amines have several times increased risk relative to their female counterparts. Male mice, which *N*-glucuronidate 4-aminobiphenyl faster than females, were found during the treatment with this carcinogen to have a 2.2-fold higher rate of DNA-adduct formation, and increased rates of bladder tumor formation relative to females, and female mice were found to have tumors only in the liver (Al-Zoughool *et al.*, 2006). In mice, coadministration of 4-aminobiphenyl with hecogenin, which in humans has been found to inhibit hepatic UGT1A4 (Uchaipichat *et al.*, 2006), was found to increase DNA-adduct formation in a statistically significant manner in the livers of male mice, and to slightly decrease adduct formation in the bladders of both male and female mice (Al-Zoughool *et al.*, 2006). The available literature regarding sex differences in human UGT activity is conflicting. On the one hand, glucuronidation of temazepam, oxazepam, propranolol, and salicylic acid was 20% to 60% higher in men than in women (Al-Zoughool *et al.*, 2006), whereas 4-methylumbelliferone glucuronidation in cryopreserved human hepatocytes was found to be an average of 40% higher in female samples ($n = 33$) than in male samples ($n = 31$). The carcinogenicity of aromatic amines is multifactorial, and involves not only hepatic *N*-glucuronidation but also hepatic oxidation, hepatic and bladder acetylation, and possibly peroxidation of *N*-hydroxy-*N*-acetyl aromatic amines in the bladder (Al-Zoughool *et al.*, 2006). Therefore, sex differences in UGT activity alone may not fully explain the sex differences observed in the carcinogenicity of aromatic amines. A similar mechanism may be involved in colon tumor formation by aromatic amines, although in this case hydrolysis of the *N*-glucuronide is probably catalyzed by β -glucuronidase in intestinal microflora. Aromatic amides (such as phenacetin) can also be *N*-hydroxylated by CYP (and peroxidases) to form hydroxamic acids: *aryl-N*(OH)-COCH₃. Under acidic conditions (such as in urine), these can lose water to form reactive nitrenium ions that are thought to contribute to the renal toxicity of phenacetin. The *N*-OH group can also be conjugated, which introduces a good leaving group. This represents a second pathway to nitrenium ion formation (Testa and Krämer, 2008, 2010).

Steroid hormones glucuronidated on the D-ring (but not the A-ring) cause cholestasis. For instance, 17 β -estradiol-glucuronide causes cholestasis in rats by inhibition of MRP2 and BSEP, which are transporters located on the apical membrane of hepatocytes and are important for biliary efflux of endobiotic and xenobiotics and formation of bile (Huang *et al.*, 2000; Stieger *et al.*, 2000). Induction of UGT activity has been implicated as an epigenetic mechanism of thyroid tumor formation in rodents (McClain, 1989; Curran and DeGroot, 1991). Inducers of UGTs cause a decrease in plasma thyroid hormone (TH) levels, which triggers a compensatory increase in thyroid stimulating hormone (TSH). During sustained exposure

to the enzyme-inducing agent, prolonged stimulation of the thyroid gland by TSH (>6 months) results in the development of thyroid follicular cell neoplasia. Glucuronidation followed by biliary excretion is a major pathway of thyroxine (T4) biotransformation in rodents, whereas deiodination is the major pathway (up to 85%) of T4 metabolism in humans. In contrast to the situation in rodents, prolonged stimulation of the thyroid gland by TSH in humans will result in malignant tumors only in exceptional circumstances and possibly only in conjunction with some thyroid abnormality. Therefore, chemicals that cause thyroid tumors in rats or mice by inducing UGT activity are unlikely to cause such tumors in humans. In support of this conclusion, extensive epidemiological data in epileptic patients suggest that phenobarbital and other anticonvulsants do not function as thyroid (or liver) tumor promoters in humans (Parkinson *et al.*, 2006).

Earlier in this chapter the metabolic activation of drugs to reactive metabolites was discussed on the basis of structural class (acidic vs neutral/basic) and is illustrated in Fig 6-57. In particular, acidic drugs (eg, NSAIDs) can undergo conjugation by UGTs to form acyl glucuronides and/or conjugation with amino acids through the formation of acyl-CoA thioesters catalyzed by mitochondrial acyl-CoA ligases (see the section "Amino Acid Conjugation"). Both conjugation pathways potentially lead to formation of chemically reactive metabolites that have the intrinsic ability to covalently modify proteins by glycation (acyl glucuronides) and/or transacylation (acyl glucuronides and acyl-CoA thioesters). Reactive acyl glucuronides glycate amine group of lysine residues through Schiff base formation (in which case the glucuronide moiety covalently modifies the protein) and they can also transacylate proteins by nucleophilic displacement reactions (in which case the glucuronic acid moiety serves as the leaving group and is not covalently bound to the protein), as shown in Fig. 6-57 (Regan *et al.*, 2010). Similarly, acyl-CoA thioesters can transacylate proteins at nucleophilic sites (such as lysine, serine, cysteine, and tyrosine residues), in which case the thio-CoA moiety is the leaving group (Grillo, 2011). An important difference between acyl glucuronides and acyl-CoA thioesters is that only the former are transported into bile where they can damage cholangiocytes and other bile duct cells (discussed later in this section). Several drugs, including the NSAIDs benoxaprofen, bromfenac, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, indoprofen, ketoprofen, ketorolac, loxoprofen, sulindac, suprofen (very similar to the diuretic, tienilic acid), tiaprofenic acid, tolmetin, and zomepirac, contain a carboxylic acid moiety that can be glucuronidated to form a reactive acyl glucuronide that can form covalent adducts with proteins. Acyl glucuronides vary widely in their reactivity, from the highly reactive zomepirac and tolmetin acyl glucuronides to the less reactive acyl glucuronides of ibuprofen and salicylic acid (Shipkova *et al.*, 2003). A relationship between the reactivity of acyl glucuronides and the substitution near the carboxylic acid has been found. In general, α -unsubstituted acetic acid derivatives such as zomepirac, tolmetin, and diclofenac exhibit the highest degree of covalent binding, while mono- α -substituted acetic acids such as fenoprofen show intermediate levels, and fully substituted α -acetic acids such as furosemide, ketoprofen, ibuprofen, and suprofen exhibit lower levels of covalent binding (Bolze *et al.*, 2002). The chemical reactivity of acyl glucuronides (as measured by glycation of albumin or a trapping agent such as the dipeptide phenylalanine-lysine) is highly correlated with its rate of isomerization whereby the xenobiotic sequentially migrates from the initial 1-*O*- β position to the 2-, 3-, and 4-positions (which can be in either the α - or β -configuration) (Wang *et al.*, 2004). It is only after the xenobiotic migrates from the 1-position that the glucuronide moiety can transiently open to its hemiacetal form and form a Schiff base with lysine residues. When

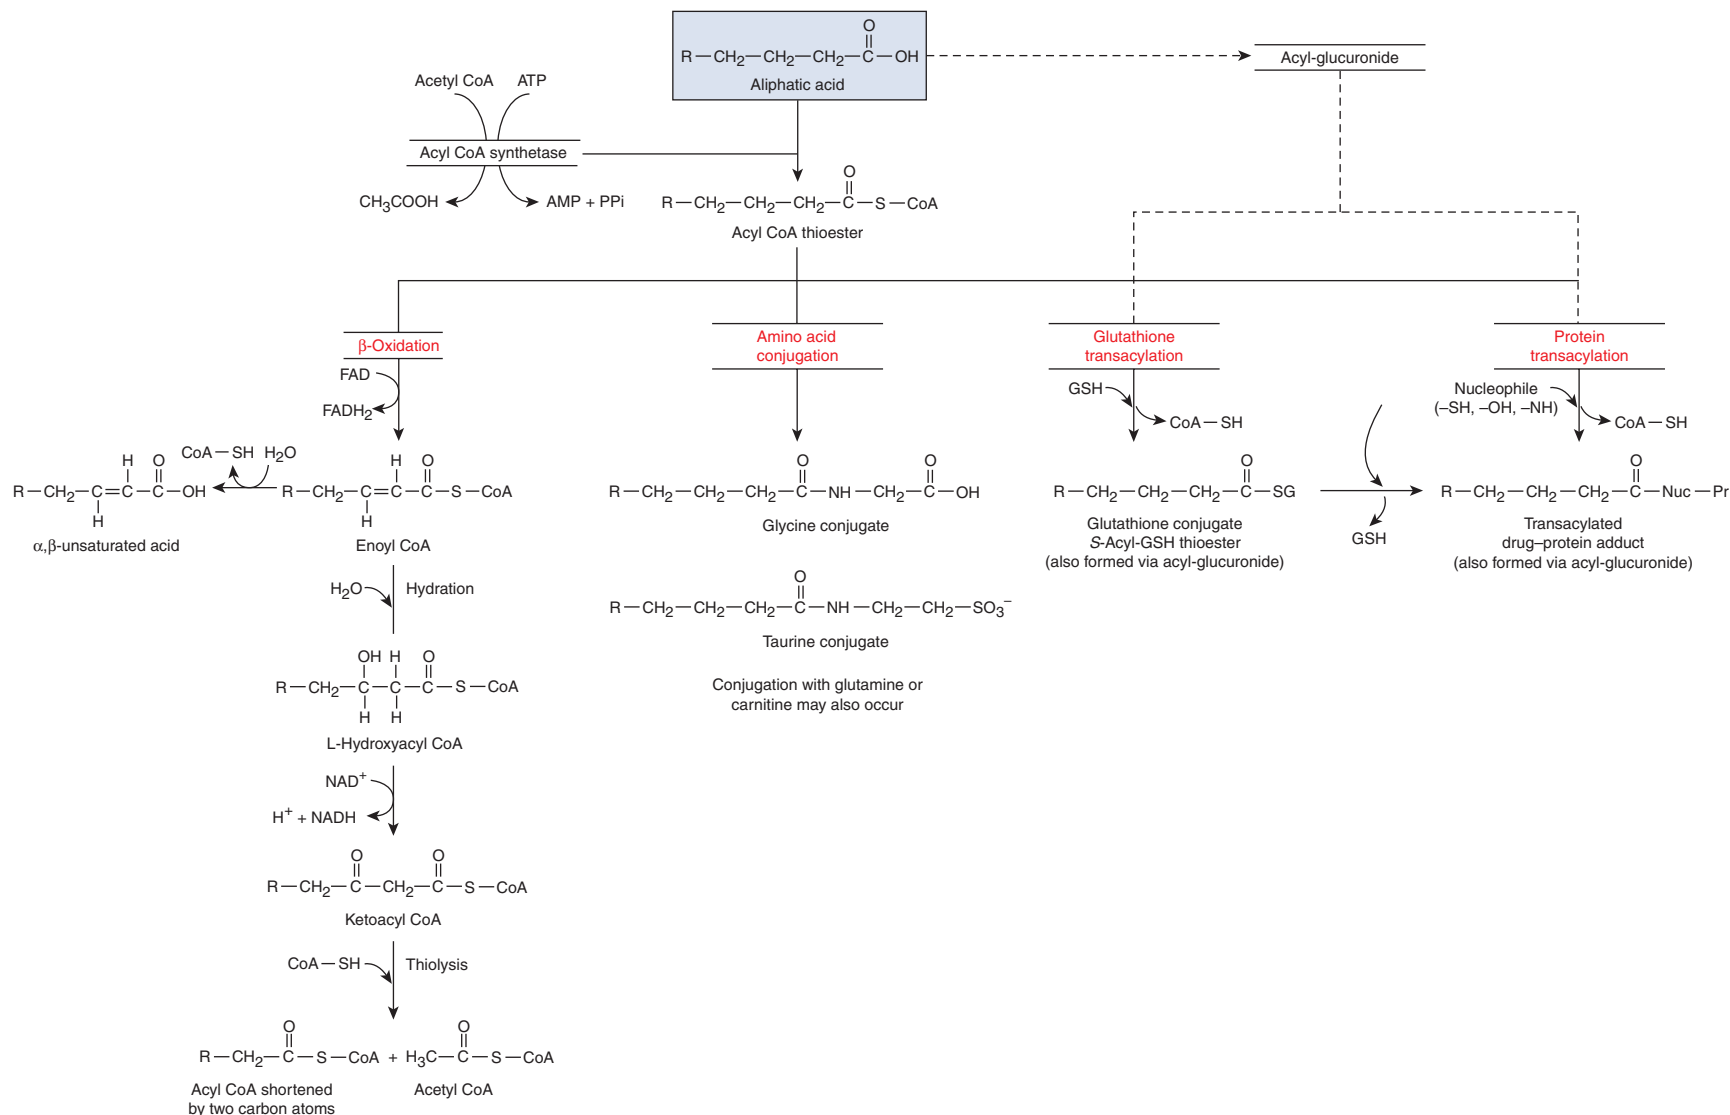

Figure 6-57. Conversion of carboxylic acid-containing xenobiotics to acyl-CoA thioesters and their subsequent biotransformation by chain shortening by β -oxidation, conjugation with amino acid, and transacylation with glutathione and protein.

incubated in protein-free phosphate buffer at pH 7.4, those acyl glucuronides with a half-life of less than 30 minutes (with the loss of the 1-*O*- β isomer occurring by a combination of isomerization and hydrolysis) include the acyl glucuronides of the particularly hepatotoxic NSAIDs zomepirac and tolmetin. Isomerization is slowed by the addition of one or two substituents on the α -carbon (next to the carboxylic acid moiety) which correlates with their reduced toxicity. However, a direct correlation between the ability of acyl glucuronides to give rise to covalent adducts with proteins such as albumin and their ability to cause drug-related toxicity has not been firmly established, and other mechanisms may come into play. For instance, diclofenac is still a widely used drug in spite of the fact that its acyl glucuronide is very reactive, whereas zomepirac, which is less reactive than these other drugs, was withdrawn from the market in 1983 (Chen *et al.*, 2006; Regan *et al.*, 2010).

Neoantigens formed by binding of acyl glucuronides to protein might be the cause of rare cases of NSAID-induced immune hepatitis. Covalent adducts with proteins in the liver, kidneys, colon, small intestine, skeletal muscle, and bladder were detected in rats administered diflunisal, and in the liver, lungs, and spleen of rats administered diclofenac of UGT activity (Shipkova *et al.*, 2003). Covalent binding of acyl glucuronides to proteins can be selective, with diclofenac acyl glucuronide forming adducts with dipeptidyl peptidase in rat liver, and with aminopeptidase N and sucrase-isomaltase in rat intestine (Shipkova *et al.*, 2003). Human and rat liver UGTs are themselves targets of adducts formed by ketoprofen acyl glucuronide, which may cause nonspecific irreversible inhibition (Shipkova *et al.*, 2003). Both acyl glucuronides and acyl-CoA thioesters can transacylate proteins either directly or after their conversion to GSH adducts. Based on *in vitro* trapping studies with *N*-acetylcysteine (NAC) as the nucleophile, the reactivity of acyl-CoA thioesters is dependent on the substitution of the α -carbon and β -carbon of the xenobiotic (Grillo, 2011). The addition of methyl groups to the α -carbon and/or oxygen to the β -carbon decreases the reactivity of acyl-CoA thioesters just as it decreases the reactivity of acyl glucuronides. In terms of binding to NAC (an indicator of transacylation reactivity), acyl-CoA thioesters and their corresponding acyl-GSH thioesters can be orders of magnitude more reactive than acyl glucuronides, for which reason the formation of acyl-CoA thioesters may contribute to the hepatotoxicity of NSAIDs and other carboxylic acid-containing drugs (Grillo, 2011).

Knights *et al.* (2007) reviewed the ability of acyl-CoA conjugates of acidic drugs to cause mitochondrial toxicity by interruption of the mitochondrial β -oxidation of fatty acids, which is dependent on their conversion to fatty acyl-CoA thioesters. Xenobiotic-CoA conjugates that are resistant to hydrolysis and are not conjugated with amino acids (*eg*, valproic acid) can sequester the pool of mitochondrial CoA and disrupt fatty acid β -oxidation, which are key events in the hepatotoxicity of valproic acid. Valproic acid is metabolized in mitochondria (major pathway) and microsomes (where it is dehydrogenated to 4-ene-valproic acid by CYP2C9 [Fig. 6-48]). In mitochondria valproic acid is converted to an acyl-CoA thioester that in turn is converted to metabolites that resemble intermediates in the β -oxidation of fatty acids, as shown in Fig. 6-57. Valproic acid is present in mitochondria primarily in the form of its acyl-CoA thioester, which is too polar to diffuse out of the mitochondrion. Taken together, these studies suggest that the conversion of carboxylic acid-containing drugs to acyl-CoA thioesters can play an important role in cell toxicity by causing mitochondrial damage (by depleting CoA and disrupting fatty acid β -oxidation) or by binding covalently to proteins (either directly or following conversion to acyl-GSH thioesters) (Knights *et al.*, 2007; Grillo, 2011).

The intrinsic reactivity of acyl glucuronides and acyl-CoA thioesters is not the only factor that contributes to the toxicity of

carboxylic acid-containing drugs and metabolites. Extrinsic factors also influence the potential for toxicity, such as dose/exposure, disposition of the parent drug and its metabolites, hydrolysis of acyl glucuronides in the gut (or even in plasma), and reexposure to the aglycone via enterohepatic circulation, transport mechanisms for the efflux of acyl glucuronides from liver into bile or blood, and, perhaps most importantly, targets of these reactive species. Dose or daily body burden is a concern for many acidic drugs (*eg*, NSAIDs) because hundreds of milligrams—or even gram quantities—are consumed daily. The reactivity of these metabolites can be assessed with relatively simple *in vitro* techniques as described above. Intrinsic reactivity can be predicted, to some extent, with structural alerts; the substitution pattern of the α -carbon is particularly informative. Transport proteins also play a crucial role in the disposition of acidic drugs and their acyl glucuronides. MRP2 and MRP3 play critical roles in the efflux of acyl glucuronides into bile and blood, respectively. Shifts in the vectorial transport of these acyl glucuronides may dictate whether toxicity is limited to the cells in which they are formed or whether these reactive metabolites enter bile where they can cause damage to biliary endothelial cells or enter the systemic circulation where they can cause damage to other tissues or blood. Just as efflux transporters are crucial for transporting these anionic compounds into blood, uptake transporters (OATPs) are involved in tissue-mediated uptake of acyl glucuronides as well as active renal elimination. Expression patterns of certain transporters may predispose or preclude certain cell types to toxicities caused by acyl glucuronides. It should be noted that unlike acyl glucuronides, acyl-CoA thioester metabolites are not transporter substrates and do not leave the cell in which they are formed. This suggests that toxicities caused by acylation of proteins by acyl-CoA thioester metabolites are restricted to the cell where the metabolite is formed (*eg*, formed in the hepatocyte and causes hepatotoxicity). In the case of acyl glucuronides and acyl-CoA thioesters, the identity of the protein adducted may determine whether or not these acidic drugs are toxic.

Sulfonation

Many of the xenobiotics and endogenous substrates that undergo *O*-glucuronidation also undergo sulfonation, as illustrated in Fig. 6-35 for acetaminophen (Mulder, 1981; Paulson *et al.*, 1986). Sulfonation generally produces a highly water-soluble sulfuric acid ester. The reaction is catalyzed by sulfotransferases (SULTs), a large multigene family of enzymes found primarily in the liver, kidney, intestinal tract, lung, platelets, and brain. In mammals, there are two major classes of SULTs: (1) membrane-bound SULTs in the Golgi apparatus and (2) soluble SULTs in the cytoplasm (Gamage *et al.*, 2006). The membrane-bound SULTs are responsible for the sulfonation of glycosaminoglycans, proteins, and peptides such as cholecystokinin, factors V and VIII, α -2-glycoprotein, gastrin, and p-selective glycoprotein ligand-1, thereby modulating their structure and function. At least 5 different Golgi-resident *N*-acetylglucosamine 6-*O*-sulfotransferases have been identified in humans. They are important for many biological processes including cell-cell adhesion, axon function, T-cell response, cell proliferation, and modulation of viral and bacterial infection (reviewed by Grunwell and Bertozzi, 2002), but they have no activity toward xenobiotics (Wang and James, 2006). Brachymorphic mice are undersized because the defect in PAPS synthesis prevents the normal sulfonation of glycosaminoglycans and proteoglycans, such as heparin and chondroitin, which are important components of cartilage. These particular sulfonation reactions are catalyzed by membrane-bound SULTs, which are thought not to play a role in xenobiotic sulfonation. This section will focus on the cytosolic

SULTs, which are known for the sulfonation of various drugs, mutagens, flavonoids, and other xenobiotics, as well as endogenous substrates such as bile acids, thyroid hormones, catecholamine neurotransmitters, and steroids.

The cofactor for the sulfonation reaction is 3'-phosphoadenosine-5'-phosphosulfate (PAPS), the structure of which is shown in Fig. 6-51. The sulfonation of aliphatic alcohols and phenols, R-OH, proceeds as follows:

Sulfonation involves the transfer of sulfonate, not sulfate (ie, SO_3^- , not SO_4^-) from PAPS to the xenobiotic. SULTs are single α/β globular proteins that contain a PAPS-binding site which is present on a characteristic 5-stranded β -sheet along with the core of the catalytic site. The central β -sheet is surrounded by α -helices (Wang and James, 2006). The sulfonate donor PAPS is synthesized from inorganic sulfate (SO_4^{2-}) and ATP in a 2-step reaction. The first reaction is catalyzed by ATP sulfurylase, which converts ATP and SO_4^{2-} to adenosine-5'-phosphosulfate (APS) and pyrophosphate. The second reaction is catalyzed by APS kinase, which transfers a phosphate group from ATP to the 3'-position of APS. The major source of sulfate required for the synthesis of PAPS is derived from cysteine through a complex oxidation sequence. Because the concentration of free cysteine is limited, the cellular concentrations of PAPS (4–80 μM) are considerably lower than those of UDPGA (200–350 μM) and GSH (5–10 mM). This topic has been thoroughly reviewed, and is outside the scope of this chapter (Klaassen and Boles, 1997). The relatively low concentration of PAPS limits the capacity for xenobiotic sulfonation. In general, sulfonation is a high-affinity but low-capacity pathway of xenobiotic conjugation, whereas glucuronidation is a low-affinity but high-capacity pathway. Acetaminophen is one of the several xenobiotics that are substrates for both SULTs and UGTs (see Fig. 6-35). The relative amount of sulfonate and glucuronide conjugates of acetaminophen is dependent on dose. At low doses, acetaminophen sulfonate is the main conjugate formed due to the high affinity of SULTs. As the dose increases, the proportion of acetaminophen conjugated with sulfonate decreases, whereas the proportion conjugated with glucuronic acid increases. In some cases, even the absolute amount of xenobiotic conjugated with sulfonate can decrease at high doses apparently because of substrate inhibition of SULT.

Sulfonation is not limited to phenols and aliphatic alcohols (which are often the products of oxidative or hydrolytic biotransformation), although these represent the largest groups of substrates for SULTs. Certain aromatic amines, such as aniline and 2-aminonaphthalene, can undergo sulfonation to the corresponding sulfamates. The primary amines in cisapride and DPC423 can also be directly *N*-sulfonated. The *N*-oxide group in minoxidil and the *N*-hydroxy group in *N*-hydroxy-2-aminonaphthalene and hydroxy-2-acetylaminofluorene (NOH-AAF) can also be sulfonated. In all cases, the conjugation reaction involves nucleophilic attack of oxygen or nitrogen on the electrophilic sulfur atom in PAPS with cleavage of the phosphosulfate bond. Table 6-19 lists some examples of xenobiotics and endogenous compounds that are sulfonated without prior biotransformation by oxidative enzymes. An even greater number of xenobiotics are sulfonated after a hydroxyl group is exposed or introduced during oxidative or hydrolytic biotransformation.

Carboxylic acids can be conjugated with glucuronic acid but not with sulfonate. However, a number of carboxylic acids, such as benzoic acid, naphthoic acid, naphthylacetic acid, salicylic acid, and naproxen, are inhibitors of SULTs (Rao and Duffel, 1991). Pentachlorophenol and 2,6-dichloro-4-nitrophenol are potent SULT inhibitors because they bind to the enzyme but cannot initiate a nucleophilic attack on PAPS due to the presence of electron-withdrawing substituents in the *ortho*- and *para*-positions on the aromatic ring.

Sulfonate conjugates of xenobiotics are excreted mainly in urine. Those excreted in bile may be hydrolyzed by aryl sulfatases present in gut microflora, which contributes to the enterohepatic circulation of certain xenobiotics. Sulfatases are also present in the endoplasmic reticulum and lysosomes, where they primarily hydrolyze sulfonates of endogenous compounds presumably in a manner analogous to that described for microsomal β -glucuronidase (Dwivedi *et al.*, 1987) (see comments on egasyn in the section "Carboxylesterases"). Sulfonation facilitates the deiodination of T4 and triiodothyronine (T3) and can determine the rate of elimination of thyroid hormones in some species. Inhibition of SULTs can occur with exposure to drugs such as mefenamic acid, salicylic acid, clomiphene, danazol, environmental chemicals, such as hydroxylated PCBs, hydroxylated PAHs, pentachlorophenol, triclosan, and bisphenol A, and dietary constituents, such as catechins, colorants, phytoestrogens, and flavonoids. Adverse effects on human health can potentially result from SULT inhibition, such as the thyroid hormone disruption that occurs with exposure to hydroxylated PCBs (Wang and James, 2006). In contrast, given that some sulfonate conjugates are chemically reactive, inhibition of their formation may be protective. There are a few reports of drug–drug interactions due to SULT inhibition. It has been reported that the sulfonation rates of both acetaminophen and salicylamide are decreased when these drugs are coadministered, and dapsone and lamivudine have been found to decrease acetaminophen sulfonation (Wang and James, 2006). Coadministration of acetaminophen with ethinyl estradiol increases its AUC by up to 54% and decreases the AUC of ethinyl estradiol sulfate by ~40%, indicating that acetaminophen may directly inhibit one or more SULTs (Rogers *et al.*, 1987). Drug–drug interactions involving induction of SULT are detailed later in this section.

Sulfonation may represent a benign metabolic pathway compared with competing pathways that can lead to the activation of promutagens and procarcinogens. For instance, sulfonation of hydroquinones, phenols, and aminophenols can prevent or reduce the formation of reactive quinones, semiquinones, and quinoneimines. Sulfonation of aromatic amines such as 2-amino-3,8-dimethylimidazo-[4,5-f]quinoxaline (MeIQx), which leads to sulfamate formation, can compete with activation by *N*-O-acetylation or *N*-O-sulfonation (Wang and James, 2006).

Like glucuronide conjugates, some sulfonate conjugates are substrates for further biotransformation. For instance, the 7- and 4-sulfates of daidzein and genistein can be sulfonated by SULT1E1 to disulfates (Nakano *et al.*, 2004). Other examples include the oxidation of sulfonate conjugates of testosterone and estrogens. Dehydroepiandrosterone-3-sulfate is 16 α -hydroxylated by CYP3A7, the major CYP enzyme expressed in human fetal liver (Ingelman-Sundberg *et al.*, 1975; Kitada *et al.*, 1987; Ohmori *et al.*, 1998). CYP2C12, which is expressed in female but not male rats, catalyzes the oxidation of a steroid *di*-sulfate (namely, 5 α -androstane-3 α ,17 β -diol-3,17-disulfate) (Ryan *et al.*, 1984).

Multiple SULTs have been identified in all mammalian species examined. An international workshop approved the abbreviation "SULT" for sulfotransferase (although ST remains a common abbreviation) and developed a nomenclature system based on amino acid sequences (and, to some extent, function). The SULTs are arranged

Table 6-19

Properties of the Human Cytosolic Sulfotransferases (SULTs)

HUMAN SULT	POLYMORPHIC?*	TISSUE DISTRIBUTION	MAJOR SUBSTRATES†
SULT1A1	Yes *1-4	Liver (very high), platelets, placenta, adrenals, endometrium, colon, jejunum, leukocytes, brain (cerebellum, occipital and frontal lobes)	4-Nitrophenol , 4-ethylphenol, 4-cresol, 2-naphthol, other phenols, acetaminophen, minoxidil, <i>N</i> -hydroxy-PhIP, T2, T3, 17 β -estradiol (and other phenolic steroids), dopamine, benzylic alcohols, 2-nitropropane, aromatic amines, hydroxylamines, hydroxamic acids, apomorphine, troglitazone, genestein, epinephrine
SULT1A2	Yes *1-6	Liver, kidney, brain, GI tract, bladder tumors	4-Nitrophenol, <i>N</i> -hydroxy-2-acetylaminofluorene, 2-naphthol, various aromatic hydroxylamines and hydroxamic acids
SULT1A3	Yes *1-4	Jejunum and colon mucosa (very high), liver (low), platelets, placenta, brain (superior temporal gyrus, hippocampus, and temporal lobe), leukocytes, fetal liver	Dopamine , 4-nitrophenol, 1-hydroxymethylpyrene, norepinephrine, salbutamol, dobutamine, vanillin, albuterol
SULT1A4		Liver, pancreas, colon, brain‡	Not characterized. Likely similar to SULT1A3
SULT1B1		Colon (highest), liver, leukocytes, small intestine	4-Nitrophenol, T2, T3, <i>r</i> -T3, T4, dopamine, benzylic alcohols
SULT1C2	Yes *1-5	Fetal lung and kidney, kidney, stomach, thyroid gland	4-Nitrophenol, <i>N</i> -hydroxy-2-AAF, aromatic hydroxylamines, thyroid hormones
SULT1C4		Kidney, ovary, spinal cord, fetal kidney, fetal lung (highest)	4-Nitrophenol, <i>N</i> -hydroxy-2-AAF, 17 β -estrone, bisphenol-A, 4-octylphenol, nonylphenol, diethylstilbestrol, 1-hydroxymethylpyrene
SULT1E1		Liver (highest), endometrium, jejunum, adrenals, mammary epithelial cells, fetal liver, fetal lung, fetal kidney	17β-Estradiol , estrone, ethinyl estradiol, 17 β -estrone, equilenin, 2-hydroxy-estrone, 2-hydroxy-estradiol, 4-hydroxy-estrone, 4-hydroxy-estradiol, diethylstilbestrol, tamoxifen, thyroid hormones, 4-hydroxylonazolac, pregnenolone, dehydroepiandrosterone, 1-naphthol, naringenin
SULT2A1	Yes *1-3	Liver (highest), adrenals, ovaries, prostate, jejunum, kidney, brain	Dehydroepiandrosterone (DHEA) , 1-hydroxymethylpyrene, 6-hydroxymethylbenzo[<i>a</i>]pyrene, hycanthone, bile acids, pregnenolone, testosterone, androgens, estrone, 17 β -estradiol, other hydroxysteroids, budesonide
SULT2B1a (SULT2B_v1)		Placenta (highest), prostate, trachea, skin	Dehydroepiandrosterone, pregnenolone, oxysterols, other hydroxysteroids
SULT2B1b (SULT2B_v2)		Lung, spleen, thymus, kidney, prostate, ovary, adrenal gland, liver (low), GI tract (low)	Cholesterol , pregnenolone, dehydroepiandrosterone, other hydroxysteroids
SULT4A1a (SULT4A_v1)		Brain: cortex, globus pallidus, islands of Calleja, septum, thalamus, red nucleus, substantia nigra and pituitary	Endogenous: 4 unidentified compounds from mouse brain homogenate [§] Other: T3, T4, estrone, 4-nitrophenol, 2-naphthylamine, 2-naphthol**
SULT4A1b (SULT4A_v2)			
SULT6B1		Testis	

Substrates in bold are reported to be selective probe substrates for the SULT listed (Coughtrie and Fisher, 2003). Data from Coughtrie and Fisher (2003), Lindsay et al. (2008), Riches et al. (2009), Salman et al. (2009), Gamage et al. (2006), Wang and James (2006), and Blanchard et al. (2004).

*Data from Lindsay et al. (2008).

†T4 is thyroxine. T2 and T3 are diiodothyronine and triiodothyronine. *r*-T3 is reverse triiodothyronine.

‡Data from Bradley and Benner (2005).

§Sakakibara et al. (2002) reported that recombinant human SULT4A1 expressed in *E. coli* (and subsequently purified) sulfonated 4 distinct endogenous substances from mouse brain homogenate.

**Sakakibara et al. (2002) reported that recombinant human SULT4A1 expressed in *E. coli* (and subsequently purified) sulfonated these prototypical SULT substrates.

into gene families that share at least 45% amino acid sequence identity. The 9 gene families identified to date (vertebrate: SULT1-SULT6; insect: SULT101; and plant: SULT201-SULT202) are subdivided into subfamilies that are at least 60% identical (Blanchard *et al.*, 2004; Gamage *et al.*, 2006). For example, SULT1 is divided into 5 subfamilies designated SULT1A to SULT1E. Two SULTs that share more than 60% similarity are considered individual members of the same subfamily. For example, SULT1A1, SULT1A2, SULT1A3, and SULT1A4 are four individual members of the human SULT1A subfamily. In general, the first published sequence in a subfamily is designated as enzyme 1 and subsequent enzymes within that subfamily are assigned on the basis of percentage amino acid identity relative to the “1” enzyme (Blanchard *et al.*, 2004). Exceptions to this rule have been made to maintain historical use of a name (eg, SULT2A1). Variant forms with different amino acid sequences encoded by the same gene are designated by “vn” at the end. For instance, the SULTs initially referenced as SULT2B1a and SULT2B1b are now called SULT2B1_v1 and SULT2B1_v2. Although 9 SULT gene families have been identified, these have not been identified in all mammalian species. Currently, SULT1 and SULT2 are the only gene families subdivided into multiple subfamilies (5 in the case of SULT1 [SULT1A-1E]; two in the case of SULT2 [SULT2A and SULT2B]).

Most of the SULTs cloned belong to one of the two families, SULT1 and SULT2. These two families are functionally different; the SULT1 enzymes catalyze the sulfonation of phenols, isoflavones, the procarcinogen *N*-OH-2-acetylaminofluorene, endogenous compounds such as 17 β -estradiol (including its glucuronide conjugate; see the section “Glucuronidation and Formation of Acyl-CoA Thioesters”), and other steroids, iodothyronines, endogenous catecholamines, and eicosanoids. The SULT2 enzymes catalyze the sulfonation of the 3 β -hydroxy groups of steroids with unsaturated A rings, bile acids, benzylic alcohols of PAHs, and other primary and secondary alcohols. A SULT that catalyzes the sulfonation of heterocyclic amines such as 2-naphthylamine, desipramine, and aniline (to form sulfamates) has been cloned from rabbit and mouse (SULT3A1).

SULT4A1 has been identified in rat, mouse, and human. These enzymes are expressed in the cerebral cortex, cerebellum, pituitary, and brainstem and do not sulfonate typical SULT substrates (Blanchard *et al.*, 2004; Gamage *et al.*, 2006). These SULTs share ~97% amino acid sequence identity across species, which suggests that SULT4A1 likely serves a critical endogenous function. The SULT4A1 sequence has also been identified as SULT5A1, but the 4A1 nomenclature has been retained. A separate gene, SULT5A1, has been cloned from mouse, but no information on its function is available. SULT6A1 has been cloned from chicken liver, and the recombinant enzyme was found to sulfonate 17 β -estradiol and corticosterone (Blanchard *et al.*, 2004). SULT6B1 has been cloned from human testis (Freimuth *et al.*, 2004). SULT201 and 202 represent two families of plant SULTs. SULTT101A1 is an insect SULT cloned from *Spodoptera frugiperda* and converts retinol to anhydroretinol via a retinyl sulfate intermediate (Blanchard *et al.*, 2004). SULT101A also exhibits SULT activity toward ethanol, dopamine, vanillin, 4-nitrophenol, serotonin, and hydroxybenzylhydrazine (Blanchard *et al.*, 2004). Thirteen cytosolic SULTs have been cloned from rat, and they belong to the SULT1, SULT2, or SULT4 gene families. The individual rat enzymes are SULT1A1, 1B1, 1C1, 1C2, 1C3, 1D1, 1E1, 1E2, 2A1, 2A2, 2A3, 2A4, and 4A1.

Eleven genes encoding 13 cytosolic SULTs have been identified in humans, and they belong to the SULT1, SULT2, or SULT4 gene families. The individual human enzymes are listed in Table 6-19. Various SNPs have been reported in most of the SULT genes with rare single-base deletions in SULT1A2 and 4A1 (Glatt and Meinl,

2004a). With a few exceptions, the functional consequences of most of these polymorphisms remain unknown. Several of the human SULT genes have multiple initiation sites for transcription, which produces different mRNA transcripts. Consequently, in some cases, different versions of the same human SULT gene have been cloned several times. For example, there are 3 alternative first exons (exons 1a, 1b, and 1c) in the human SULT1A3 gene (none of which contains a coding region), and 5 SULT1A3 cDNAs have been cloned from various human tissues, each with a unique 5'-region (Nagata and Yamazoe, 2000).

Riches *et al.* (2009) quantified 5 of the major SULT enzymes (SULT1A1, 1B1, 1E1, 2A1, and 1A3) in human liver, small intestine, kidney, and lung cytosol with quantitative immunoblotting techniques. In human liver cytosol, the rank order of protein expression was as follows: SULT1A1 (53%) > 2A1 (27%) > 1B1 (14%) > 1E1 (6%) > 1A3 (0%). Kidney was similar to liver inasmuch as SULT1A1 was the major enzyme expressed (40%), followed by SULT1B1 (31%) > 1A3 (28%) > 2A1 (1%) > 1E1 (0%). In the small intestine, SULT1B1 and 1A3 were most highly expressed enzymes (36% and 31%, respectively), followed by SULT1A1 (19%) > 1E1 (8%) > 2A1 (6%). Lastly, SULT1E1 protein was most highly expressed in lung (40%), followed by SULT1A1 (20%) > 1A3 (19%) > 1B1 (12%) > 2A1 (9%). Further details on the tissue expression of SULTs are summarized in Table 6-19.

Historically, human liver cytosol was found to contain two phenol SULT activities (PST) that could be distinguished by their thermal stability; hence, they were known as TS-PST (*thermally stable*) and TL-PST (*thermally labile*) (Weinshilboum, 1992a; Weinshilboum *et al.*, 1997). It is now known that TS-PST actually reflects the activity of two SULTs, namely, SULT1A1 and SULT1A2, which share 93% identity, whereas TL-PST reflects the activity of SULT1A3 (and likely SULT1A4), which is 60% similar to both SULT1A1 and 2 (Gamage *et al.*, 2006). Hence, the 4 members of the SULT1A gene subfamily in human were represented functionally by TS-PST and TL-PST activity. SULT1A1 and SULT1A2 function as homodimers and heterodimers, and are coregulated. Although these two individual SULTs are not catalytically identical, they are sufficiently similar to consider them as the single activity traditionally known as TS-PST. Because of differences in their substrate specificity, SULT1A1/2 and 1A3 were also known as phenol-PST and monoamine-PST, respectively. SULT1A3 preferentially catalyzes the sulfonation of catecholamines such as dopamine, epinephrine, and levodopa, whereas SULT1A1 and 1A2 preferentially catalyze the sulfonation of simple phenols, such as phenol, 4-nitrophenol, minoxidil, and acetaminophen. SULT1A1 and 1A2 also catalyze the *N*-sulfonation of 2-aminonaphthalene. SULT1A1/2 and SULT1A3 can also be distinguished by differences in their sensitivity to the inhibitory effects of 2,6-dichloro-4-nitrophenol.

The expression of SULT1A1 and 1A2 in human liver is largely determined by genetic factors, which also determines the corresponding SULT activity in blood platelets. Inherited variation in platelet SULT1A1 and 1A2 largely reflects genetic polymorphisms in these enzymes. One allelic variant of SULT1A1 known as SULT1A1*2 (Arg₂₁₃ → His₂₁₃) is associated with decreased activity in platelets but not liver, and decreased thermal stability (Glatt and Meinl, 2004a). This particular genetic polymorphism is common in both Caucasians and Nigerians (with an allele frequency of 31% and 37%, respectively), and is correlated with interindividual variation in the sulfonation of acetaminophen. Low SULT1A1 and 1A2 activity predisposes individuals to diet-induced migraine headaches, possibly due to impaired sulfonation of unidentified phenolic compounds in the diet that cause such headaches. Interestingly, SULT1A1 has been implicated in the pharmacological effect of tamoxifen by sulfonation

of the 4-hydroxymetabolite, which was shown to be a potent inducer of apoptosis in certain breast cancer cell lines. Contrary to expectation, the lower activity SULT1A1*2 allele did not improve the efficacy of tamoxifen in breast cancer patients by decreasing clearance of 4-hydroxytamoxifen. It was the wild-type allele that, paradoxically, was correlated with improved outcomes with tamoxifen therapy (Nowell and Falany, 2006). A fourth member of the human SULT1A subfamily, SULT1A4, has been described, which appears to be a duplication of SULT1A3, and these two enzymes share >99% sequence identity (Bradley and Benner, 2005; Gamage *et al.*, 2006). The genes for both of these SULTs lie on chromosome 16p, which contains a segmental duplication that results in two nearly identical, transcriptionally active copies of SULT1A3 and SULT1A4. Each

copy shares exons with an adjacent copy of SULT1A1. Four nonsynonymous SNPs were reported for these genes, which show different enzyme activities (Gamage *et al.*, 2006).

Human SULT1B1, like the corresponding enzyme in other species, catalyzes the sulfonation of thyroid hormones, 2-naphthol, and dopamine. SULT1B1 levels in human liver cytosol vary widely, possibly due to polymorphisms (eg, Glu₁₈₆ → Gly₁₈₆ and Glu₂₀₄ → Asp₂₀₄) (Glatt and Meinel, 2004a). SULT1B1 is also expressed in human colon, small intestine, and blood leukocytes. Humans have two SULT1C enzymes (SULT1C2 and SULT1C4). Their function has not been determined, although the corresponding rat enzyme (SULT1C1) catalyzes the sulfonation of NOH-AAF (see Fig. 6-58). SULT1C2 is expressed at high levels in the thyroid, stomach, and

Figure 6-58. Role of sulfonation in the generation of tumorigenic metabolites (nitrenium or carbonium ions) of 2-acetylaminofluorene, safrole, and 7,12-dimethylbenz[a]anthracene (DMBA).

kidneys (Blanchard *et al.*, 2004). High levels of SULT1C4 are expressed in fetal liver and kidney, with hepatic levels declining in adulthood, but it is also present in adult ovary and brain.

Human SULT1E1 has been identified as a high-affinity estrogen SULT. SULT1A1 also catalyzes the sulfonation of estrogens, such as 17 β -estradiol, but it does so with a much lower affinity than does SULT1E1. The sulfonation of ethinyl estradiol in human hepatocytes is inducible by rifampin (Li *et al.*, 1999), which raises the possibility that SULT1E1 is an inducible enzyme. In addition to human liver, SULT1E1 is expressed in placenta, breast, brain, testes, adrenal glands, and uterine tissue. SULT1E1 has been studied in SULT1E1-deficient mice, and it was shown that these mice had spontaneous fetal loss caused by placental thrombosis, which was reversible by administration of antiestrogens (Gamage *et al.*, 2006).

SULT2A1 is the human alcohol SULT, long known as DHEA-ST (for its ability to sulfonate dehydroepiandrosterone [DHEA]). In addition to DHEA, substrates for SULT2A1 include steroid hormones, bile acids, and cholesterol. Furthermore, SULT2A1 converts several procarcinogens to electrophilic metabolites, including hydroxymethyl PAHs, NOH-AAF, and 1-hydroxysafrole, as shown in Fig. 6-58. The thermal stability of SULT2A1 is intermediate between that of the 4 phenol SULTs (SULT1A1/2 and 1A3/4), and the enzyme is resistant to the inhibitory effects of 2,6-dichloro-4-nitrophenol. In humans, SULT2A1 selectively catalyzes the *N*-sulfonation of quinolone drugs, such as ciprofloxacin, moxifloxacin, garenoxacin, and other amine drugs such as desipramine and metoclopramide (Senggunprai *et al.*, 2009). SULT2A1 is not expressed in blood platelets, but the activity of this enzyme has been measured in human liver cytosol. It is also expressed in adrenal cortex, brain, and intestine (Blanchard *et al.*, 2004). SULT2A1 is bimodally distributed, possibly due to a genetic polymorphism that apparently lies outside of the coding region, and perhaps outside of the SULT2A1 gene itself, with a high-activity group composed of ~25% of the population (Glatt and Meinel, 2004a). Several SULT2A1 SNPs have been identified, but the underlying basis for the high-activity group remains to be determined as these polymorphisms appear to be too rare to explain the bimodal distribution.

Human SULT2B1 is also a DHEA-sulfotransferase. It is expressed in placenta, prostate, and trachea. The SULT2B1 gene can be transcribed from one of the two exons, both of which contain coding sequences; hence, two forms of SULT2B1 (known as 2B1_v1 and 2B1_v2) with different N-terminal amino acid sequences can be transcribed by alternate splicing of precursor mRNA. This situation is analogous to the alternative splicing of multiple exons 1 in the UGT1 gene family (see Fig. 6-55). SULT2B1_v1 catalyzes the sulfonation of pregnenolone, and SULT2B1_v2 can catalyze the sulfonation of both pregnenolone and cholesterol (Blanchard *et al.*, 2004).

The SULT enzymes were previously categorized into 5 classes based on their catalytic activity. These 5 functional classes were: *arylsulfotransferase*, which sulfonates numerous phenolic xenobiotics; *alcohol SULT*, which sulfonates primary and secondary alcohols including nonaromatic hydroxysteroids (for which reason these enzymes are also known as hydroxysteroid SULTs); *estrogen SULT*, which sulfonates estrone and other aromatic hydroxysteroids; *tyrosine ester SULT*, which sulfonates tyrosine methyl ester and 2-cyanoethyl-*N*-hydroxythioacetamide; and *bile salt SULT*, which sulfonates conjugated and unconjugated bile acids. The *arylsulfotransferase* and *estrogen SULT* are composed largely of SULT1 enzymes, which catalyze the sulfonation of phenolic xenobiotics, catechols, and aromatic (phenolic) steroids. The *alcohol SULT* and *bile salt SULT* are composed largely of SULT2 enzymes,

which catalyze the sulfonation of a variety of primary and secondary alcohols, bile acids, and hydroxysteroids (such as DHEA).

In rats, SULT activity varies considerably with sex and age. In mature rats, phenol SULT activity (SULT1A activity) is higher in males, whereas alcohol SULT and bile acid SULT activities (SULT2 activities) are higher in females. Sex differences in the developmental expression of individual SULTs are the result of a complex interplay between gonadal, thyroidal, and pituitary hormones (particularly growth hormone), which similarly determine sex differences in CYP enzyme expression. However, compared with CYP enzymes, the SULTs are refractory or only marginally responsive to the enzyme-inducing effects of AhR and CAR activators such as 3-methylcholanthrene and phenobarbital, respectively, although one or more individual SULT2 enzymes are inducible by PXR agonists such as PCN. Likewise, SULT1A1, 2A1, or 2E1 expressed in Caco-2 cells are refractory to various PAHs, and 3-methylcholanthrene has no effect on SULT1A1 and 1A3 mRNA levels in primary human hepatocytes (Gamage *et al.*, 2006). From rodent studies, it is generally held that AhR agonists have suppressive effects on SULT regulation. 2-AAF, TCDD, 3-methylcholanthrene, and β -naphthoflavone markedly suppress SULT1A1 and 2A activities and mRNA levels in rat livers (Gamage *et al.*, 2006). In contrast, there is evidence that the rat liver hydroxysteroid SULTs (SULT2s) may be inducible by tamoxifen and estrogens (Gamage *et al.*, 2006). For mouse SULT2A2, a functional nuclear response element responsive for CAR has been reported (Gamage *et al.*, 2006). Human SULT2A1 has been reported to be regulated by FXR, PXR, VDR, and PPAR α , whereas SULT1A1, 2A1, and 2A9 genes in mice are regulated by CAR (Tirona and Kim, 2005; Gamage *et al.*, 2006). There are conflicting data regarding the influence of CAR ligands on SULT1A1 and 1A3. One study reports an 11-fold increase in SULT1A1 mRNA in primary human hepatocytes by the CAR ligand, CITCO, whereas another study could not reproduce these results for either SULT1A1 or 1A3 (Gamage *et al.*, 2006). The glucocorticoid dexamethasone has been reported to induce both murine and human SULT2A1 through PXR and GR activation (Gamage *et al.*, 2006). Human SULT2A1 mRNA and protein have also been reported to be induced by rifampin, vitamin D₃, phenobarbital, TCPOBOP, and the PPAR α -agonist, ciprofibrate (Runge-Morris and Kocarek, 2005).

Induction of SULTs by rifampin, on the other hand, may be clinically relevant. Rifampin (600 mg q.d.) has been reported to cause up to a 190% increase in the clearance of ethinyl estradiol (35 μ g q.d.) (Barditch-Crovo *et al.*, 1999). The interaction between ethinyl estradiol-containing oral contraceptives and antibiotics such as rifampin is often attributed to the induction of CYP3A4, which is the major CYP involved in the *oxidative* metabolism of ethinyl estradiol (eg, Ortho-Evra[®] prescribing information). Several lines of evidence suggest that induction of CYP3A4 is not the predominant mechanism by which rifampin increases the clearance of ethinyl estradiol. First, Li *et al.* (1999) reported that treatment of primary cultures of human hepatocytes with rifampin (33.3 μ M) caused up to a 3.3-fold increase in ethinyl estradiol 3-*O*-sulfate formation. Second, SULTs 1A1, 1A2, 1A3, 1E1, and 2A1 catalyze the 3-*O*-sulfonation of ethinyl estradiol with K_m values ranging from 6.7 to 4500 nM, nearer the pharmacologically relevant concentrations (Schrage *et al.*, 2004). Finally, it is known that ethinyl estradiol is predominantly excreted in bile and urine as the 3-sulfate and, to a lesser extent, the 3-glucuronide (Li *et al.*, 1999), which suggests that 3-sulfonation is the major pathway of ethinyl estradiol metabolism. Taken together, these data suggest that induction of SULTs can be clinically relevant at least for low-dose drugs that can be sulfonated with high affinity.

Extrapolation of animal data with regard to biotransformation by SULTs is confounded by the number of SULTs, the expression pattern of SULTs, and pronounced sexual dimorphisms in many rodents (Gamage *et al.*, 2006). For instance, expression of SULTs in humans is largely extrahepatic, whereas SULT expression in rodents is predominantly hepatic. For instance, based on RT-PCR measurements of mRNA levels in human tissues, SULT1A3 is expressed at the greatest level in the small intestine, 1B1 in the colon, 2B1 in the placenta, and 4A1 in the brain (Nishimura and Naito, 2006). Of the SULTs that have been characterized by RT-PCR in various human tissues, only SULT1A1, 1E1, and 2A1 are predominantly expressed in the liver (Nishimura and Naito, 2006).

Additionally, humans have 4 members of the SULT1A subfamily, whereas rodents have only one. In contrast, rats have 4 members of the SULT2A subfamily, whereas humans have only a single SULT2A gene. Human equivalents of mouse SULT3A1 and 5A1 have not yet been identified in humans (Gamage *et al.*, 2006). There are also significant differences between other mammalian species. For instance, SULT activity is low in pigs but high in cats. The high SULT activity in cats offsets their low capacity to conjugate xenobiotics with glucuronic acid.

In general, sulfonation is an effective means of decreasing the pharmacological and toxicological activity of xenobiotics. There are cases, however, in which sulfonation increases the toxicity of foreign chemicals because certain sulfonate conjugates are chemically unstable and degrade to form potent electrophilic species. As shown in Fig. 6-58, sulfonation plays an important role in the activation of aromatic amines, methyl-substituted PAHs, and safrole to tumorigenic metabolites. To exert its tumorigenic effect in rodents, safrole must be hydroxylated by CYP to 1'-hydroxysafrole, which is then sulfonated to the electrophilic and tumor-initiating metabolite, 1'-sulfooxysafrole (Boberg *et al.*, 1983). 1'-Hydroxysafrole is a more potent hepatotumorigen than safrole. Two lines of evidence support a major role for sulfonation in the hepatotumorigenic effect of 1'-hydroxysafrole. First, the hepatotumorigenic effect of 1'-hydroxysafrole can be inhibited by treating mice with the SULT inhibitor, pentachlorophenol. Second, the hepatotumorigenic effect of 1'-hydroxysafrole is markedly reduced in brachymorphic mice, which have a diminished capacity to sulfonate xenobiotics because of a genetic defect in PAPS synthesis. The sulfo-conjugates of benzylic and allylic alcohols, aromatic hydroxylamines, and hydroxamic acids (including those in cooked meat) are short-lived electrophiles capable of reacting with nucleophilic substances including proteins and DNA (Wang and James, 2006). Sulfonation can also convert procarcinogens and promutagens to electrophilic nitrenium or carbocation intermediates such as NOH-AAF, 1-hydroxymethylpyrene (1-HMP), 1'-hydroxysafrole, and the cooked food mutagen *N*-hydroxy-2-amino-1-methyl-6-phenylimidazo(4,5-*b*)pyridine (*N*-OH-PhIP) (Wang and James, 2006). The initial metabolite in 2-AAF activation is the hydroxamic acid formed by CYP1A2. Under acidic conditions (such as in urine), hydroxamic acids can lose water to form reactive nitrenium ions. This pathway is thought to contribute to the renal toxicity of phenacetin (Testa and Krämer, 2008, 2010).

Some drugs must be converted to a sulfonate conjugate to exert their desired effect, including triamterene, cicletanine, and minoxidil (Wang and James, 2006). Sulfonation (as well as glucuronidation) converts morphine to more potent analgesics than the parent, with morphine-6-sulfate being 30 times more potent and with morphine-6-glucuronide being 45 to 800 times more potent than morphine itself in rats (Wang and James, 2006). Similarly, several sulfonated steroids such as pregnenolone sulfate and DHEA sulfate interact directly with neurotransmitter receptors. It has been found

that pregnenolone sulfate and DHEA sulfate enhance memory in mice. Prevention of hydrolysis of these sulfates by the steroid sulfatase inhibitor (*para*-*O*-sulfamoyl)-*N*-tetradecanoyl tyramine increases the memory enhancement caused by DHEA sulfate in rats, which suggests there is an important role of these sulfates in the central nervous system (Wang and James, 2006).

Polymorphisms with consequences for the bioactivation of xenobiotics have been reported. For instance, the human SULT1A*Arg (*1) allelozyme expressed in *S. typhimurium* is 12- to 350-fold more active in the sulfonation of 2-acetylaminobenzene, 2-nitropropoane, 2,4-dinitrobenzylalcohol, (-)-1-(α -hydroxyethyl) pyrene, and 1-hydroxymethylpyrene to mutagens than are cells expressing SULT1A1*His (Gamage *et al.*, 2006). Enantioselective sulfonation of promutagens has been reported, as in the case of 1-(α -hydroxyethyl) pyrene, for which SULT2A1 exhibits a 15-fold preference for the (+)-enantiomer, and SULT1E1 exhibits a 160-fold preference for the (-)-enantiomer (Gamage *et al.*, 2006).

Methylation

Methylation is a common but generally minor pathway of xenobiotic biotransformation. It differs from most other conjugation reactions because it often decreases the water solubility of xenobiotics and masks functional groups that might otherwise be metabolized by other conjugating enzymes. One exception to this rule is the *N*-methylation of pyridine-containing xenobiotics, such as nicotine, which produces quaternary ammonium ions that are water-soluble and readily excreted. Another exception is the *S*-methylation of thioethers to form positively charged sulfonium ions, a reaction catalyzed by thioether methyltransferase (TEMT), which has only been identified in mice (Weinshilboum *et al.*, 1999). The cofactor for methylation is *S*-adenosylmethionine (SAM), the structure of which is shown in Fig. 6-51. The methyl group bound to the sulfonium ion in SAM has the characteristics of a carbonium ion and is transferred to xenobiotics and endogenous substrates by nucleophilic attack from an electron-rich heteroatom (*O*, *N*, or *S*). Consequently, the functional groups involved in methylation reactions are phenols, catechols, aliphatic and aromatic amines, *N*-heterocyclics, and sulfhydryl-containing compounds. The conversion of benzo[*a*]pyrene (B[*a*]P) to 6-methylbenzo[*a*]pyrene is a rare example of *C*-methylation. Another reaction that appears to involve *C*-methylation, the conversion of cocaine to ethylcocaine, is actually a transesterification reaction catalyzed by CES1, as shown in Fig. 6-5. Metals can also be methylated. Both inorganic mercury and arsenic can be dimethylated, and inorganic selenium can be trimethylated. The selenium atom in ebselen is methylated following the ring opening of this anti-inflammatory drug. Some examples of xenobiotics and endogenous substrates that undergo *O*-, *N*-, or *S*-methylation are shown in Fig. 6-59. During these methylation reactions, SAM is converted to *S*-adenosyl-L-homocysteine (SAH). This section will cover the following methyltransferases: arsenic (III) methyltransferase (AS3MT), catechol-*O*-methyltransferase (COMT), glycine *N*-methyltransferase (GNMT), histamine *N*-methyltransferase (HNMT), indolethylamine *N*-methyltransferase (INMT), nicotinamide *N*-methyltransferase (NNMT), phenylethanolamine *N*-methyltransferase (PNMT), phenol *O*-methyltransferase (POMT) (thiol methyltransferase [TMT]), TEMT, and thiopurine methyltransferase (TPMT). Other methyltransferases that have been implicated as drug-metabolizing enzymes include guanidinoacetate *N*-methyltransferase (GAMT) and phosphatidylethanolamine *N*-methyltransferase (PEMT) (Nishimura and Naito, 2006).

Figure 6-59. Examples of compounds that undergo O-, N-, or S-methylation.

The O-methylation of phenols and catechols is catalyzed by two different enzymes known as COMT and the enzyme historically termed POMT (Weinshilboum, 1989, 1992b). POMT is a microsomal enzyme that methylates phenols but not catechols, and COMT is both a cytosolic and microsomal enzyme with the converse substrate specificity, that is, an absolute requirement for catechol substrates (Weinshilboum, 2006). COMT plays a greater role in the biotransformation of catechols than POMT plays in the biotransformation of phenols. It should be noted that there is strong evidence to suggest that the membrane-bound POMT is the same enzyme as TMT (Weinshilboum, 2006). COMT was originally described as a cytosolic, Mg^{2+} -requiring, monomeric enzyme (Mr 25,000). However, in rats and humans, the enzyme is encoded by the COMT gene (on chromosome 22 in humans) with two different promoters and transcription initiation sites. Transcription at one site produces a cytosolic form of COMT, whereas transcription from the other site produces a membrane-bound form by adding 50 hydrophobic amino acids to the N-terminal of the microsomal COMT, which targets this form to the endoplasmic reticulum (Weinshilboum *et al.*, 1999; Weinshilboum, 2006). The microsomal COMT is expressed at high levels in the brain and lymphocytes (Weinshilboum, 2006). The cytosolic form of COMT is present in virtually all tissues, including erythrocytes, but the highest concentrations are found in liver and kidney. The membrane-bound form is more highly expressed in brain.

Substrates for COMT include several catecholamine neurotransmitters, such as epinephrine, norepinephrine, and dopamine;

and catechol drugs, such as the anti-Parkinson disease agent levodopa (L-3,4-dihydroxyphenylalanine) and the antihypertensive drug methyldopa (α -methyl-3,4-dihydroxyphenylalanine). Catechol estrogens, which are formed by 2- or 4-hydroxylation of the steroid A-ring, are substrates for COMT, as are drugs that are converted to catechols by two consecutive hydroxylation reactions (as in the case of phenobarbital, duloxetine, and diclofenac), by ring opening of a phenyl methylenedioxy (benzodioxole) group (as in the case of stiripentol and 3,4-methylenedioxymethamphetamine), or by hydrolysis of vicinal esters (as in the case of ibopamine). Formation of catechol estrogens, particularly 4-hydroxyestradiol, has been suggested to play an important role in estrogen-induced tumor formation in hamster kidney, rat pituitary, and mouse uterus (Zhu and Liehr, 1993) (see the section "CYP1B1"). These tissues contain high levels of epinephrine or dopamine, which inhibit the O-methylation of 4-hydroxyestradiol by COMT. Nontarget tissues do not contain high levels of catecholamines, which suggests that 4-hydroxyestradiol induces tumor formation in those tissues that fail to methylate and detoxify this catechol estrogen. These observations in animals are especially intriguing in view of subsequent epidemiological evidence demonstrating that low COMT activity appears to increase the risk of breast cancer, with odds ratios ranging from 1.7 to 3.0 (Weinshilboum, 2006).

In the 1970s, when COMT levels in erythrocytes (predominantly the cytosolic form) were measured in human subjects, it was apparent that there was a subpopulation that displayed low levels of this enzyme. Segregation analysis indicated that erythrocyte COMT

activity was an autosomal codominant trait, and that erythrocyte levels correlated with relative COMT levels in liver and lymphocyte cytosol (Weinshilboum, 2006). It was subsequently found that COMT is encoded by a single gene with alleles for a low-activity form (COMT^L) and high-activity form (COMT^H) (Weinshilboum, 1989, 1992b, 2006; Weinshilboum *et al.*, 1999). This polymorphism results from a single G → A transition in exon 4 that results in the substitution Val₁₀₈Met in cytosolic COMT and Val₁₅₈Met in microsomal COMT (Weinshilboum *et al.*, 1999; Weinshilboum, 2006). The presence of methionine at position 108 in the cytosolic enzyme not only decreases the catalytic activity of COMT but also decreases the thermal stability of the enzyme, which has long been used to differentiate COMT^L (thermolabile) from COMT^H (thermostable). In Caucasians, these allelic variants are expressed with equal frequency, so that 25% of the population is homozygous for either the low- or high-activity enzyme, and 50% is heterozygous and has intermediate COMT activity. COMT activity is generally higher in Asians and African Americans due to a higher frequency of the COMT^H allele (~75% for Asians and African Americans compared with ~50% for Caucasians; McLeod *et al.*, 1994). Subsequent resequencing of the COMT gene has revealed numerous SNPs, with at least 8 that occur with a frequency >10% in Caucasians, and 11 such SNPs in African Americans. Several of these SNPs are found in the intronic regions. A list of current COMT (and many other) alleles can be found at <http://alfred.med.yale.edu/alfred/index.asp>.

The genetically determined levels of COMT in erythrocytes correlate with individual differences in the proportion of levodopa converted to 3-*O*-methyldopa and the proportion of methyldopa converted to its 3-*O*-methyl metabolite. *O*-Methylation is normally a minor pathway of levodopa biotransformation, but 3-*O*-methyldopa is the major metabolite when levodopa is administered with a dopa decarboxylase inhibitor, such as carbidopa or benserazide, which is common clinical practice. High COMT activity, resulting in extensive *O*-methylation of levodopa to 3-*O*-methyldopa, has been associated with poor therapeutic management of Parkinson disease and an increased incidence of drug-induced toxicity (dyskinesia). A large number of epidemiological studies have been performed to examine the effects of the COMT Val_{108/158}Met polymorphism, and there is no evidence that the genetic polymorphism in COMT represents a risk modifier for the development of Parkinson disease (Weinshilboum *et al.*, 1999). However, Egan *et al.* (2001) have demonstrated that COMT genotype was related in an allele-dosage manner to cognitive performance, with individuals homozygous for Met₁₀₈ (COMT^L phenotype) demonstrating increased executive cognition, as measured by the Wisconsin Card Sorting Test. The impact of the Met₁₀₈ allele was attributed to decreased dopamine catabolism in the prefrontal cortex, which results in enhanced neuronal function. Conversely, those individuals who are homozygous for Val₁₀₈ (COMT^H phenotype) appear to have decreased executive cognition, and may be at a slightly increased risk of developing schizophrenia (Egan *et al.*, 2001).

Several *N*-methyltransferases have been described in humans and other mammals, including PNMT, which catalyzes the *N*-methylation of the neurotransmitter norepinephrine to form epinephrine; HNMT, which specifically methylates the imidazole ring of histamine and closely related compounds (Fig. 6-59); and NNMT, which methylates compounds containing a pyridine ring, such as nicotinamide, or an indole ring, such as tryptophan and serotonin (Weinshilboum, 1989, 1992b; Weinshilboum *et al.*, 1999). PNMT is a cytosolic enzyme expressed at high levels in adrenal medullary chromaffin cells, and in neurons of the medulla oblongata, hypothalamus, as well as in sensory nuclei of the vagus nerve and the retina, and is not thought to play a significant role

in the biotransformation of xenobiotics (Ji *et al.*, 2005; Testa and Krämer, 2008, 2010).

HNMT is a cytosolic enzyme (Mr 33,000) that is highly expressed in kidney, liver, colon, prostate, ovary, and spinal cord cells (Horton *et al.*, 2005). Its activity (which can be measured in erythrocytes) varies 6-fold among individuals due to a genetic polymorphism (C → T) that results in a point mutation, namely, Thr₁₁₅Ile. The latter allele (Ile₁₁₅) is quite common in Caucasians and Han Chinese (10% frequency) and encodes a variant of HNMT with decreased catalytic activity and thermal stability. HNMT may influence efficacy of some drugs by a mechanism that is not yet fully understood. For instance, individuals who are heterozygous for the Ile₁₁₅ allele have been found to exhibit significantly decreased methylprednisolone-induced cortisol suppression relative to (Thr₁₁₅)-homozygous individuals (Hon *et al.*, 2006). Several other polymorphisms in the noncoding region of the HNMT gene have also been identified. HNMT can be inhibited by several antihistamines, quinacrine, amodiaquine, metoprine, and tacrine (Horton *et al.*, 2005).

NNMT is a monomeric, cytosolic enzyme (Mr ~30,000) that appears to be a member of a family of methyltransferases that includes PNMT and TEMT (the thioether *S*-methyltransferase present in mouse lung). It catalyzes the *N*-methylation of nicotinamide and structurally related pyridine compounds (including pyridine itself) to form positively charged pyridinium ions. Nicotinic acid (niacin), a commonly used lipid-lowering agent, is converted to nicotinamide *in vivo*, which is then methylated by NNMT (or it is incorporated into nicotinamide adenine dinucleotide [NAD]). In contrast to many other methyltransferases, NNMT is not expressed in erythrocytes.

NNMT activity in human liver, like HNMT activity in erythrocytes, varies considerably from one individual to the next, and has a trimodal distribution dependent on variations in mRNA and protein levels, and up to 25% of the general population has high NNMT levels (Souto *et al.*, 2005; Williams *et al.*, 2005). It is not known to what extent genetic polymorphisms account for this variation. However, 10 SNPs in the untranslated regions of the gene have been detected in a Spanish population (Souto *et al.*, 2005). A genome-wide scan for genes associated with plasma homocysteine levels determined that there was a statistically significant association with the NNMT gene, and, moreover, that 1 SNP (dbSNP ID#: rs694539) has a greater statistically significant association with homocysteine levels ($P = .017$) (Souto *et al.*, 2005). Homocysteine plasma levels are an independent intermediate risk marker for osteoporotic fractures, congestive heart failure, venous thrombosis, myocardial infarction, stroke, and Alzheimer disease (Souto *et al.*, 2005). In humans, the only source of homocysteine is from the demethylation of methionine in a multistep pathway that involves SAM-dependent methyltransferases to form *S*-adenosylhomocysteine, the immediate precursor to homocysteine. Taken together, these data suggest that high methyltransferase activity could contribute to hyperhomocysteinemia. Of the many SAM-dependent methyltransferase genes examined for an association with homocysteine levels, only NNMT (which is highly expressed in the liver) was found to show a significant association (Souto *et al.*, 2005). NNMT is reported to be expressed in the brain and has been implicated as a component of the etiology of idiopathic Parkinson disease because it can convert 4-phenylpyridine to MPP⁺, which is known to cause Parkinson disease symptoms due to its toxic effect on neuronal mitochondria (see the section "Amine Oxidases" and Fig. 6-29) (Williams *et al.*, 2005).

There are numerous other human *N*-methyltransferases (as well as *O*-, *S*-, and *C*-methyltransferases) that appear to play

relatively specific roles in the methylation of endogenous compounds, and most have not been well characterized with regard to their capability to methylate xenobiotics (there are at least 39 SAM-dependent methyltransferases in humans) (Souto *et al.*, 2005). For instance, INMT catalyzes the *N*-methylation of tryptamine and structurally related compounds (Thompson *et al.*, 1999). Other such enzymes that were initially thought to play a role only in the *N*-methylation of endogenous compounds were later found to play a role, albeit a minor one, in the *N*-methylation of one or more xenobiotics. Amine *N*-methyltransferase (AMNT, also called arylamine *N*-methyltransferase or nicotine *N*-methyltransferase), which is highly expressed in human thyroid and is also found in adrenal gland and lung, exhibits some activity toward tryptamine and has been also found to preferentially methylate the pyridine nitrogen of *R*-nicotine, which gives rise to nicotine isomethonium ions (Hukkanen *et al.*, 2005). GNMT is thought to play an important role in the regulation of methyl group metabolism in the liver and pancreas through regulation of the ratio between *S*-adenosyl-L-methionine and SAH. Rat data show that the tetrameric form of the GNMT has catalytic activity, and the dimeric form binds PAHs. There is also evidence that the dimeric form of human GNMT sequesters B[a]P, and thereby decreases its cytotoxic effects (Chen *et al.*, 2004b; Lee *et al.*, 2006).

The system that is used to classify human *N*-methyltransferases may not be appropriate for other species. In guinea pigs, for example, both nicotine and histamine are methylated by a common *N*-methyltransferase. Guinea pigs have an unusually high capacity to methylate histamine and xenobiotics. The major route of nicotine biotransformation in the guinea pig is methylation, although *R*-nicotine is preferentially methylated over its *S*-enantiomer (Cundy *et al.*, 1985). Guinea pigs also methylate the imidazole ring of cimetidine.

S-Methylation is an important pathway in the biotransformation of sulfhydryl-containing xenobiotics, such as the antihypertensive drug captopril, the antirheumatic agent *D*-penicillamine, the antineoplastic and immunosuppressive drugs 6-mercaptopurine, 6-thioguanine, and azathioprine, metabolites of the alcohol deterrent disulfiram, and the deacetylated metabolite of the antidiuretic, spironolactone. In humans, *S*-methylation is catalyzed by at least 2 enzymes, TPMT and TMT (which may be the same enzyme as POMT).

TPMT is a cytoplasmic enzyme that preferentially methylates aromatic and heterocyclic compounds such as the thiopurine drugs 6-mercaptopurine, 6-thioguanine, and azathioprine. TMT is a microsomal enzyme that preferentially methylates aliphatic sulfhydryl compounds such as captopril, *D*-penicillamine, and disulfiram derivatives. It has also been found to methylate the heterocyclic thiol-containing leaving groups of some cephalosporins (Wood *et al.*, 2002), the thiazolidinedione drug, MK-0767, a dual α/γ PPAR agonist (Karanam *et al.*, 2004), dithiothreitol (Weinshilboum, 2006), and some thiofuran flavoring agents (Lake *et al.*, 2003). Although a gene that encodes TMT has not yet been definitively identified, there is strong evidence to suggest that the membrane-bound POMT is the same enzyme as TMT, which means that TMT could also catalyze the *O*-methylation of phenols (Weinshilboum, 2006).

Both TMT and TPMT are present in erythrocytes at levels that reflect the expression of TPMT and TMT in liver and other tissues. Although TPMT and TMT are independently regulated, their expression in erythrocytes is largely determined by genetic factors. TPMT is encoded by a single gene with alleles for a low-activity form (TPMT^L) and for a high-activity form (TPMT^H). The allele frequencies of TPMT^L and TPMT^H are 0.06 and 0.94, respectively,

which produces a trimodal distribution of TPMT activity with low, intermediate, and high activity expressed in 0.3%, 11.1%, and 88.6% of Caucasians, respectively. At least 28 separate genetic polymorphisms have been identified and most are associated with low TPMT activity, with the *2, *3A, and *3C alleles accounting for greater than 95% of the TPMT^L phenotype (Weinshilboum, 2006; Ujii *et al.*, 2008; Wang *et al.*, 2010a). In Caucasians, the allele that is most commonly associated with the TPMT^L phenotype is TPMT*3A (5%), which contains two nonsynonymous SNPs: Ala₁₅₄Thr and Tyr₂₄₀Cys (Wood *et al.*, 2006). These amino acid changes (and those in the TPMT*3B and *3C variants) lead to aggregation and rapid degradation of expressed TPMT by a ubiquitin/proteasome-dependent mechanism (Wang *et al.*, 2005). Another variant, TPMT*4, results in alternative TPMT mRNA splicing and reduced enzyme expression, leading to low TPMT activity in individuals carrying this allele (Wang *et al.*, 2010a).

Cancer patients with low TPMT activity are at increased risk for thiopurine-induced myelotoxicity, in contrast to the potential need for higher-than-normal doses to achieve therapeutic levels of thiopurines in patients with high TPMT activity (Weinshilboum, 1989, 1992b). The thiopurine drugs metabolized by TPMT have a relatively narrow therapeutic index, and are used to treat life-threatening illnesses such as acute lymphoblastic leukemia or organ-transplant patients. The thiopurines are also oxidized by xanthine oxidoreductase (XOR), but since there is extensive variation in TPMT activity and XOR is not present in hematopoietic tissues, TPMT activity in these tissues is more important in the avoidance of life-threatening myelosuppression at standard doses (Weinshilboum, 2006). Phenotyping for the TPMT genetic polymorphism represents one of the first examples in which testing for a genetic variant has entered standard clinical practice (Weinshilboum *et al.*, 1999). The clinical relevance of TPMT polymorphisms is reflected by the inclusion of TPMT as a "valid biomarker" for pharmacogenomics, along with CYP2D6 polymorphisms, in the FDA's 2005 "Guidance for Pharmacogenomic Data Submission." TPMT can be inhibited by benzoic acid derivatives, which also complicates therapy with drugs that are metabolized by TPMT. Patients with inflammatory bowel disorders such as Crohn disease are often treated with thiopurine drugs, which are metabolized by TPMT, and with sulfasalazine or olsalazine, which are potent TPMT inhibitors. The combination of these drugs can lead to thiopurine-induced myelosuppression.

A genetic polymorphism for TMT also has been described, but its pharmacological and toxicological significance remains to be determined. The molecular basis for the polymorphism has not been determined, but studies have shown that 98% of the 5-fold individual variation in erythrocyte TMT activity is due to inheritance, with an allele for high TMT activity having a frequency of 0.12. TMT is relatively specific for aliphatic sulfhydryl compounds such as 2-mercaptoethanol, captopril, *D*-penicillamine, and NAC. It also rapidly methylates a dihydro metabolite of ziprasidone that is formed by AO as shown in Fig. 6-4 (Obach *et al.*, 2005). TMT is present at high levels in the colonic mucosa and is also expressed in liver microsomes and erythrocyte membranes. It is not inhibited by benzoic acid derivatives, but it is inhibited by the CYP inhibitor proadifen (aka SKE-525A) (Weinshilboum *et al.*, 1999).

Some of the hydrogen sulfide produced by anaerobic bacteria in the intestinal tract is converted by *S*-methyltransferases to methane thiol and then to dimethylsulfide. Another source of substrates for *S*-methyltransferases are the thioethers of GSH conjugates. GSH conjugates are hydrolyzed to cysteine conjugates, which can either be acetylated to form mercapturic acids or cleaved by cysteine-conjugate β -lyase (CCBL1). This β -lyase pathway converts the cysteine

conjugate to pyruvate, ammonia, and a sulfhydryl-containing xenobiotic, which is a potential substrate for *S*-methylation.

Methylation can also lead to increased toxicity. AS3MT is a methyltransferase (previously called Cyt19) that methylates inorganic arsenic to form methylarsonic and dimethylarsonic acids, which are more cytotoxic and genotoxic than arsenate and arsenite (Wood *et al.*, 2006). As many as 27 polymorphisms have been identified in this gene, with 2 rare alleles that cause markedly decreased activity and immunoreactive protein levels, and one frequent allele (ie, ~10% in both African Americans and Caucasians) that causes increased activity and immunoreactive protein levels (Wood *et al.*, 2006). Up to 1% of African Americans and Caucasians would be expected to be homozygous for the allele that encodes the high-activity AS3MT, and this may potentially lead to increased arsenic toxicity in such individuals.

Acetylation

N-Acetylation is a major route of biotransformation for xenobiotics containing an aromatic amine (R-NH₂) or a hydrazine group (R-NH-NH₂), which are converted to aromatic amides (R-NH-COCH₃) and hydrazides (R-NH-NH-COCH₃), respectively (Evans, 1992). Xenobiotics containing primary aliphatic amines are rarely substrates for *N*-acetylation, a notable exception being cysteine conjugates, which are formed from GSH conjugates and converted to mercapturic acids by *N*-acetylation in the kidney (see the section “Glutathione Conjugation”). In rare cases, *N*-acetylation can occur on aliphatic basic amino groups as in the cases of the antibacterial agent trovafloxacin and the primary metabolite of the β -adrenoreceptor blocker propranolol (Testa and Krämer, 2008, 2010). In a few cases, the *N*-acetylation of aliphatic acidic amine groups (such as a sulfonamide) has also been documented, an example of which is the anticonvulsant agent zonisamide (Testa and Krämer, 2008, 2010). Like methylation, *N*-acetylation masks an amine with a nonionizable group, so that many *N*-acetylated metabolites are less water-soluble than the parent compound. An exception is the *N*-acetylation of the acidic amine (the sulfonamide) in zonisamide; in this case *N*-acetylation increases ionization (by lowering the pK_a from ~10 to ~5) and, hence, its water solubility. *N*-Acetylation of isoniazid also increases its water solubility and facilitates its urinary excretion.

The *N*-acetylation of xenobiotics is catalyzed by *N*-acetyltransferases (NATs) and requires the cofactor acetyl coenzyme A (acetyl-CoA), the structure of which is shown in Fig. 6-51. The reaction occurs in 2 sequential steps according to a *ping-pong Bi-Bi* mechanism (Hein, 1988). In the first step, the acetyl group from acetyl-CoA is transferred to a cysteine residue in the NAT active site with release of CoA (E-SH + CoA-SCOCH₃ → E-S-COCH₃ + CoA-SH). In the second step, the acetyl group is transferred from the acylated enzyme to the amino group of the substrate with regeneration of the enzyme. For strongly basic amines, the rate of *N*-acetylation is determined by the first step (acetylation of the enzyme), whereas the rate of *N*-acetylation of weakly basic amines is determined by the second step (transfer of the acetyl group from the acylated enzyme to the acceptor amine). In certain cases (discussed below), NATs can catalyze the *O*-acetylation of xenobiotics.

NATs are cytosolic enzymes found in liver and many other tissues of most mammalian species, with the notable exception of the dog, fox, and musk shrew (*Suncus marinus*) which are unable to acetylate xenobiotics (a notable exception being the ability of dogs to *N*-acetylate cyanamide, which contains an acidic amine group) (Nakura *et al.*, 1995; Trepanier *et al.*, 1997; Sim *et al.*, 2008; Testa and Krämer, 2008, 2010). In contrast to

other xenobiotic-biotransforming enzymes, the number of NATs known to play a role in xenobiotic metabolism is limited (Vatsis *et al.*, 1995; Boukouvala and Fakis, 2005). NAT activities are distinguishable from other NATs such as those involved in melatonin synthesis and serotonin metabolism (arylalkylamine NATs) but are indistinguishable from the group of bacterial enzymes termed *N*-hydroxyarylamine *O*-acetyltransferases (Boukouvala and Fakis, 2005). Rabbits and hamsters express only 2 NAT enzymes, known as NAT1 and NAT2, whereas mice and rats express 3 enzymes, namely, NAT1, NAT2, and NAT3. The Human Genome Organisation (HUGO) Gene Nomenclature Committee (<http://www.gene.ucl.ac.uk/nomenclature>) has designated NAT as the official symbol for arylamine *N*-acetyltransferases. The two well-known and characterized xenobiotic-acetyating human enzymes are NAT1 and NAT2, which are encoded by two highly polymorphic genes located on chromosome 8. Other HUGO-approved human NAT gene symbols include NAT6, NAT8 to 10, NAT14, and NAT16, located on other chromosomes. The activities and expression pattern of these enzymes have not yet been definitively characterized, although some of these genes have been associated with atopic dermatitis or psoriasis (NAT9) and nasopharyngeal cancer (NAT6) (Helms *et al.*, 2003; Bowcock and Cookson, 2004; Duh *et al.*, 2004; Yamada and Ymamoto, 2005; Morar *et al.*, 2006). Individual NATs and their allelic variants were named in the order of their description in the literature, which makes for a somewhat confusing nomenclature system (Vatsis *et al.*, 1995). For example, in humans, the “wild-type” NAT1 and NAT2 alleles are designated NAT1*4 and NAT2*4, respectively, because they are the most common alleles in some but not all ethnic groups (Hein, 2006). For NAT enzymes, the term “wild type” may be somewhat arbitrary because it depends on ethnicity. The official Web site for maintaining and updating NAT allele nomenclature is <http://www.louisville.edu/medschool/pharmacology/NAT.html>. The frequency of some SNPs and alleles in various ethnic groups is available online from the National Cancer Institute’s SNP500Cancer database (<http://snp500cancer.nci.nih.gov>).

In each species examined, NAT1 and NAT2 are closely related proteins (79%–95% identical in amino acid sequence) with an active-site cysteine residue (Cys₆₈) in the N-terminal region (Grant *et al.*, 1992; Vatsis *et al.*, 1995). In addition to the active-site cysteine residue, the presence of a histidine residue (His₁₀₇) and an aspartate residue (Asp₁₂₂) are required for activity, forming a catalytic triad necessary for the transfer of an acetyl group from acetyl-CoA to the substrate (Sandy *et al.*, 2005; Sim *et al.*, 2008). Human NAT1 and NAT2 genes are composed of intronless open reading frames of 870 bp on the same chromosome with a NAT pseudogene (NATP1) between them, and encode proteins of 290 amino acids that share 87% homology in the coding region (Boukouvala and Fakis, 2005; Hein, 2006). In spite of this apparently simple structure, NAT genes are fairly complex. For instance, comparisons of genomic and cDNA clones of the human NAT2 gene performed in the early 1990s revealed that the 5′ untranslated region is contained in a “noncoding exon,” 8 kb upstream of the coding region (Boukouvala and Fakis, 2005). A similar type of unusual structure was later revealed for NAT2 genes in rabbit, hamster, mouse, and rat. More recent sequence alignments of expressed sequence tags (ESTs) with genomic sequences reveal that the presence of one or more upstream “noncoding exons” is typical for all vertebrate NAT genes, with the contiguous coding region contained in a single exon in the 3′ untranslated region (Boukouvala and Fakis, 2005). Furthermore, the splice site nearest the coding region is universally conserved at position 6, relative to the first codon. The primary transcript of both NAT1 and 2 genes is also subject to alternative

intron splicing in human, rat, and possibly chicken, whereas alternative splicing for NAT2 has been observed in rabbit and hamster. Alternative splicing in the case of NATs generates mRNAs with variable 5' untranslated regions. The presence of "noncoding exons" lying upstream of higher eukaryotic genes (especially intronless genes) is common, and their transcription is likely required for transport of the entire transcript to the cytoplasm (Boukouvala and Fakis, 2005). The differential transcription of upstream noncoding exons has been frequently associated with cell-specific regulation of transcription and translation, and recent studies show that certain noncoding NAT exons are present to different extents in different tissues (Boukouvala and Fakis, 2005). There is also evidence of differential utilization of multiple tandem poly-adenosine repeats in the 3' untranslated regions in different species, but the precise effect of polyadenylation of NATs remains unknown (Boukouvala and Fakis, 2005).

Despite their coexistence on the same chromosome, NAT1 and NAT2 are independently regulated proteins. For instance, human NAT1 protein and/or mRNA have been detected in every tissue examined (eg, liver, gastrointestinal tract, leukocytes, erythrocytes, bladder, uroepithelial cells, mammary, lung, placenta, kidney, pineal gland, skeletal muscle, heart, brain, and pancreas) and are present from the blastocyst stage, whereas NAT2 is thought to be mainly expressed in liver and intestine. However, most (but not all) of the tissues that express NAT1 also appear to express low levels of NAT2, at least at the level of mRNA (Debiec-Rychter *et al.*, 1999). Hein (2006) has also challenged the hypothesis that NAT2 is expressed mainly in the liver and intestine, and noted that the *O*-acetylation of *N*-hydroxy-4-aminobiphenyl in human urinary bladder cytosol did not correlate with NAT1 activity (4-aminobenzoic acid [PABA] *N*-acetylation), consistent with acetylation by both enzymes. Regulation of human NAT1 is complex, and involves a promoter region composed of an AP-1 box flanked by 2 TCATT boxes (Boukouvala and Fakis, 2005). The 3' TCATT box is required for expression, whereas the 5'-box attenuates promoter activity. Transcription factors such as c-Fos/Fra, c-Jun, and YY1 bind to the NAT1 promoter (Boukouvala and Fakis, 2005). In addition, because transcription of human NAT1 can begin with different upstream "noncoding exons," it is likely that there are additional promoters that regulate expression.

NAT1 and NAT2 also have different but overlapping substrate specificities, although no substrate is exclusively *N*-acetylated by one enzyme or the other. Substrates preferentially *N*-acetylated by human NAT1 include 4-aminobenzoic acid (PABA), 4-aminosalicylic acid, sulfamethoxazole, and sulfanilamide, whereas substrates preferentially *N*-acetylated by human NAT2 include isoniazid, hydralazine, procainamide, dapson, aminoglutethimide, and sulfamethazine. Some investigators have used PABA as a selective probe substrate for wild-type NAT1, and either sulfamethazine or sulfadiazine as selective probe substrate for wild-type NAT2 (Winter and Unadkat, 2005). Some xenobiotics, such as the carcinogenic aromatic amine, 2-aminofluorene (2-AF), are *N*-acetylated equally well by NAT1 and NAT2. The calcium-sensitizing agent levosimendan, developed for the treatment of congestive heart failure, has a pharmacologically active *N*-acetylated metabolite produced by NAT2 (Testa and Krämer, 2008, 2010). Other drugs that are substrates for either NAT1 or NAT2 include acebutolol, amantadine, amonafide, amrinone, benzocaine, declopramide, metamizole, and phenelzine (Gonzalez and Tukey, 2006; Sirot *et al.*, 2006; Sim *et al.*, 2008).

Several drugs are *N*-acetylated following their biotransformation by hydrolysis, reduction, or oxidation. For example, caffeine is *N*₃-demethylated by CYP1A2 to paraxanthine (Fig. 6-45), which

Figure 6-60. Examples of substrates for the human *N*-acetyltransferases, NAT1, and the highly polymorphic NAT2.

is then *N*-demethylated to 1-methylxanthine and *N*-acetylated to 5-acetylamino-6-formylamino-3-methyluracil (AFMU) by NAT2. The ratio of AFMU to 1-methylxanthine can be used to determine acetylator phenotype (Testa and Krämer, 2008, 2010). Other drugs converted to metabolites that are *N*-acetylated by NAT2 include sulfasalazine, nitrazepam, and clonazepam. Examples of drugs that are *N*-acetylated by NAT1 and NAT2 are shown in Fig. 6-60. It should be noted, however, that there are species differences in the substrate specificity of NATs. For example, PABA is preferentially *N*-acetylated by NAT1 in humans and rabbits but by NAT2 in mice and hamsters.

Genetic polymorphisms for *N*-acetylation have been documented in humans, hamsters, rabbits, and mice (Evans, 1992; Vatsis *et al.*, 1995; Hirvonen, 1999; Hein *et al.*, 2000; Sim *et al.*, 2008). A series of clinical observations in the 1950s established the existence of *slow* and *fast acetylators* of the antitubercular drug isoniazid. In general, ~50% of patients treated with isoniazid have adverse events such as peripheral neuropathy and hepatotoxicity. These adverse effects are more pronounced in slow acetylators (discussed later in this section). Slow acetylators also exhibit a higher incidence of adverse events with clonazepam, hydralazine, procainamide, and sulfonamides (Sirot *et al.*, 2006). The incidence of the slow acetylator phenotype is high in Middle Eastern populations (eg, ~92% in Egyptians), intermediate in Caucasian and African populations (eg, ~50%–59% in Caucasian Americans, Australians, and Europeans; ~41% in African Americans; ~50%–60% in black Africans), and low in Asian populations (eg, <20% in Chinese; ~8%–10% in Japanese) (Sirot *et al.*, 2006). Many studies have demonstrated the

typical bimodal distribution of fast and slow acetylators with drugs such as isoniazid, but the use of other drugs such as caffeine or sulfamethazine exhibits slow, intermediate, and fast acetylators (Hein, 2006). Parkin *et al.* (1997) also demonstrated that isoniazid elimination is trimodal, and that phenotype and genotype were concordant.

The slow acetylator phenotype is caused by various mutations in the NAT2 gene that decrease either NAT2 activity or enzyme stability. At least 36 allelic variants of human NAT2 have been documented. For example, a point mutation T₃₄₁C (which causes the amino acid substitution Ile₁₁₄Thr) decreases V_{max} for *N*-acetylation without altering the K_m for substrate binding or the stability of the enzyme. This mutation (which is the basis for the NAT2*5 allele) is the most common cause of the slow acetylator phenotype in Caucasians (eg, frequency >50% in the United Kingdom) but is rarely observed in Koreans (ie, <5%) (Hein, 2006). (Note: There are 10 known NAT2*5 alleles, designated NAT2*5A to NAT*5J.) The alleles containing only the Ile₁₁₄Thr substitution are NAT2*5A (which also contains a silent C₄₈₁T nucleotide change) and NAT2*5D. The others contain this and at least one other nucleotide and/or amino acid substitution, and NAT2*5B confers the “slowest acetylator” phenotype (Patin *et al.*, 2006). The NAT2*7 allele is more prevalent in Asians than Caucasians or Africans (Hein, 2006), and involves either a point mutation G₈₅₇A (ie, NAT2*7A) or both this change and C₂₈₂T (ie, NAT2*7B). Both of these changes cause the amino acid substitution Gly₂₈₆Glu, which decreases the stability, rather than the activity, of NAT2. NAT2*6 (more common in southern India) and NAT2*14 (present mainly in Africa and Spain) also result in one or more amino acid changes that lead to decreased NAT2 activity, whereas the amino acid change in NAT2*12 (present mainly in Africa and Spain) does not decrease activity (Hein, 2006). Within the slow NAT2 acetylator phenotype there is considerable variation in rates of xenobiotic *N*-acetylation. This is partly because different mutations in the NAT2 gene have different effects on NAT2 activity and/or enzyme stability, heterozygotes retain moderate NAT2 activity, and the *N*-acetylation of “NAT2-substrates” by NAT1 becomes significant in slow acetylators.

The slowest acetylator haplotype (NAT2*5B, which has the strongest association with bladder cancer) appears to have been positively selected for in only the last 6500 years in western and central Eurasians, which suggests that slow acetylation conferred an evolutionary advantage within this population, contrary to much of the recent epidemiological data (Patin *et al.*, 2006). Moreover, because most of the NAT2 polymorphisms that lead to slow acetylation are present at high frequencies in various populations, it would seem that varied rates of acetylation may be an important human adaptation to environmental variables. Because acetylation can be very important in the determination of the interaction between human populations and many xenobiotics in their particular environment (eg, through different diets and lifestyles), it is not surprising that they are recent targets for natural selection.

NAT1 and NAT2 used to be referred to as *monomorphic* and *polymorphic* NATs because only the latter enzyme was thought to be genetically polymorphic. However, at least 26 allelic variants have now been documented for the human NAT1 gene, although these variants are less prevalent than the NAT2 allelic variants; hence, there is less genetically determined variation in the metabolism of “NAT1 substrates.” Nevertheless, there is evidence that phenotypic differences in the *N*-acetylation of 4-aminosalicylic acid are distributed bimodally, consistent with the existence of low- and high-activity forms of NAT1. Furthermore, an extremely slow acetylator of 4-aminosalicylic acid has been identified with mutations in both NAT1 alleles: one that decreases NAT1 activity and stability and one that encodes a truncated and catalytically inactive form

of the enzyme. Two NAT1 variants, NAT1*10 and NAT1*11, are gain-of-function polymorphisms that lead to increased efficiency of protein translation (Wang *et al.*, 2011b). Individuals homozygous for NAT1*10 or heterozygous for NAT1*11 are classified as fast acetylators, whereas those rare individuals who are homozygous for NAT1*11 have been classified as ultrafast acetylators (Wang *et al.*, 2011b). Both NAT*10 and NAT*11 alleles are risk modifiers of sulfamethoxazole-induced hypersensitivity in HIV/AIDS patients, such that individuals who are NAT1 *fast* acetylators but are also NAT2 *slow* acetylators are protected against this type of hypersensitivity (Wang *et al.*, 2011b). It has also been demonstrated that NAT1*16 but not NAT1*10 or NAT1*11 causes a 50% decrease in NAT1 activity and NAT1 protein levels in COS-1 cell cytosol (Soucek *et al.*, 2004). Cascorbi *et al.* (2001) found that individuals who express NAT1*10 and NAT2*4 (ie, intermediate NAT1 activity and normal NAT2 activity) were at a significantly lower risk of bladder cancer, especially when exposed to environmental carcinogens. It is therefore likely that the interplay between NAT1 and NAT2 phenotypes is relevant to the susceptibility to certain carcinogens.

Genetic polymorphisms in NAT2 have a number of pharmacological and toxicological consequences for drugs that are *N*-acetylated by this enzyme. The pharmacological effects of the antihypertensive drug hydralazine are more pronounced in slow NAT2 acetylators. Slow NAT2 acetylators are predisposed to several drug toxicities, including nerve damage (peripheral neuropathy) from isoniazid and dapsone, systemic lupus erythematosus from hydralazine and procainamide, and the toxic effects of coadministration of the anticonvulsant phenytoin with isoniazid. Slow NAT2 acetylators who are also deficient in glucose-6-phosphate dehydrogenase are particularly prone to hemolysis from certain sulfonamides. HIV-infected individuals of the slow acetylator phenotype suffer more often from adverse drug events and, among patients with Stevens Johnson syndrome, the overwhelming majority are slow acetylators. Fast NAT2 acetylators are predisposed to the myelotoxic effects of amonafide because *N*-acetylation retards the clearance of this antineoplastic drug.

Early epidemiological studies suggested that rapid NAT2 acetylators were at increased risk for the development of isoniazid-induced liver toxicity; however, the current consensus is that slow NAT2 acetylation is a risk modifier for isoniazid-induced hepatotoxicity while rapid acetylators are protected from toxicity. Following its acetylation by NAT2, isoniazid can be hydrolyzed to isonicotinic acid and acetylhydrazine (CH₃CO–NHNH₂). The latter metabolite can be *N*-hydroxylated by FMO or CYP to a reactive intermediate, as shown in Fig. 6-38. The generation of a reactive metabolite from acetylhydrazine would seem to provide a mechanistic basis for enhanced isoniazid hepatotoxicity in fast acetylators. However, acetylhydrazine can be further acetylated to diacetylhydrazine (CH₃CO–NHNH–COCH₃), and this detoxication reaction is also catalyzed by NAT2. Therefore, acetylhydrazine is both produced and detoxified by NAT2; hence, slow acetylation, not fast acetylation, becomes the risk modifier for isoniazid-induced hepatotoxicity, just as it is for isoniazid-induced peripheral neuropathy. Isoniazid can also be directly hydrolyzed to yield isonicotinic acid and hydrazine (H₂N–NH₂). Hydrazine (also a toxic substance used as rocket propellant) has been proposed to be the hepatotoxic metabolite of isoniazid as slow acetylators have significantly higher plasma concentrations of hydrazine relative to rapid acetylators (Testa and Krämer, 2008, 2010; Metushi *et al.*, 2011). Rifampin and alcohol have been reported to enhance the hepatotoxicity of isoniazid. These drug interactions are probably the result of increased *N*-hydroxylation of acetylhydrazine due to CYP induction

Figure 6-61. Role of *N*-acetyltransferase in the *O*-acetylation of *N*-hydroxy-2-aminofluorene (*N*-hydroxy-2-AF) and the intramolecular rearrangement of *N*-hydroxy-2-acetylaminofluorene (*N*-hydroxy-2-AAF).

rather than due to an alteration in NAT2 activity. This is further corroborated by studies in which slow acetylators who also carried the high-activity CYP2E1 c1/c1 genotype had more severe hepatotoxicity (Metushi *et al.*, 2011). Isoniazid is an antitubercular drug, and its inactivation by NAT2 is interesting from the perspective that several organisms, including *M. tuberculosis*, express a NAT2-like enzyme, which has implications for isoniazid-resistance in tuberculosis.

Aromatic amines can be both activated and deactivated by NATs (Kato and Yamazoe, 1994; Hirvonen, 1999; Hein *et al.*, 2000). The NATs detoxify aromatic amines by converting them to the corresponding amides because aromatic amides are less likely than aromatic amines to be activated to DNA-reactive metabolites by CYP, peroxidases such as PHS, and UGTs (see the section “Glucuronidation and Formation of Acyl-CoA Thioesters”). However, NATs can activate aromatic amines if they are first *N*-hydroxylated by CYP because NATs can also function as *O*-acetyltransferases and convert hydroxylamines to acetoxy esters (*aryl*-NHOH → *aryl*-NH-O-COCH₃). As shown in Fig. 6-12, the acetoxy esters of hydroxylamines, like the corresponding sulfonate

esters (Fig. 6-58), can break down to form highly reactive nitrenium and carbonium ions that bind to DNA. NATs catalyze the *O*-acetylation of *N*-hydroxyaromatic amines by two distinct mechanisms. The first reaction, which is exemplified by the conversion of *N*-hydroxyaminofluorene to *N*-acetoxyaminofluorene, requires acetyl-CoA and proceeds by the same mechanism previously described for *N*-acetylation. The second reaction is exemplified by the conversion of 2-acetylaminofluorene (2-AAF) to *N*-acetoxyaminofluorene, which does not require acetyl-CoA but involves an intramolecular transfer of the *N*-acetyl group from nitrogen to oxygen. These reactions are shown in Fig. 6-61.

Genetic polymorphisms in NAT2 have been reported to influence susceptibility to aromatic amine-induced bladder and colon cancer (see the section “Glucuronidation and Formation of Acyl-CoA Thioesters”) (Evans, 1992; Kadlubar, 1994; Hirvonen, 1999; Hein *et al.*, 2000; Sim *et al.*, 2008). Bladder cancer is thought to be caused by bicyclic aromatic amines (benzidine, 2-aminonaphthalene, and 4-aminobiphenyl), whereas colon cancer is thought to be caused by heterocyclic aromatic amines, such as the products of amino acid pyrolysis (eg, 2-amino-6-methylimidazo[4,5-*b*]

pyridine or PhIP, and others listed in Table 6-14). Epidemiological studies suggest that slow NAT2 acetylators are more likely than fast NAT2 acetylators to develop bladder cancer from cigarette smoking and from occupational exposure to bicyclic aromatic amines. The possibility that slow NAT2 acetylators are at increased risk for aromatic amine-induced cancer is supported by the finding that dogs, which are poor acetylators, are highly prone to aromatic amine-induced bladder cancer. By comparison, fast NAT2 acetylators appear to be at increased risk for colon cancer from heterocyclic aromatic amines.

The influence of acetylator phenotype on susceptibility to aromatic amine-induced cancer can be rationalized on the ability of NATs to activate and detoxify aromatic amines and by differences in the substrate specificity and tissues distribution of NAT1 and NAT2 (recall that NAT1 is expressed in virtually all tissues, whereas NAT2 is expressed mainly in the liver and intestinal tract). Both NAT1 and NAT2 catalyze the *O*-acetylation (activation) of *N*-hydroxy bicyclic aromatic amines, whereas the *O*-acetylation of *N*-hydroxy heterocyclic aromatic amines is preferentially catalyzed by NAT2. Bicyclic aromatic amines can also be *N*-acetylated (detoxified) by NAT1 and NAT2, but heterocyclic aromatic amines are poor substrates for both enzymes. Therefore, the fast acetylator phenotype protects against aromatic amine-induced bladder cancer because NAT2 (as well as NAT1) catalyzes the *N*-acetylation (detoxification) of bicyclic aromatic amines in the liver. In slow acetylators, a greater proportion of the bicyclic aromatic amines are activated through *N*-hydroxylation by CYP1A2. These *N*-hydroxylated aromatic amines can be activated by *O*-acetylation, which can be catalyzed in the bladder itself by NAT1. A high level of NAT1 in the bladder is a risk modifier for aromatic amine-induced bladder cancer. In addition, the fast acetylator phenotype potentiates the colon cancer-inducing effects of heterocyclic aromatic amines. These aromatic amines are poor substrates for NAT1 and NAT2, so that high levels of NAT2 in the liver do little to prevent their *N*-hydroxylation by CYP1A2. The *N*-hydroxylated metabolites of heterocyclic aromatic amines can be activated by *O*-acetylation, which can be catalyzed in the colon itself by NAT2. The presence of NAT2 (and NAT1) in the colons of fast acetylators probably explains why this phenotype is a risk modifier for the development of colon cancer.

Whether fast acetylators are protected from or predisposed to the cancer-causing effects of aromatic amines depends on the nature of the aromatic amine (bicyclic vs heterocyclic) and on other important risk modifiers. Both the activation of aromatic amines by *N*-glucuronidation and the activation of *N*-hydroxy aromatic amines by sulfonation are suspected of playing an important role in the incidence of bladder and colon cancer. These and other risk modifiers may explain why some epidemiological studies, contrary to expectation, have shown that slow NAT2 acetylators are at increased risk for aromatic amine-induced bladder cancer, as was demonstrated for benzidine manufacturers in China (Hayes *et al.*, 1993).

The *N*-acetylation of aromatic amines (a detoxication reaction) and the *O*-acetylation of *N*-hydroxy aromatic amines (an activation reaction) can be reversed by a microsomal enzyme called arylacetamide deacetylase (gene symbol AADAC) (Probst *et al.*, 1994). This enzyme is similar to but distinct from the microsomal carboxylesterases that hydrolyze esters and amides. AADAC can potentially alter the overall balance between detoxication and activation of aromatic amines.

Overall, it would appear that low NAT2 activity increases the risk of bladder, breast, liver, and lung cancers, and decreases the risk of colon cancer, whereas low NAT1 activity increases the

risk of bladder and colon cancers and decreases the risk of lung cancer (Hirvonen, 1999). The individual risks associated with particular NAT1 and/or NAT2 acetylator genotypes are small, but they increase when considered in conjunction with other susceptibility genes and/or exposure to carcinogenic aromatic and heterocyclic amines. Because of the relatively high frequency of allelic variants of NAT1 and NAT2, the attributable risk of cancer in the population may be high (Hein *et al.*, 2000).

Amino Acid Conjugation

There are two principal pathways by which xenobiotics are conjugated with amino acids, as illustrated in Fig. 6-62. The first involves conjugation of xenobiotics containing a carboxylic acid group with the *amino group* of amino acids such as glycine, glutamine, and taurine (see Fig. 6-51). This pathway involves activation of the xenobiotic by conjugation with coenzyme A (CoA), which produces a xenobiotic-CoA thioester that reacts with the *amino group* of an amino acid to form an amide linkage. The second pathway involves conjugation of xenobiotics containing an aromatic hydroxylamine (*N*-hydroxy aromatic amine) with the *carboxylic acid group* of such amino acids as serine and proline. This pathway involves activation of an amino acid by aminoacyl-tRNA-synthetase, which reacts with an aromatic hydroxylamine to form a reactive *N*-ester (Kato and Yamazoe, 1994).

The conjugation of benzoic acid with glycine to form hippuric acid (see Fig. 6-1) was discovered in 1842, making it the first biotransformation reaction discovered (Knights *et al.*, 2007). The first step in this conjugation reaction involves activation of benzoic acid to an acyl-CoA thioester. This reaction requires ATP and is catalyzed by acyl-CoA synthetase (ATP-dependent acid:CoA ligase [AMP forming]). The second step is catalyzed by acyl-CoA:amino acid *N*-acyltransferase, which transfers the acyl moiety of the xenobiotic to the amino group of the acceptor amino acid. The reaction proceeds by a *ping-pong Bi-Bi* mechanism, and involves transfer of the xenobiotic to a cysteine residue in the enzyme with release of CoA, followed by transfer of the xenobiotic to the acceptor amino acid with regeneration of the enzyme. The second step in amino acid conjugation is analogous to amide formation during the acetylation of aromatic amines by NAT. Substrates for amino acid conjugation are restricted to certain aliphatic, aromatic, heteroaromatic, cinnamic, and arylacetic acids.

The ability of xenobiotics to undergo amino acid conjugation depends on steric hindrance around the carboxylic acid group, and by substituents on the aromatic ring or aliphatic side chain. In rats, ferrets, and monkeys, the major pathway of phenylacetic acid biotransformation is amino acid conjugation. However, due to steric hindrance, diphenylacetic acid cannot be conjugated with an amino acid, so the major pathway of diphenylacetic acid biotransformation in these 3 species is acyl glucuronidation. Bile acids are endogenous substrates for glycine and taurine conjugation. However, the activation of bile acids to an acyl-CoA thioester is catalyzed by a microsomal enzyme, cholesteryl-CoA synthetase, and conjugation with glycine or taurine is catalyzed by the cytosolic enzyme, bile acid-CoA:amino acid *N*-acyltransferase (BACAT, gene symbol BAAT) (Falany *et al.*, 1994; Testa and Krämer, 2008, 2010). BACAT is expressed at high levels in the liver, kidney, gallbladder, and intestine, with lower levels in the adrenal gland, muscle, lung, and brain, which suggests that it may have substrates other than bile acids (O'Byrne *et al.*, 2003). In vitro studies show that BACAT can form glycine conjugates of long-chain fatty acids, and also possesses thioesterase activity toward the same substrates (O'Byrne *et al.*, 2003). In contrast to bile acids, the

Figure 6-62. Conjugation of xenobiotics with amino acids.

activation of xenobiotics occurs mainly in mitochondria, which appear to contain multiple acyl-CoA ligases. There are 3 acyl-CoA ligases that are involved in the formation of a xenobiotic acyl-CoA intermediate, namely, the short-, medium-, and long-chain acyl-CoA ligase (Testa and Krämer, 2008, 2010). These enzymes are also involved in endogenous fatty acid activation. Of particular importance to amino acid conjugation is the medium-chain [butyrate]-CoA ligase present in the mitochondrial matrix, which converts medium-chain fatty acids (C₄-C₁₂) to CoA thioesters to initiate β -oxidation (Knights *et al.*, 2007). In humans, two

distinct forms of medium-chain fatty acid CoA ligases have been characterized, HXM-A (48 kDa) and HXM-B (49 kDa), each of which has overlapping substrate specificities. Common substrates of HXM-A and HXM-B include benzoate, propionate, hexanoate, octanoate, valproate, and salicylate (Knights *et al.*, 2007). The formation of xenobiotic acyl-CoA conjugates is interesting because of their potential to cause mitochondrial toxicity by inhibiting fatty-acid β -oxidation due to a combination of CoA sequestration and direct inhibition of acyl-CoA ligases (Knights *et al.*, 2007; Testa and Krämer, 2008, 2010). Some xenobiotic

acyl-CoA conjugates can also act as reactive electrophiles and form protein adducts with immunogenic potential (see the section “Glucuronidation and Formation of Acyl-CoA Thioesters”). The second step in the conjugation of xenobiotics with amino acids is catalyzed by cytosolic and/or mitochondrial forms of *N*-acyltransferase, expressed primarily in the liver and kidney (Knights *et al.*, 2007). Amino acid conjugation is apparently catalyzed by separate *N*-acyltransferases specific for each amino acid (Gopaul *et al.*, 2003). Glycine-*N*-acyltransferase and glutamine-*N*-phenylacetyltransferase have been isolated from human hepatic mitochondria (Gopaul *et al.*, 2003).

There are several examples of xenobiotics that undergo amino acid conjugation as a major metabolic pathway, such as the hypolipidemic drug nicotinic acid (niacin) that is conjugated with glycine to form nicotinuric acid (Iwaki *et al.*, 1996; Testa and Krämer, 2008, 2010). In humans, over 90% of a dose of acetylsalicylic acid (aspirin) is hydrolyzed to salicylic acid, of which 75% is excreted in urine as the glycine conjugate, salicyluric acid (Knights *et al.*, 2007; Testa and Krämer, 2008, 2010). Whereas benzoic acids and small analogs generally are conjugated with glycine, larger substrates such as 4-phenylbutanoic acid are generally conjugated with glutamine. 4-Phenylbutanoic acid is a drug used in the treatment of hyperammonemia caused by genetic errors in urea synthesis. Conjugation of 4-phenylbutanoic acid with glutamine contributes to nitrogen elimination under conditions of impaired urea synthesis (Kasumov *et al.*, 2004; Testa and Krämer, 2008, 2010). Taurine (along with glycine) plays an important role in the conjugation of bile acids. The herbicide 4-chloro-2-methylphenoxyacetic acid (MCPA) forms both taurine and glycine conjugates in dogs, but only trace glycine conjugates in rats (Lappin *et al.*, 2002; Testa and Krämer, 2008, 2010). The PPAR α agonist MRL-II exhibits dose-dependent formation of acyl glucuronides and taurine conjugates, major biliary metabolites in dogs, with lower doses favoring the formation of the taurine conjugate (Kim *et al.*, 2004; Testa and Krämer, 2008, 2010). While few reports of xenobiotic taurine conjugates in humans exist, taurine conjugation of the NSAID ibuprofen is a minor metabolite eliminated in urine almost solely as the *S*-enantiomer (Shirley *et al.*, 1994; Testa and Krämer, 2008, 2010).

An important difference between the amino acid conjugates of xenobiotics and bile acids is their route of elimination: bile acids are secreted into bile, whereas amino acid conjugates of xenobiotics are eliminated primarily in urine. The addition of an endogenous amino acid to xenobiotics may facilitate this elimination by increasing their ability to interact with the tubular organic anion transport system in the kidney. The precursor to amino acid conjugation, namely, the xenobiotic acyl-CoA thioester, is not transported out of the cell and is not detected in bile, plasma, or urine, but it can be detected in tissue samples and in vitro test systems. The formation of xenobiotic acyl-CoA thioesters in adipose tissue (and their further metabolism to more complex lipid conjugates) can be a relatively long-lived repository for certain acidic drugs. Consequently, in mass balance studies (ie, in studies of the disposition of a radio-labeled drug) the formation of acyl-CoA thioesters and their lipid derivatives in adipose tissue can contribute to incomplete recovery of radioactivity in the case of acidic drugs and drugs that are extensively metabolized to one or more carboxylic acid-containing metabolites.

In addition to glycine, glutamine, and taurine, acceptor amino acids for xenobiotic conjugation include ornithine, arginine, histidine, serine, aspartic acid, and several dipeptides, such as glycylglycine, glycyltaurine, and glycylvaline. The acceptor amino acid used for conjugation is both species- and xenobiotic-dependent.

For benzoic, heterocyclic, and cinnamic acids, the acceptor amino acid is glycine, except in birds and reptiles, which use ornithine. Arylacetic acids are also conjugated with glycine except in primates, which use glutamine. In mammals, taurine is generally an alternative acceptor to glycine. Taurine conjugation is well developed in nonmammalian species and carnivores. Whereas most species conjugate bile acids with both glycine and taurine, cats and dogs conjugate bile acids only with taurine.

Amino acid conjugation of carboxylic acid-containing xenobiotics is an alternative to glucuronidation. Conjugation of carboxylic acid-containing xenobiotics with amino acids has long been considered a predominantly detoxication reaction. However, as outlined in the section “Glucuronidation and Formation of Acyl-CoA Thioesters,” there is growing evidence that the toxicity of certain NSAIDs is due in part to the formation of reactive acyl-CoA thioesters (the precursors to amino acid conjugates), which represents an alternative activation pathway to the formation of reactive acyl glucuronides, as illustrated in Fig. 6-57. Amino acid conjugation of ibuprofen, ketoprofen, and related *profens* (2-substituted propionic acid NSAIDs) is significant for two reasons: it limits the formation of potentially toxic acyl glucuronides and it leads to chiral inversion (the interconversion of *R*- and *S*-enantiomers) (Shirley *et al.*, 1994). The latter reaction requires conversion of the profen to its acyl-CoA thioester, which undergoes chiral inversion by 2-arylpropionyl-CoA epimerase (this involves the intermediacy of a symmetric, conjugated enolate anion). Chiral inversion may explain why the *R*- and *S*-enantiomers of several profen NSAIDs have comparable anti-inflammatory effects in vivo, even though the *S*-enantiomers are considerably more potent than their antipodes as in vitro inhibitors of cyclooxygenase (the target of NSAID therapy). There is also evidence that the acyl-CoA thioesters of the *R*-enantiomers are pharmacologically active and contribute to the therapeutic effect by inhibiting COX-2 (Neupert *et al.*, 1997; Levoine *et al.*, 2004; Testa and Krämer, 2008, 2010). In general, amino acid conjugation is a high-affinity–low-capacity reaction, whereas glucuronidation is a high-capacity–low-affinity reaction. At low substrate concentrations, amino acid conjugation can be the predominant reaction.

Amino acid conjugation of *N*-hydroxy aromatic amines (hydroxylamines) is an activation reaction because it produces *N*-esters that can degrade to form electrophilic nitrenium and carbonium ions (Anders, 1985; Kato and Yamazoe, 1994). Conjugation of hydroxylamines with amino acids is catalyzed by cytosolic aminoacyl-tRNA synthetases and requires ATP (Fig. 6-62). Hydroxylamines activated by aminoacyl-tRNA synthetases include *N*-hydroxy-4-aminoquinoline 1-oxide, which is conjugated with serine, and *N*-hydroxy-Trp-P-2, which is conjugated with proline. (*N*-Hydroxy-Trp-P-2 is the *N*-hydroxylated metabolite of Trp-P-2, a pyrolysis product of tryptophan [see Table 6-14].) It is now apparent that the hydroxylamines formed by the CYP-dependent *N*-hydroxylation of aromatic amines can potentially be activated by numerous reactions, including *N*-glucuronidation by UGTs (Fig. 6-56), *O*-acetylation by NAT (Fig. 6-12), *O*-sulfonation by SULT (Fig. 6-58), and conjugation with amino acids by seryl- or prolyl-tRNA synthetase (Fig. 6-62).

Various amino acid conjugates of valproic acid, including glutamine, glutamate, and glycine conjugates, have been detected in urine, plasma, and cerebrospinal fluid (CSF) of patients administered this antiepileptic (Gopaul *et al.*, 2003). CSF concentrations of the glutamine and glutamate conjugates of valproic acid were 5 and 9 times higher than in plasma, which suggests that these conjugation reactions in the brain decrease levels of the excitatory neurotransmitter glutamic acid and decrease the incidence of seizure

(Gopaul *et al.*, 2003). Taken together, these data suggest that amino acid conjugation in the brain may play a role in the mechanism of action of valproic acid.

Glutathione Conjugation

The preceding section described the conjugation of xenobiotics with certain amino acids, including some simple dipeptides, such as glycyltaurine. This section describes the conjugation of xenobiotics with the tripeptide glutathione (GSH) in a reaction also known as glutathionylation, which is fundamentally different from other conjugation reactions. Whereas glucuronidation, sulfonation, and all of the other previously described conjugation reactions involve conjugation of nucleophilic xenobiotics or their nucleophilic metabolites, GSH conjugation occurs with electrophilic xenobiotics or their electrophilic metabolites. GSH is composed of glycine, cysteine, and glutamic acid (the latter being linked to cysteine via the γ -carboxyl group, not the usual α -carboxyl group, as shown in Fig. 6-51). Glutathione transferase (GST) activity was first discovered as the enzyme-catalyzed conjugation of GSH with halogenated compounds such as chloronitrobenzenes and bromosulfophthalein (Mannervik *et al.*, 2005; Higgins and Hayes, 2011). The activity was initially designated GSH *S*-aryltransferase, and GST activities toward other substrates such as alkyl halides and epoxides were called *S*-alkyl and *S*-epoxide transferases. The original names were later replaced with letter designations once the overlapping substrate specificity was described, and it was recognized that GSTs do not simply conjugate xenobiotics with GSH but also catalyze reactions such as hydroperoxide reduction (an example of which is shown in Fig. 6-18 as part of the metabolism of carbon tetrachloride), dehydrohalogenation (as shown in Figs. 6-20 [general mechanisms] and 6-21 [dechlorination of DDT]), thiolysis (the general mechanism for disulfide cleavage is shown in Fig. 6-14), disulfide interchange, and isomerization (Mannervik *et al.*, 2005; Higgins and Hayes, 2011). Although the abbreviation “GST” has survived to describe the enzyme family, the term “glutathione *S*-transferase” is technically incorrect because the glutathionyl group (GS-) is transferred rather than a single sulfur atom (Mannervik *et al.*, 2005) (the correct term is glutathione transferase). GSTs function endogenously as part of a defense mechanism against reactive oxygen species (ROS); GSTs reduce the formation of hydroperoxides of fatty acids, phospholipids, and cholesterol and protect against the redox cycling of many quinone-containing compounds by conjugating them with GSH (Hayes *et al.*, 2005; Testa and Krämer, 2010). GSTs also play a role in other endogenous functions such as the degradation of aromatic amino acids, steroid hormone synthesis, eicosanoid synthesis (leukotrienes are GSH conjugates), and modulation of signaling pathways (Hayes *et al.*, 2005; Higgins and Hayes, 2011; Oakley, 2011).

Substrates for glutathionylation include an enormous array of electrophilic xenobiotics, or xenobiotics that can be biotransformed to electrophiles. GSH conjugates are thioethers that form by nucleophilic attack of GSH thiolate anion (GS⁻) with an electrophilic carbon or heteroatom (*O*, *N*, and *S*) in the xenobiotic or its metabolite. Michael acceptors are also conjugated with GSH (discussed later in this section). The sulfhydryl group in GSH has a pK_a value of ~ 9.0 ; hence, at physiological pH, only $\sim 1\%$ of GSH is present in the thiolate anion (GS⁻) form. A primary function of GSTs is to lower the pK_a of GSH by more than 2 orders of magnitude (to pK_a 6–7), such that most (>50%) of the GSH bound to GST is in the reactive anionic form, which is stabilized by hydrogen bonding with a tyrosine, serine, or cysteine residue in the active site (Testa and Krämer,

2008, 2010). GSH, cysteine, *N*-acetylcysteine (NAC), and various analogs (esters and amides) are used in vitro to trap electrophilic metabolites formed by CYP in liver microsomes. In this system, which lacks the cytosolic GSTs, only $\sim 1\%$ of GSH is present in the thiolate anion (GS⁻), compared with 6% of cysteine and up to 16% for certain cysteine esters, which is why agents other than GSH are widely used to trap electrophilic metabolites formed by CYP in vitro (Reed, 1985). Cysteine has 6-fold greater ionization than GSH at physiological pH; however, the concentration of GSH in liver is ~ 50 times greater than that of cysteine, and its ionization is greatly increased by binding to GSTs.

The synthesis of GSH involves formation of the peptide bond between cysteine and glutamic acid, followed by peptide bond formation with glycine. The first and overall rate-limiting reaction is catalyzed by γ -glutamylcysteine synthetase (γ -GCL), the second by GSH synthetase. At each step, ATP is hydrolyzed to ADP and inorganic phosphate (Testa and Krämer, 2008, 2010). Due to the sheer multiplicity of GSTs, they cannot be collectively inhibited or induced; therefore, the importance of glutathionylation in xenobiotic toxicity in vivo is often assessed by altering levels of GSH. This can be achieved by (1) inhibiting GSH synthesis, (2) depleting GSH, or (3) increasing GSH levels through Nrf2 activation. Inhibition of GSH synthesis can be achieved with buthionine-*S*-sulfoximine (BSO), which inhibits γ -GCL, the enzyme that catalyzes the first reaction in GSH synthesis (Ballatori *et al.*, 2009a). Michael acceptors such as diethyl maleate (DEA) and phorone are commonly used in vivo to deplete GSH levels in experimental animals. Other agents, such as 2-cyclohexen-1-one and 2-cyclohepten-1-one, selectively decrease cerebral GSH levels in comparison with BSO treatment (Masukawa *et al.*, 1989; Yoneyama *et al.*, 2008). Lastly several agents can activate Nrf2, which induces γ -GCL, the rate-limiting step in GSH synthesis. Nrf2 activators include butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), ethoxyquin, and low doses of acetaminophen (Higgins and Hayes, 2011).

The conjugation of xenobiotics with GSH is catalyzed by GSTs in cytosol, microsomes (ie, the membrane-associated proteins in eicosanoid and glutathione metabolism [MAPEG] family), and mitochondria (Hayes *et al.*, 2005; Higgins and Hayes, 2011; Oakley, 2011). Most GSTs were originally found in the soluble cell fraction, and they are referred to as cytosolic or soluble GSTs, even though they may also be found in the nucleus or peroxisomes (Mannervik *et al.*, 2005; Higgins and Hayes, 2011; Oakley, 2011). The only mitochondrial GST found to date has traditionally been referred to as Kappa GST (detailed later in this section), and although it dimerizes (as do the cytosolic GSTs), Kappa GST has a structure that is distinct from the cytosolic GSTs and is also present in peroxisomes, which suggests that it is involved in fatty acid β -oxidation (Hayes *et al.*, 2005; Mannervik *et al.*, 2005; Morel and Aninat, 2011). The microsomal GSTs (or MAPEGs) are an independent group of proteins which are integral microsomal and mitochondrial membrane components. It should also be noted that some GSTs have nonenzymatic functions such as binding of zeaxanthin in the retina and c-Jun N-terminal kinase 1 by GST P1-1, and were initially designated by other names (Mannervik *et al.*, 2005). There are also other proteins that are homologous to some GSTs but are not yet known to serve as detoxication enzymes, such as the chloride intracellular channels (CLIC) (Mannervik *et al.*, 2005; Littler *et al.*, 2010). Hence, proteins that are already characterized and named may eventually be designated as GSTs, as was the case with GSH-dependent hematopoietic prostaglandin D synthase (HPGDS), now determined to be GST S1-1 due to similarities with the Sigma class GSTs expressed in nonmammalian

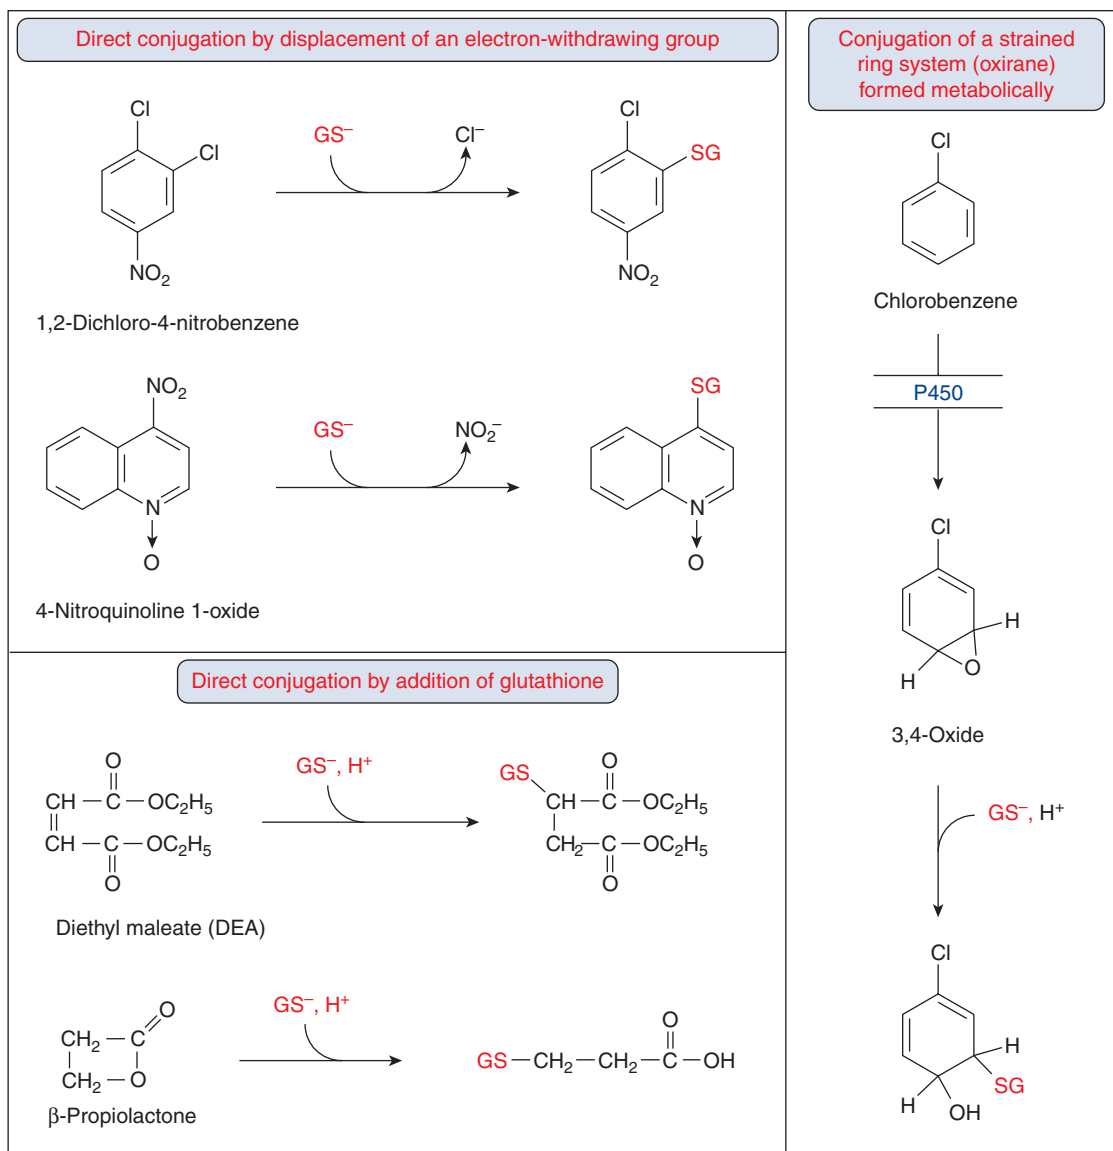

Figure 6-63. Examples of glutathione conjugation of xenobiotics with an electrophilic carbon. GS^- represents the anionic form of glutathione.

organisms. The GSTs are present in most tissues, with high concentrations in the liver, intestine, kidney, testis, adrenal, and lung.

Substrates for GST share 3 common features: they are hydrophobic, they contain an electrophilic atom, and they react nonenzymatically with GSH at some measurable rate. The mechanism by which GST increases the rate of GSH conjugation involves deprotonation of GSH to GS^- by an active-site tyrosine or serine, which functions as a general base catalyst (Atkins *et al.*, 1993; Dirr *et al.*, 1994). In the case of the Omega class GSTs, the active site contains a cysteine residue (Mukherjee *et al.*, 2006; Board, 2011). The concentration of GSH in liver is extremely high (5–10 mM) relative to plasma (0.5–10 μM); hence, the nonenzymatic conjugation of certain xenobiotics with GSH can be significant (Testa and Krämer, 2008, 2010). However, some xenobiotics are conjugated with GSH stereoselectively, indicating that the reaction is largely catalyzed by GST. Like GSH, the GSTs are themselves abundant cellular components, accounting for up to 10% of the total cellular protein. These enzymes bind, store, and/or transport a number of compounds that are not substrates for GSH conjugation. The cytoplasmic protein formerly known as ligandin, which binds heme, bilirubin, steroids,

azo-dyes, polycyclic aromatic hydrocarbons (PAHs), and thyroid hormones (THs), is an Alpha class GST (Oakley, 2011).

As shown in Fig. 6-63, substrates for GSH conjugation can be divided into two groups: those that are sufficiently electrophilic to be conjugated directly and those that must first be biotransformed to an electrophilic metabolite prior to conjugation. The second group of substrates for GSH conjugation includes reactive intermediates (often formed by CYP) such as oxiranes (arene oxides and alkene epoxides), nitrenium ions, carbonium ions, and free radicals. The conjugation reactions themselves can be divided into two types: *displacement reactions*, in which GSH displaces an electron-withdrawing group, and *addition reactions*, in which GSH is added to an activated double bond or strained ring system. Table 6-20 provides examples of typical substrates for each of the characterized GSTs.

The displacement of an electron-withdrawing group by GSH typically occurs when the substrate contains halide, sulfate, sulfonate, phosphate, or a nitro group (ie, good *leaving groups*) attached to an allylic or benzylic carbon atom. Displacement of an electron-withdrawing group from aromatic xenobiotics is decreased by the

Omega	GSTO1	GST O1-1	Monomethylarsonic acid, dehydroascorbic acid		
	GSTO2	GST O2-2	Monomethylarsonic acid, dehydroascorbic acid		
Mitochondrial	Kappa	GSTK1	GST K1-1	CDNB, CuOOH, (<i>S</i>)-15-hydroperoxy-5,8,11,13-eicosatetraenoic acid	
Microsomal (MAPEGs)	Clan 1	MGST2	MGST2	CDNB, LTA ₄ → LTC ₄ , (<i>S</i>)-5-hydroperoxy-8,11,14- <i>cis</i> -6- <i>trans</i> -eicosatetraenoic acid	
		MGST3	MGST3	CDNB, LTA ₄ → LTC ₄ , (<i>S</i>)-5-hydroperoxy-8,11,14- <i>cis</i> -6- <i>trans</i> -eicosatetraenoic acid	
		LTC4S	LTC ₄ S	LTA ₄ → LTC ₄	
	Clan 2	PTGEs	PGES1	PGH ₂ → PGE ₂	
		MGST1	MGST1	CDNB, CuOOH, hexachlorobuta-1,3-diene	
	Clan 3	ALOX5AP	FLAP	Arachidonic acid binding (nonenzymatic)	

Δ^5 -ADD, Δ^5 -androstene-3,17-dione; BCDE, benzo[*g*]chrysene diol epoxide; BCNU, 1,3-bis(2-chloroethyl)-1-nitrosourea; BPDE, benzo[*a*]pyrene diol epoxide; BPhDE, benzo[*c*]phenanthrene diol epoxide; CDE, chrysene-1,2-diol 3,4-epoxide; CDNB, 1-chloro-2,4-dinitrobenzene; COMC-6, crotonylloxymethyl-2-cyclohexenone; CuOOH, cumene hydroperoxide; DBADE, dibenz[*a,h*]anthracene diol epoxide; DBPDE, dibenzo[*a,l*]pyrene diol epoxide; EA, ethacrynic acid; EPNP, 1,2-epoxy-3-(*p*-nitrophenoxy)propane; *N*-acetoxy-PhIP, *N*-acetoxy-2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine. Data from Hayes *et al.* (2005), Mannervik *et al.* (2005), and Higgins and Hayes (2011).

*GST S1-1 is also the glutathione-dependent prostaglandin D synthase.

presence of other substituents that donate electrons to the aromatic ring (–NH₂, –OH, –OR, and –R). Conversely, such displacement reactions are increased by the presence of other electron-withdrawing groups (–F, –Cl, –Br, –I, –NO₂, –CN, –CHO, and –COOR). This explains why 1,2-dichloro-4-nitrobenzene and 1-chloro-2,4-dinitrobenzene, each of which contains 3 electron-withdrawing groups, are commonly used as substrates for measuring GST activity *in vitro*, and one or more members of all 3 GST families can catalyze this conjugation reaction (Hayes *et al.*, 2005; Higgins and Hayes, 2011). GST can catalyze the *O*-demethylation of dimethylvinphos and other methylated organophosphorus compounds. The reaction is analogous to the interaction between methyl iodide and GSH, which produces methylglutathione and iodide ion (GS[–] + CH₃I → GS–CH₃ + I[–]). In this case, iodide is the leaving group. In the case of dimethylvinphos, the entire organophosphate molecule (minus the methyl group) functions as the leaving group.

The addition of GSH to a carbon–carbon double bond is also facilitated by the presence of a nearby electron-withdrawing group; hence, substrates for this reaction typically contain a double bond attached to –CN, –CHO, –COOR, or –COR (ie, they are Michael acceptors). The double bond in diethyl maleate (DEA) is attached to 2 electron-withdrawing groups and readily undergoes a Michael addition reaction with GSH, as shown in Fig. 6-63. The loop diuretic, ethacrynic acid, contains an α/β -unsaturated ketone that readily reacts with GSH and other sulfhydryls by Michael addition. The conversion of acetaminophen to a GSH conjugate involves addition of GSH to an activated double bond, which is formed during the CYP-dependent dehydrogenation of acetaminophen to NAPQI, as shown in Fig. 6-35.

An interesting feature of GSH conjugation is the potential for nonenzymatic GSH conjugation in xenobiotic metabolism. The mechanism for this nonenzymatic activity is based on

electrophilicity or nucleophilicity of potential reactants (Testa and Krämer, 2008, 2010). Electrophiles and nucleophiles are scaled according to their hardness or softness, and this determines whether a nonenzymatic or GST-catalyzed enzymatic reaction will be favored. Hard electrophilic sites are highly localized positive charges that maintain a high charge density during the approach of a nucleophilic reactant (ie, they are not readily polarized). On the other hand, soft electrophilic sites have a low charge density (ie, a delocalized charge) and are easily polarized by an approaching nucleophilic reactant (Testa and Krämer, 2008, 2010). Since GSH acts as a soft nucleophile, it will react spontaneously with soft electrophiles, such as in the case of 1-(4-nitrophenoxy)propane-2,3-oxide, which is a poor GST substrate, but reacts spontaneously with GSH (Testa and Krämer, 2008, 2010). Hard electrophiles are unlikely to react spontaneously with GSH and require the catalytic facilitation of GSTs (Testa and Krämer, 2008, 2010).

Arene oxides and alkene epoxides, which are often formed by CYP-dependent oxidation of aromatic hydrocarbons and alkenes, are examples of strained ring systems that open during the addition of GSH (Fig. 6-63). In many cases, conjugation of arene oxides with GSH proceeds stereoselectively, as shown in Fig. 6-64 for the 1,2-oxides of naphthalene. The GSH conjugates of arene oxides may undergo rearrangement reactions, which restore aromaticity and possibly lead to migration of the conjugate to the adjacent carbon atom (through formation of an episulfonium ion), as shown in Fig. 6-64. Conjugation of quinones and quinoneimines with GSH also restores aromaticity, as shown in Fig. 6-35 for NAPQI, the reactive metabolite of acetaminophen. Compared with glucuronidation and sulfonation, conjugation with GSH is a minor pathway of acetaminophen biotransformation, even though the liver contains high levels of both GSH and GSTs. The relatively low rate of GSH conjugation reflects the slow rate of formation of NAPQI, which is catalyzed by CYP (Fig. 6-35).

GSH can also conjugate xenobiotics with an electrophilic heteroatom (*O*, *N*, and *S*) as shown in Fig. 6-65. In each of the examples shown in Fig. 6-65, the initial conjugate formed between

GSH and the heteroatom is cleaved by a second molecule of GSH to form oxidized GSH, which is also known as glutathione disulfide (GSSG). The initial reactions shown in Fig. 6-65 are catalyzed by GST, whereas the second reaction (which leads to GSSG formation) generally occurs nonenzymatically. Analogous reactions leading to the reduction and cleavage of disulfides have been described previously (see Fig. 6-14). Some of the reactions shown in Fig. 6-65, such as the reduction of hydroperoxides to alcohols, can also be catalyzed by glutathione peroxidase (GPX), which is a selenium-dependent enzyme. For their role in the reduction of hydroperoxides, the GSTs are sometimes called nonselenium-requiring GPXs. For instance, one or more members of the mammalian cytosolic, microsomal, and mitochondrial GSTs exhibit GPX activity toward cumene hydroperoxide (Hayes *et al.*, 2005). Cleavage of the nitrate esters of nitroglycerin releases nitrite, which can be converted to the potent vasodilator, nitric oxide (NO). The ability of sulfhydryl-generating chemicals to partially prevent or reverse tolerance to nitroglycerin suggests that GSH-dependent denitration may play a role in nitroglycerin-induced vasodilation, although ALDH2 is recognized as the principal enzyme responsible for activating nitroglycerin as discussed in the section "Aldehyde Dehydrogenase" (Marchitti *et al.*, 2008).

Cytosolic or mitochondrial GSTs catalyze two important isomerization reactions, namely, the conversion of the endoperoxide, PGH₂, to the prostaglandins PGD₂ and PGE₂ and the conversion of Δ⁵ steroids to Δ⁴ steroids, such as the formation of androstenedione from androst-5-ene-3,17-dione. Another physiological function of GST is the synthesis of leukotriene C₄, which is catalyzed by the microsomal GSTs, namely, MGST2, MGST3, and LTC₄S (see Table 6-20).

GSH conjugates formed in the liver can be effluxed into bile by MRP2 (ABCC2) on the canalicular membrane, or they can be transported into blood by various transporters on the sinusoidal membrane such as MRP1 (ABCC1), MRP3 (ABCC3), MRP4 (ABCC4), MRP5 (ABCC5), and MRP6 (ABCC6) (Giacomini and Sugiyama, 2006; Ballatori *et al.*, 2009a; Klaassen and Aleksunes, 2010). MRP7 (ABCC10) and MRP8 (ABCC11)

have also been implicated in the transport of GSH conjugates (Ballatori *et al.*, 2009a). GSH itself is often cotransported with other xenobiotics or xenobiotic metabolites, namely, by MRP2 into bile, and by MRP1, MRP4, and MRP5 into blood (Ballatori *et al.*, 2009a). This cotransport is exemplified by drugs such as vincristine, etoposide, and vinblastine, each of which stimulates MRP-mediated GSH transport (Ballatori *et al.*, 2009a). BCRP (ABCG2) is also involved in GSH transport (Brechbuhl *et al.*, 2010). Furthermore, GST and MRP overexpression can act synergistically to confer multiple-drug resistance in many cancers, and can affect the efficacy of chemotherapeutic drugs such as chlorambucil, etoposide, ethacrynic acid, vincristine, and doxorubicin (Sau *et al.*, 2010).

GSH conjugates can be converted to mercapturic acids (*N*-acetylcysteine conjugates) in the kidney and excreted in urine. As shown in Fig. 6-66, the conversion of GSH conjugates to mercapturic acids involves the sequential cleavage of glutamic acid and glycine from the GSH moiety, followed by *N*-acetylation of the resulting cysteine conjugate. The first 2 steps in mercapturic acid synthesis are catalyzed by γ -glutamyltransferase (GGT1; located primarily in the liver) and membrane alanyl aminopeptidase

(ANPEP; located in the kidney). The GSH conjugate, leukotriene C_4 , is similarly hydrolyzed by GGT1 to form leukotriene E_4 .
